John Clark

Introduction to the Principles of Grammar

During the evolution of a mind, it is not, nor can be, rational, i.e. cannot function by, or produce, functional grammar systems…

One of the earliest sources which point out the fact humanity will be functionally illiterate is today known, cumulatively, as the Judeo-Christian Scripture. This is possibly the only book in our history that repeatedly tells the reader humanity will not even be able to read that book until a certain time in human history, i.e., a stage in human evolution. Language does separate mankind from the other animals, however, mankind is not yet functionally literate and cannot take advantage of that distinction to the point he will survive.

Proving this is rather simple, unless one is hopelessly illiterate. Ask your computer: *How many parts of speech are possible*? Every moment that a computer is functioning, it produces all the things it can do by simple binary recursion. The Bible put this fact into a metaphor about life:—

Adam and Eve are a Conjugate Binary Pair that, *by Complete Induction and Deduction*, *produce the human race*.

As written, if one cannot read the book, then literacy is the key to opening it, just like any other book. The Key to the House of David, a simple puzzle, is simply literacy, something most of mankind believe that they are capable of, but by example prove to be the opposite.

If the metaphor is too esoteric then one has the *Dialogs* of Plato where Plato called binary recursion *Dialectic*, speech as a binary function. Or one can study Euclid’s *Elements*. Or one can refer to the definition of any thing as a relative constrained by correlatives, which again, Plato called nouns and verbs. One can even examine their own body, for any particular sense can abstract either the form, limit, of a thing, or it can abstract the material difference which is again a simple binary distinction.

Binary recursion, when applied to the construction of grammar systems, produce methods of naming, or one can say counting, in order to manage memory. Binary recursion, used for the construction of grammar systems, produce four, and only four, categories of grammar, or four distinct methods of binary recursion: Common Grammar, Arithmetic, Algebra and Geometry. The functionally illiterate cannot comprehend or take advantage of this, of being literate.

These works give a study some material by which to study illiteracy and literacy alike.

Mankind actually believes that one grammar can contradict another, a stance championed by the Einsteins of the world, however, binary recursion is not different from itself, and binary recursion can only produce a binary result. In the words of a famous prophet, “Let your yea’s be yea’s and your nay’s be nay’s.” Which, only the functionally literate can manage.

Your computer is a machine that contradicts you every day, but long before that, your thoughts and actions, have contradicted simple reason.

Language is Universal and Intelligible, i.e. it requires intelligence to grasp it. It cannot be taught, spoken, written, or seen. While Grammar is Particular and Perceptible, which, by the simple binary recursion exampled by Language, produces exactly four methods of binary recursion for human survival: Common Grammar, Arithmetic, Algebra and Geometry. These four are also called Standards of Mental Behavior that produce Standards of Social Behavior. Psychology is commensurate with the principles of Language functionally resident in the mind of man as simple grammar systems.

PRINTED IN GREAT BRITAIN

PREFACE

THE volumes of which this is the first have the purpose of introducing the reader to those parts of geometry which appear most important in developments taking place to-day. The present volume is devoted to the indispensable logical preliminaries. It assumes only those relations of position, for points, lines and planes, which, furnished with a pencil, a ruler, some rods and some string, a student may learn by drawing diagrams and making models. It seeks to set these relations in an ordered framework of deduction, gradually rendered comprehensive and precise enough to include all the subsequent theory; to this end it puts aside, at first, most of those intricate details which make up the burden of what is generally called elementary geometry. That such a plan can be carried through, thanks to the work of many generations of thinkers, is well enough known; and experience has shewn that many students, especially of the class who look forward to becoming Engineers or Physicists, to whom the geometry of the usual textbooks is tiresome, find such a course stimulating and easy, when the matter is properly presented to them. The mathematician who has followed such a course will find that he has no cause to think he has learnt the wrong things. The preliminary theorems in this method of approaching the subject are indeed of Greek origin; only, these are here made to lead to general principles, giving a command of detail unknown to the Greeks. Subsequent volumes will deal, on the basis of the results obtained in this volume, with conics (and circles), with quadric surfaces and cubic curves in space, and with cubic surfaces and certain quartic surfaces. These volumes are ready to print; it is hoped that they may appear in no long time.

Speaking in more detail of the present volume, it rejects the consideration of distance, and of congruence, as fundamental ideas; these are, in effect, replaced by a theory of related ranges; the geometry usually described with the help of the notion of distance appears later, in a more general, but not more difficult, form. By what means it is possible, so to dispense with this notion, should be of interest to others than the student of geometry. An account is given, however, of the consequences of accepting as fundamental the continuity of the real points of the line. As it is necessary to provide for the consideration of the so-called imaginary elements, room has been given to the justification of these; the ideas to which they lead are indeed an essential part of the power which belongs to the point of view adopted. The references to the theory of space of more than three dimensions are also vital to the plan of the work; it will be seen later with what simplicity this theory enables us to deal with curves and surfaces whose properties can otherwise be developed only at great length, with complicated analysis. The geometrical theory is accompanied by an algebraic symbolism, which serves to help to fix ideas, and for purposes of verification; it is necessary also to include the proof that this symbolism is appropriate to the purpose. It is held, however, that the geometrical argument should be complete in itself, independently of the symbols; a geometry should have such a comprehensive grasp of geometrical relations that all its results are clear by consideration of the geometrical entities alone.

The writer is under great obligations to Mr J. B. Peace, M.A., for his interest in the work, and to the Staff of the University Press for their ready cooperation, especially at this time of difficulty in the production of books.

H. F. B.

26 *September* 1921

The present Reprint gives the opportunity of taking account of many kind suggestions made for the improvement of the text. And three brief Notes have been added at the end of the Volume, the first of these mainly with the intention of making more explicit the point of view adopted for the so-called imaginary elements; this seems the natural view, and logically satisfactory.

22 *December* 1928

Erratum. In Ex. 9, p. 175, *instead of* "by taking three positions of P upon p," *read* "in general, by taking three positions of P upon the real line p through the intersection of the two given lines, so chosen that the corresponding points U, V, W are in line"

TABLE OF CONTENTS

PAGES

INTRODUCTORY . . . . 1—3

CHAPTER I. ABSTRACT GEOMETRY

Section I. Propositions of Incidence

Propositions of Incidence in three dimensions 4, 5

The transversal to two lines from a point 5

Desargues' theorem . . . . 6—8

Remarks in regard to Desargues' theorem . . . . . . 8—10

The fourth harmonic point . . . . 10—12

First properties of the harmonic relation . . . . . . 12—14

An important construction determining a sixth point from five given points of a line . . . . 14—16

Remarks 16, 17

A theorem in regard to a chain of perspectivities; reduction to two links 17, 18

Proof for the case of ranges on skew lines . . . . . . 18—21

General proof of the theorem . . . . 21—25

Examples in regard to related ranges . . . . 25—33

Propositions of Incidence in space not limited to three dimensions 33—36

Examples of the Propositions of Incidence in space of four and five dimensions . . . . 36—42

On the Principle of Duality in general 42, 43

On projection from one space to another 43

Section II. The correspondence of the points of two lines. Pappus' theorem

Preliminary remarks . . . . 43—45

Conditions that the correspondence of two related ranges should be of threefold freedom 45, 46

Brianchon hexagons and another form of the conditions . . 46, 47

Pappus' theorem. Is true if the conditions are satisfied . . 47, 48

Pappus' theorem. The conditions follow if Pappus' theorem be assumed 48, 49

Alternative proof of the equivalence of Pappus' theorem with the conditions . . . . 49—51

Equivalence of Pappus' theorem with the conditions for the case of ranges in one plane . . . . 51—53

PAGES
Related ranges on the same line 53, 54
Pappus' theorem and the Principle of Duality 54, 55
Related ranges in space of more than three dimensions . . 55, 56
Examples in connexion with Pappus' theorem . . . . 56—62

Section III. Introduction of algebraic symbols

The laws of operation of the symbols employed . . . . 62—66
Examples of symbols obeying these laws . . . . . . 66—69
Preliminary remarks in regard to the use of the symbols in geometry 69, 70
The symbolical representation of the Propositions of Incidence . 70—72
Examples of the application of the symbolism . . . . 72—74
Interpretation of the fundamental laws of the algebraic symbols . 74—81
Representation of the algebraic effect of Pappus' theorem in three dimensions . . . . 81—83
Examples of the symbols; the commutative law of multiplication. 83—93

CHAPTER II. REAL GEOMETRY

Section I. The Propositions of Incidence. Introduction of a plane, and of a space

Preliminary remarks 94, 95
Betweenness for points of a line. Segments. 95, 96
Points determined by three points. Intersections of lines determined therewith . . . . 96—100
Points of a plane system . . . . 100—103
Separation of the points of a plane effected by a line therein . 103, 104
Space systems, defined by four points not lying in a plane . . 104—106
Extension to fourfold and higher space 106

Section II. The extension of the Real Geometry by means of Postulated Elements

Purpose of the Section. 107
Extended form of Desargues' theorem, for lines and planes with a common point . . . . 107—109
Fundamental theorem for the correspondence of the lines and planes of two stars . . . . 109—114
Postulated Points . . . . 114—116
Remark on the theory of postulated elements 117
Application of the theory of postulated elements. Separation . 117, 118
Separation for four points in harmonic relation . . . . . 118—120
The impossibility of Desargues' theorem from plane Propositions of Incidence 120, 121

Section III. A deduction of Pappus' theorem from the extended Real Geometry

PAGES

The abstract notion of order 121, 122
Remarks in regard to the preceding formulation . . . . 122—125
A theorem in regard to corresponding positions of an abstract order 125—127
Application of the theory of an abstract order. Pappus' theorem . 128—130
Alternative deduction of related ranges, based on a harmonic net 130—136
Consequences of the equable distribution of points of the harmonic net 136, 137
Introduction of symbols, in particular of the iterative symbols . 137—140

CHAPTER III. ABSTRACT GEOMETRY, RESUMED

Related spaces; justification of the symbols. Geometrical assumption for imaginary elements; replacement of imaginary elements by series of real elements

General discussion of the problems of this chapter . . . 141—148
Theory of two related plane systems . . . . 148—150
Two related threefold systems, or spaces . . . . . 150—152
Case of two spaces both of n dimensions 152
Comparison of the correspondence between two spaces with the correspondence between either space and the symbols used to represent it . . . . 152—155
A geometrical existence theorem for the solution of an algebraic equation . . . . 155—164
Statement of the further Axiom henceforth assumed in the Abstract Geometry 164, 165
Aggregates of real elements with the properties of imaginary elements 165—172
The preceding aggregates in the general Abstract Geometry . 172—175

NOTE I . . . . 184—187

NOTE II . . . . 188—191

NOTE III . . . . 192—194

INDEX TO THE TEXT 195

INTRODUCTORY

THE present is the first volume of a brief attempt to place the reader in touch with the main ideas dominant in contemporary geometry. For this purpose an account of many of the preliminary facts of geometry is indispensable, but in later stages a good deal of variety was possible in the selection, and no complete recital of geometrical theorems is aimed at. In several respects the views taken are not those usual in current textbooks; but it is believed that the system here suggested is logically complete, and does not require that long preliminary study of elementary geometry to which at present so much time is devoted. In particular it is desired to enter a protest against the custom of regarding so-called projective geometry as based upon metrical geometry; in the present account *distance*, as a primary conception, does not enter at all. And an attempt is made to include as soon as possible the indispensable ideas of geometry of more than three dimensions, and of geometry of so-called imaginary points. While the view is taken that all geometrical deduction should finally be synthetic, it is also held that to exclude algebraic symbolism would be analogous to preventing a physicist from testing his theories by experiment; and it becomes part of the task to justify the use of this symbolism.

It was impossible on such a plan to avoid discussing the logical foundations—and to this the present volume is devoted. Here difficulties of exposition arise from the desire to be brief, and not to be pedantic. It is not so much aimed at to give a faithful transcript of views elsewhere stated to be final, as to suggest a position which may appeal to the reader's logical sense as likely to be satisfying with further analysis. Logically, Chapter II, headed *Real Geometry*, should have come first, and should have been developed in greater detail. To the writer, after much experience as a teacher, that seemed unpractical. He has thought it better to state at once, in Chapter I, rather as working hypotheses, the greater part of the foundations on which the whole is to be based, reserving however, for Chapter III, an account of the grounds on which imaginary elements are introduced, as well as a more formal *résumé* of the logical position adopted. Thus Chapter II is a less abstract, but so far as the writer can judge the reader's view, a more toilsome analysis of fundamental conceptions than Chapter I. Incidentally, the particular geometrical propositions of Chapter I furnish a good deal of practice in the habit of geometrical construction in three dimensions, which, to the writer, appears logically prior to a detailed consideration of plane figures.

A Science grows up from the desire to bring the results of observation, of the relations of a class of facts which appear to be connected, under as few general propositions as possible. Into these propositions it is generally found necessary, or convenient, when the science has reached a sufficient development, to introduce abstract entities, transcending actual observation, whose existence is only asserted by the postulation of their mutual relations. If the science is to be arranged as a body of thought developed deductively, it is necessary to begin by formulating fundamental relations connecting *all* the entities which are to be discussed, from which other properties are to follow as a logical consequence. If this is done we may in the first instance regard all the entities involved in these fundamental propositions as being abstract, even those to which we attach names agreeing with the names borne by entities which we regard as subject to actual observation. The usefulness of the science, for the purpose for which it was undertaken, will depend on the agreement of the relations obtained for these latter entities with those which we can observe. It would seem that this process of substituting conceived entities, limited by supposed interrelations, for those which are regarded as objects of experience, belongs to every science. But it is clear that the degree of abstractness which may usefully and safely be applied is a matter for judgment and choice, conditioned by knowledge of the matter in hand, even in dealing with the same experiences. In geometry, as applied to the external world, we cannot but be conscious, for instance, in dealing with the points of a line, of the difference between those points which we regard as accessible and those which we regard as the others; and then, given two points of the line, of the difference between those points which we think of as between these, and those not between these; and then, finally, of the order in which several points of the line, which we can think of simultaneously, are arranged. None of these considerations however is taken account of in Chapter I; nor indeed do they enter finally into the abstract system of geometry which we set up. But it is to be expected that, if we take account of them, we may be able to analyse further some of the conceptions which we have adopted without analysis in Chapter I. It is to shew how this can be carried through that Chapter II is written. In particular this Chapter gives grounds on which the fundamental theorem for the correspondence of points on two straight lines may be based. The theory is built up in this Chapter with the use only of points supposed accessible and lying in a limited (unclosed) region, and there are some striking differences between the propositions and those of Chapter I; for instance it is not assumed that two lines in a plane necessarily have a point of intersection; and a line in a plane divides the points of the plane into two distinct sets. It is therefore of importance to shew that there is no inconsistency in afterwards disregarding these special results, as we do; this is effected by shewing that we may consider the limited space as a portion of a closed space in which the more general, if less definite, propositions of Chapter I are true. This step is of interest too as shewing how the detailed considerations which make up the usual elementary expositions of the so-called non-Euclidian geometry are superseded by the more general point of view. To some extent the comparison between the two points of view is analogous to the comparison between the theory of quadratic equations in which there may or may not be two roots, and the theory in which there are always two roots.

The writer is not of those who hold that the process of analysing the fundamental conceptions and setting out the sufficient axioms can ever be final; any such formulation, it would seem, must be subject to the possibility that other logical alternatives of consecutive thought may be revealed. Indeed the progress of science appears to consist in the very gradual unfolding of such alternative, or more embracing, conceptions. The history of Mathematics furnishes many examples, none more instructive and interesting than in the case of non-Euclidian geometry. But the instinct to such analysis is not less imperative than the instinct to all scientific thinking, and in geometry as in other subjects the attempt has been fruitful in a better understanding of the subject-matter. From those who would base upon the confession of the incompleteness of the analysis a refusal to enter upon it the writer would appeal to this instinct, which is more fundamental than formal logic.

Such a volume as this would be impossible save for the work and insight of a long line of other writers. In the Bibliography at the end an attempt is made to give the most necessary acknowledgments. In the text the view is sometimes taken that, in Mathematics, an indication may be more acceptable than an exposition; one remembers the words of Desargues (1636, *Oeuvres* I, 420) "la démonstration est...en notes sans discours pour le soulagement de la veuë et de l'esprit."

CHAPTER I

ABSTRACT GEOMETRY

SECTION I. PROPOSITIONS OF INCIDENCE

Propositions of incidence in three dimensions. The entities with which we deal in the first instance we call by the names, *point*, *line*, and *plane*. These are any objects which are subject to the following laws of combination, which we call the Propositions of Incidence, together with another law, explained below (Sect. II). It is provisionally assumed that these laws are self-consistent and, when properly explained, are sufficient to enable the reader to form a clear impression whether any statement made in regard to these entities is a consequence, or not, of the fundamental laws. It is also very frequently assumed provisionally, when, in the course of a geometrical construction, two points are obtained by certain rules and it is desired to continue the construction with the help of the line joining these points, that these points do not coincide. In many cases it may be easy to shew that the coincidence of the points would involve an undesired limitation in the given points of the figure. But there are cases in which it may seem to be consistent with the assumed fundamental propositions to assume either that the two points always coincide, or that they do not always coincide. The former is excluded if shewn invalid when, to the original hypotheses, others, consistent with these, are added (cf. pp. 11, 119). We adopt words which are in common use, but it is not to be assumed that in effect the meanings which we attach to these are co-extensive with the usual meanings. As is customary we frequently employ diagrams to fix ideas and clarify statements, representing a line by a mark made on the paper and a point by a dot thereon. Notwithstanding this formal and abstract method of statement, the whole object of the theory is of course, as has been stated, to deal with the ideas suggested by our ordinary experience; *it is this experience itself which has gradually suggested the abstract statement.* The Propositions may be stated as follows:

Through an arbitrary point there pass an infinite number of lines, of which one passes through any other arbitrary point. Thus a line is determined uniquely by any two points. The line contains an infinite number of points beside the two determining ones, and is determined by any two of these. Through any given line there pass an infinite number of planes, of which one passes through any point not lying on the given line. Thus a plane is determined uniquely by any three points which do not lie in line. The plane contains an infinite number of points beside the three determining ones, and is determined by any three of these which do not lie in line. The plane entirely contains the line which is determined by any two of its points. Thus if two lines have a common point, and we take two other points, one on each of the lines, the plane determined by the three points contains both the lines; that is, two lines with a common point determine a plane, containing both the lines. It is also true that two lines which are in the same plane have a common point. We have said that there is an infinite number of planes all containing the points of any given line; it is also true that any two planes have common points, lying on a line, or that any two planes intersect in a line. It will be seen below that this statement ceases to be true when we are not limiting ourselves to space of three dimensions. Further it is true (still in space of three dimensions), that any plane contains a point of any line (and contains all the points of the line if it contains two of these), or that a line and a plane intersect in one point. Thus any three planes, which have not in common all the points of a line, have a point in common, that namely where the line of intersection of two of the planes meets the third plane. If now we compare this with the earlier statement that three points not in line determine a plane, and compare the other statements with one another in pairs, as for instance the statement that two points determine a line with the statement that two planes determine a line, the statement that a line and a point determine a plane with the statement that a line and a plane have a point in common, the statement that two lines in a plane have a point in common with the statement that two lines intersecting in a point lie in a plane, we see that there is a complete descriptive correspondence between the relations of points, lines and planes on the one hand, and the relations of planes, lines and points on the other hand. Two propositions obtained one from the other by this interchange will be said to be *dual*, or *reciprocal*, or *correlative*. If we limit our consideration to the points and lines of a single plane it is at once seen that there is a similar reciprocity between propositions relating to points and lines and other propositions relating to lines and points. And a similar duality will be found to subsist in any space of higher dimensions.

We now at once deduce several immediate consequences of these Propositions of Incidence.

The transversal to two lines from a point. Given any two lines a, b, which do not intersect, or, as we shall often say, are *skew* to one another, and a point, P, which does not lie on either of these lines, a single line can be drawn from P to meet both a and b. For

P and a determine a plane, as do P and b; and P is among the points common to these planes, that is, it is on their line of intersection. But this line, being on the plane Pa, intersects the line a, and, being on the plane Pb, intersects the line b; it is thus such a line as is desired. Conversely, any line through P which meets the line a and b must be on both the planes Pa and Pb, and must therefore be the line we have found. The correlative proposition is that there lies in any plane not containing either of two given skew lines a line which meets both; the join namely of the points where the plane intersects the respective lines.

Desargues' theorem. If two triads of points, A, B, C and A', B', C', be such that the three joining lines AA', BB', CC' meet in one point, say O, then the two lines BC, $B'C'$ meet, say in the point P, and similarly the lines CA, $C'A'$ meet, say in Q, and the lines AB, $A'B'$ meet, say in R, and the three points P, Q, R are in line. Conversely, given two triads of points, A, B, C and A', B', C', such that the lines BC, $B'C'$ intersect, say in P, that the lines CA, $C'A'$ intersect, say in Q, and that the lines AB, $A'B'$ intersect, say in R, while P, Q, R are in line, then the lines AA', BB', CC' cointersect. (See the Frontispiece of the Volume.)

It is supposed that the points A, B, C are not in line, so that they determine a plane, and similarly that A', B', C' determine a plane. Take first the case when these planes are different. Suppose further that no one of the joins BC, CA, AB is in the plane $A'B'C'$, and no one of the joins $B'C'$, $C'A'$, $A'B'$ is in the plane ABC. Then the fact that the lines BB', CC' intersect involves that the points B, B', C, C' are in one plane, and hence that the lines BC, $B'C'$ meet. Their point of intersection, say P, lies then on BC which is in the plane ABC, and on $B'C'$ which is in the plane $A'B'C'$, so that P lies on the line of intersection of these two planes. The point, Q, of intersection of the lines CA, $C'A'$, similarly found, as well as the point, R, of intersection of the lines AB, $A'B'$, are equally on the line of intersection of the planes ABC, $A'B'C'$. So that the former statement made is clearly true. Conversely if the lines BC, $B'C'$ meet in the point P, while CA, $C'A'$ meet in Q and AB, $A'B'$ meet in R, then, still assuming the planes ABC, $A'B'C'$ to be different, and assuming that no one of the lines BC, $B'C'$, CA, $C'A'$, AB, $A'B'$ is common to both planes, the points P, Q, R are evidently in the line of intersection of these planes. The fact that the lines BC, $B'C'$ intersect, involves that the lines BB' and CC' intersect, while similarly the line AA' intersects both of these. Now the lines BB', CC' determine a plane, and the line AA' does not lie in this plane, since we have assumed that the planes ABC, $A'B'C'$ are different; wherefore the line AA' meets this plane in a point and can only intersect both BB' and CC' by passing through their point of intersection. Thus the lines AA', BB', CC' meet in a point, as we desired to shew.

We have explicitly excluded, for the sake of simplicity, the possibility of one of the six lines $BC, \ldots$ lying in both planes, which is easily seen to be unimportant. Incidentally we see that if three lines be such that every two of them have a common point, then the three lines lie all in one plane, or pass through one point.

Next suppose the two triads A, B, C and A', B', C' to be in one plane, it being assumed as before that A, B, C are not in line and A', B', C' are not in line. Then, first, let the lines AA', BB', CC' meet in one point, O. Draw through O any line not lying in the plane of the two triads, and let P, P' be any two points on this line. Then the intersecting lines $AA'O$ and $PP'O$ determine a plane, and the lines AP, $A'P'$, lying therein, intersect in a point, say A''. Similarly the lines BP, $B'P'$ meet in a point, say B'', and the lines CP, $C'P'$ meet in a point, say C''. As P is not in the plane of ABC, $A'B'C'$, it is clear that the points A'', B'', C'' are not in this plane; further A'', B'', C'' are not in line, since otherwise, as the plane containing this line and P would contain the points A, B, C, these would be in line; finally the plane which is thus determined by the points A'', B'', C'' does not contain, for instance, the line AB, for otherwise the plane of AB and $A''B''$, which contains P, would contain C'' and C, and A, B, C would be in line. Hence it follows from what is proved above, as the lines AA'', BB'', CC'' meet in P, that there is, in the plane of ABC and $A'B'C'$, a line, where this plane is met by the plane $A''B''C''$, and upon this line three points, say L, M and N, such that the lines BC, $B''C''$ meet in L, the lines CA, $C''A''$ meet in M and the lines AB, $A''B''$ meet in N. The point L is then the point where the plane of ABC and $A'B'C'$ is met by the line $B''C''$, and M, N are similarly the points where this plane is met by $C''A''$ and $A''B''$. By considering that the three lines $A'A''$, $B'B''$, $C'C''$ meet in the point P', we prove however, in the same way, that $B'C'$ passes through L, and that $C'A'$, $A'B'$ respectively pass through M and N. We have thus proved that if two triads of points ABC, $A'B'C'$, in the same plane, be such that the joining lines AA', BB', CC' meet in a point, then the three points of intersection $(BC, B'C')$, $(CA, C'A')$, $(AB, A'B')$ are in line. Conversely, for two triads of points ABC, $A'B'C'$ in the same plane, assume that the three points $(BC, B'C')$, $(CA, C'A')$, $(AB, A'B')$ are in line. Denote these points respectively by L, M, N. Draw through the line LMN a plane, other than the original plane of ABC, $A'B'C'$; draw through the points L, M, N, in this new plane, respectively the lines $LB''C''$, $MC''A''$, $NA''B''$, giving by their intersections a further triad A'', B'', C'' in this new plane. This new plane does not contain any one of the lines BC, CA, AB, $B'C'$,

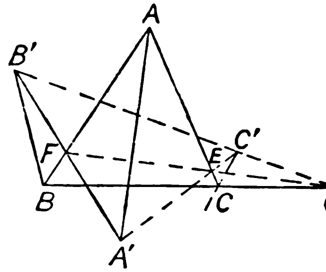
$C'A'$, $A'B'$, and it is supposed that the lines $LB''C''$, $MC''A''$, $NA''B''$ are all drawn so as not to lie in the original plane of ABC, $A'B'C'$. Then, as the lines BC, $B''C''$ meet in the point L, the lines CA, $C''A''$ meet in the point M, and the lines AB, $A''B''$ meet in the point N, it follows from what has preceded that the three lines AA'', BB'', CC'' meet in a point, say P, which does not lie in either the original plane or the new plane. It follows similarly, as the lines $B'C'$, $B''C''$ meet in the point L, and $C'A'$, $C''A''$ in M, and $A'B'$, $A''B''$ in N, that the lines $A'A''$, $B'B''$, $C'C''$ meet in a point, say P', not lying in either of the two planes described. Now let O be the point where the line PP' meets the original plane of ABC, $A'B'C'$. Then, since the lines AP, $A'P'$ intersect, in the point A'', and the points A, A', P, P' are not in line, these lines determine a plane, and therefore the line AA' intersects the line PP'. This intersection can only be at O, where the line PP' meets the original plane containing A and A'. Thus the line AA' passes through O, as, similarly, do also the lines BB' and CC'. We have thus proved that if two triads ABC, $A'B'C'$, of points in one plane, neither triad being in line, be such as to have three intersections (BC, $B'C'$), (CA, $C'A'$), (AB, $A'B'$) lying in line, then the three joining lines AA', BB', CC' meet in a point.

The aggregate of the four theorems now established will be referred to as Desargues' theorem. (See *Oeuvres de Desargues, par M. Poudra*, Paris, 1864, t. I, pp. 413, 430.)

Remarks in regard to Desargues' theorem. (*a*) The reader will notice that the theorem for two triads of points in one plane is proved by considerations involving the existence of points not lying in this plane. From the previously given Propositions of Incidence it is possible to select those which relate only to the geometry of points and lines lying in one plane. It is an interesting fact that the theorem of Desargues for two triads of points lying in this plane cannot be proved as a consequence only of the propositions of incidence relating to geometry in this plane—as we shall prove below (Chap. II). The propositions of incidence for one plane appear to furnish no criterion for deciding whether three constructed points lie in line; such criterion arises only when the line enters as the intersection of two planes. And they appear to furnish no criterion for deciding whether three constructed lines meet in one point; such criterion arises only when the point enters as the intersection of the plane with a line not lying therein.

(*b*) We have said that two lines intersect one another when they lie in one plane; thus they intersect one another when there are two points A, A' on one of the lines, a, and two points B, B' on the other line, b, such that the cross joins AB, $A'B'$ meet; for then the two lines a, b lie in the plane of these lines AB, $A'B'$. Let

F be the intersection of AB and $A'B'$; and let C be any other point not lying on either of the lines a, b. Desargues' theorem furnishes a construction for the line joining C to the point of intersection of the lines, a, b; and this construction depends only on the points A, A' and B, B' by which these lines may be supposed to be determined. For, on the given line BC, in the plane ABC, wherein A is also given, take a point O and join it to the given point F of the line AB. Let the joining line meet AC in the point E. The plane determined by the points O, B', F contains the points A' on $B'F$, and E on FO; thus the line $A'E$ intersects OB', say in C'. We now have two triads of points, ABC and $A'B'C'$, such that the lines BC, $B'C'$ meet in O, the lines CA, $C'A'$ meet in E, and the lines AB, $A'B'$ meet in F, while the points O, E, F are in line. It therefore follows that the line CC' passes through the intersection of the given lines AA' and BB'.



That this construction should be useful when the point of intersection of the lines AA', BB' is not accessible depends on the possibility of taking O in such a position upon BC that the two points E, C' should be accessible (see Chapter II). The construction is valid when C is in the plane of the two lines AA', BB'; when C is not in this plane the line from C to the intersection of these lines may also be defined as the line of intersection of the two planes CAA' and CBB'.

(c) If we have two tetrads of points, A, B, C, D and A', B', C', D', with the property that the four lines AA', BB', CC', DD' meet in one point O, it being supposed that neither tetrad consists of four points lying on a plane, then it can be shewn that every two corresponding joining lines in the two figures, such as BC and $B'C'$, intersect one another, and that the six points of intersection so arising are in one plane, and are the intersections in pairs of four lines of that plane.

In fact, the lines DA, $D'A'$, in the plane of the lines ODD', OAA', must intersect, say in P; so the lines DB, $D'B'$ must intersect, say in Q, and the lines DC, $D'C'$ must intersect, say in R. The points P, Q, R are then not in line, since the points D, A, B, C are not in a plane; and thus the points P, Q, R define a plane. Again, as the joins of corresponding points of the two triads DBC and $D'B'C'$, namely DD', BB' and CC', meet, in O, it follows from Desargues' theorem that the lines BC, $B'C'$ intersect in a point of the line QR, where Q is the point $(DB, D'B')$ and R is the point $(DC, D'C')$, say in X. Similarly the lines CA, $C'A'$ meet in a point, say Y, of the line *RP*, and *AB*, *A'B'* meet in a point, say *Z*, of the line *PQ*. The points *X*, *Y*, *Z* are on the plane *ABC*, and are thus in line, the line of intersection of the planes *ABC* and *PQR*. This proves the result stated.

(*d*) Two figures, such as the triads *ABC*, *A'B'C'* of Desargues' theorem, or the two tetrads just considered, are said *to be in perspective*, when to any point *P* of one figure there corresponds a point *P'* of the other figure, such that all lines, like *PP'*, which join two corresponding points, pass through the same point.

We may notice that the figure which arises in the proof of Desargues' theorem for the case of two triads in one plane, consists of three triads, of which every two are in perspective, the three centres of perspective being in line; while each set of three corresponding joining lines, such as *BC*, *B'C'*, *B''C''*, is formed of three lines which meet in a point. In all there are fifteen points and twenty lines; each line contains three of the points, and through each point there pass four of the lines. If we denote the points *P*, *P'*, *A''*, *B''*, *C''* respectively by the binary symbols, each formed with two numbers, 04, 05, 01, 02, 03, then it is appropriate to denote the points *A*, *B*, *C*, *A'*, *B'*, *C'* respectively by the symbols 14, 24, 34, 15, 25, 35, the point of meeting of the three lines *BC*, *B'C'*, *B''C''* by 23, the point of meeting of the three lines *CA*, *C'A'*, *C''A''* by 31, and that of *AB*, *A'B'*, *A''B''* by 12, using 45 for the point of meeting of *AA'*, *BB'*, *CC'*. The points are then denoted by all the combinations of six symbols two at a time. Each line is met by nine others, lying in threes in three planes; the three triads so formed, one in each of these planes, are two and two in perspective, the centres of perspective being in line.

The figure arising in the proof of Desargues' theorem for two triads not lying in the same plane is simpler. Here there are five planes, ten lines, consisting of the lines of intersection of the planes in pairs, and ten points, consisting of the intersections of the planes in threes.

Example. If two triads of points, *A*, *B*, *C* and *A'*, *B'*, *C'*, be such that the lines *AB'*, *A'B* intersect, say in *R*, also *AC'*, *A'C* intersect, say in *Q*, while *AB*, *A'B'* intersect in *H*, and *BC*, *B'C'* intersect, in *F*, then prove that *BC'*, *B'C* intersect, say in *P*, and that *AC*, *A'C'* intersect, say in *G*, and that each of the four sets *FGH*, *FQR*, *GRP*, *HPQ* consists of three points in line.

The fourth harmonic point. We come now to an important construction by which we pass from three given points of a line to another unique point of this line. For the construction itself it is assumed that a plane can be drawn through the line, and for the proof that the fourth point of the line which is constructed is unique it is assumed that two planes can be drawn through the line. Thus the construction supposes that the line lies in space of three dimensions, though the result of the construction relates only to points lying on a line.

Let A, B, C be three arbitrary points lying on a line. Through this line draw an arbitrary plane. In this plane draw three lines, one through each of the points A, B, C, but otherwise arbitrary, forming by their intersections a triad P, Q, R, so that the line QR passes through the point A, while RP passes through B and PQ passes through C. *Now regard A, B, C as consisting of a pair of points, and a third point*; let A, B be the pair. Join to A the point of intersection of the line (RP) drawn through B with the line (PQ) drawn through C; that is, join AP. Similarly join to B the point of intersection of the line (QR) drawn through A with the line (PQ) drawn through C; that is, join BQ. Let the lines AP and BQ meet in the point U. Join U to the point of intersection of the line (QR) drawn through A with the line (RP) drawn through B; that is, join UR. Let UR meet AB in D. Then D is the point to be constructed corresponding to the separation of the points A, B, C into the pair A, B and the third point C. Temporarily, assuming D, C do not coincide, it may be denoted by

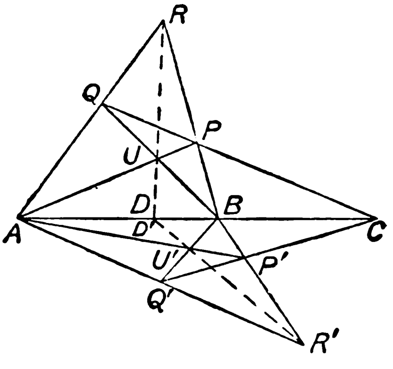
$$D=(A, B)/C.$$

We may similarly construct two other points, appropriately represented respectively by

$$(B, C)/A \text{ and } (C, A)/B,$$

with which we are not concerned for the moment.

To prove that the point D is the same whatever be the lines QR, RP, PQ we proceed as follows. Draw through the given line another plane, and therein make a similar construction, with lines $Q'R'$, $R'P'$, $P'Q'$ passing respectively through A, B and C. We shew first that the points D, D' in which RU, $R'U'$ meet AB are the same. In fact the planes RAR', RBR', are intersected by the plane $QPCP'Q'$ respectively in the lines QQ' and PP'; these lines, lying in a plane, must then meet, and their point of meeting must be on the line RR' containing all the points common to the planes RAR', RBR'. Let this common point of the lines QQ', PP' be called O. Again the planes PAP', QBQ' are met by the plane $QQ'OP'P$ respectively in the lines PP' and QQ';



these lines, lying in a plane, must then meet in a point on the line of intersection UU' of the planes PAP', QBQ'.

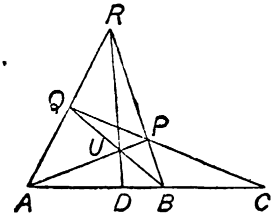
Thus the line UU' passes through the intersection, O, of the lines PP' and QQ', through which the line RR' also passes. But, from the fact that UU' and RR' meet, it follows that the lines RU and $R'U'$ lie in a plane, so that these intersect; and their intersection, being common to the planes RAB, $R'A'B'$ in which they respectively lie, must be on the line AB.

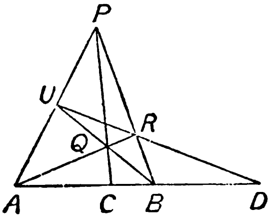
Next suppose that in the plane PQR other lines are drawn through A, B, C, namely AQ_1R_1 through A, and BR_1P_1 through B, and CP_1Q_1 through C; and let AP_1, BQ_1 meet in U_1, while R_1U_1 meets AB in D_1. By the argument just given it follows that D_1 coincides with the point, D', in which $R'U'$ meets AB. And this has been shewn to coincide with the point, D, in which RU meets AB.

The position of D is thus independent of the lines AQR, BRP, CPQ.

First properties of the harmonic relation. (*a*) It is clear from the construction that no change is made in D by the interchange of the points A and B. Thus we may equally write

$$D=(B, A)/C.$$



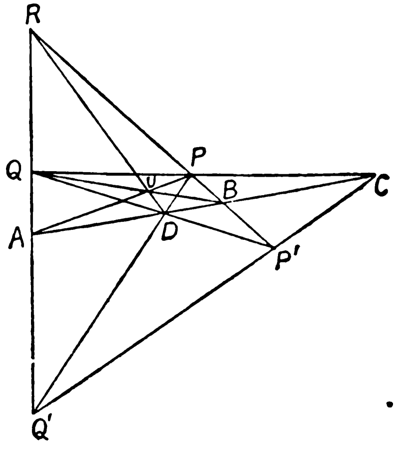


(*b*) Again, as we may see using the same figure but calling the points originally named P, Q, R, U, C, D respectively by the names R, U, P, Q, D, C, we can pass from the point D to the point C by a construction which is descriptively identical with that by which we passed from C to D. Thus we may also write

$$C=(A, B)/D,$$

and, like the couple A, B, the points C, D form a couple of interchangeable points.

(*c*) And in fact one of these couples may be interchanged with the other. For, it is clear from the original construction that if U_1 be any point on the line RD, and the lines AU_1, BU_1 meet RB and RA respectively in P_1 and Q_1, then P_1Q_1 passes through C; we have only to replace the line CPQ by the line CQ_1; if the intersection of this with RB be joined to A, the joining line must meet BQ_1 in a point lying on RD, that is, in U_1. Hence, interchanging the parts played by the lines CBA and CPQ, if the line PD meet RA in Q', and the line QD meet RB in P', it follows from the fact that the lines PA, QB meet on RD that the line $Q'P'$ passes through C.



Now consider the point which would be expressed by

$$(D, C)/B.$$

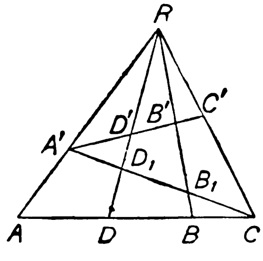
To obtain this point by the rule, we may draw respectively through the points D and C the lines DP' and CP, and then through the point B the line $P'BP$, meeting the two former respectively in the points P' and P; then, if the lines $P'C$ and PD meet in Q', we are to join Q' to the point of intersection of the lines DP' and CP, that is to the point Q. The joining line QQ' will then meet DC in the point required; and this is the point A. Hence we have

$$A = (D, C)/B,$$

which shews that the couples A, B and C, D may be interchanged.

We may then speak of *the points of either couple as being harmonic conjugates of one another in regard to the points of the other couple.*

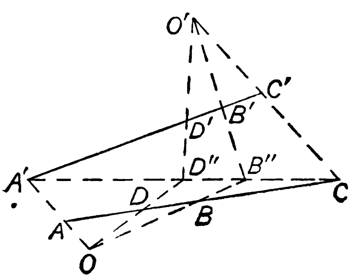
(d) We have stated that two figures are said to be in perspective when to any point, P, of one figure there corresponds a point, P', of the other, such that the joining lines, PP', all pass through the same point. It is easy to see that if four points A', D', B', C' of one line be in perspective with four points A, D, B, C respectively, of another line, which are such that C, D are harmonic conjugates in regard to A, B, then also C', D' are harmonic conjugates in regard to A', B'.



If, in the original figure, the line RU meet the line CPQ in the point X, then X is the harmonic conjugate of C in regard to P and Q. For, from P, Q are drawn, respectively, the lines PA, QB, meeting in U, and the line CAB, drawn from C, meets these respectively in A and B; then the lines AQ, BP meet in the point R, and the line RU meets the line PQ in the point X.

Hence taking the points A', D', B', C' respectively in perspective with the points A, D, B, C, from the centre R, where C, D are harmonic conjugates in regard to A and B, let the line CA' meet the lines RD and RB respectively in D_1 and B_1. From the remark just made, it follows first that C, D_1 are harmonic conjugates in regard to A' and B_1; and then it similarly follows that C', D' are harmonic conjugates in regard to A' and B'.

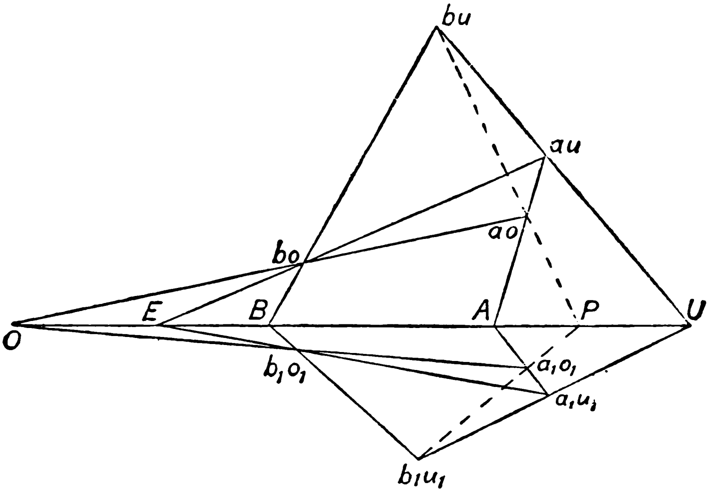
(e) Conversely if on each of two lines we have a set of four points in harmonic relation, they can be regarded as both arising by perspective from the same set of four points in harmonic relation lying on another line.



For let C, D be harmonic conjugates in regard to A, B, on one line, and C', D' be harmonic conjugates in regard to A', B', on another line; join $A'C$ and take O any point on $A'A$; let OD, OB meet $A'C$ in D'', B'' respectively; let CC' and $B''B'$ meet in O' and let $O'D'$ meet $A'C$ in D_1. Then, by what is remarked under (d), C and D'' are harmonic conjugates in regard to A' and B'', while C and D_1 are also harmonic conjugates in regard to A' and B''. Thus D_1 is the same as D'', and the two given sets are both in perspective with the harmonic set A', D'', B'', C.

(f) When the points that can exist on a line are further conditioned as in Chapter II below, it will be found that if the points C, D are harmonic conjugates in regard to the points A, B, then C and D are necessarily separated from one another, in the sense there explained, by A and B. Without these conditions, to speak of a separation would be unmeaning. But we shall, in accordance with a general assumption referred to at the beginning (above, p. 4), assume provisionally that the point D does not coincide with C unless C coincides with A or with B. A geometry, of fifteen points in all, has been suggested in which D always does coincide with C (Fano, "Sui postulati fondamentali...," *Giorn. di Mat.*, XXX, 1892, p. 106). See the Bibliography, and p. 119, below.

An important construction determining a sixth point from five given points of a line. The five given points are to be regarded as consisting of two couples and another point; for clearness sake we shall at present speak of this last point as the determining point. Denote the points of one couple by A, B, those of the other couple by O, U; let E be the determining point, and P the point to be determined. Draw any plane through the line, and therein draw lines, denoted respectively by a, b, o, u, one through each of the points A, B, O, U of the two given couples. We associate one of the two lines a, b with one of the two lines o, u, and the other of a, b with the remaining one of o, u; this is possible in two ways; take the association of a with u and of b with o, denoting the intersection of a and u by (a, u), and the intersection of b and o by (b, o). The lines a, b, o, u are to be any lines of the plane taken subject to the condition that the two points (a, u), (b, o) shall lie on a line, say e, which passes through the determining point E. Then by the other possibility of association we have two other points which may be respectively denoted by (a, o) and (b, u). The line, say p, which joins these, gives, by its intersection with the original line, the point, P, which is determined, in the one of two possible ways chosen, as the result of the construction. The other method of association would require the lines a, b, o, u to be such that the points (a, o) and (b, u) shall lie on a line, e', passing through E, and then the line, p', containing the points (a, u) and (b, o), would meet the original line in a point, P', which would be the point determined by the construction. For our purpose it will be found to be very important that the Propositions of Incidence assumed do not enable us to prove that P and P' coincide.



That, subject to the condition that the points (a, u), (b, o) shall lie on a line through E, the point P is the same whatever be the lines a, b, o, u, may be proved as in a previous case.

Draw through the original line any other plane, and therein, through the points A, B, O, U, respectively, any lines a_1, b_1, o_1, u_1, subject to the condition that the points (a_1, u_1) and (b_1, o_1) shall lie on a line through E, completing the figure as before. We shew that the line joining the points (a_1, o_1) and (b_1, u_1) also passes through P. For, first, the three lines joining the respective pairs of points

(a, u) and (a_1, u_1), (b, o) and (b_1, o_1), (a, o) and (a_1, o_1)

meet in a point, namely in the point of intersection of the three planes

$$[e, e_1], \quad [a, a_1], \quad [o, o_1],$$

where e, e_1 are the lines through E in the two planes respectively; this follows because each of these planes contains two of the three joining lines in question, or each of the lines is the line of intersection of two of these planes. Similarly, the three lines joining the respective pairs of points

$$(b, o) \text{ and } (b_1, o_1), \quad (a, u) \text{ and } (a_1, u_1), \quad (b, u) \text{ and } (b_1, u_1)$$

meet in a point, namely in the point of intersection of the three planes

$$[e, e_1], \quad [b, b_1], \quad [u, u_1],$$

each of these lines being common to two of these planes.

From these two facts it follows that the two lines joining the respective pairs of points

$$(a, o) \text{ and } (a_1, o_1), \quad (b, u) \text{ and } (b_1, u_1)$$

must intersect one another. From this it follows that the two lines joining the respective pairs of points

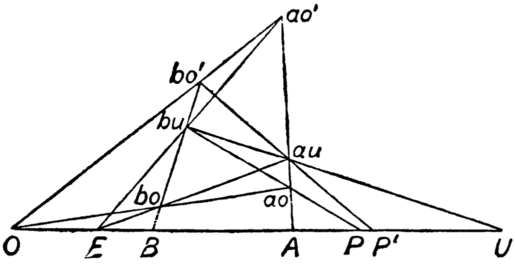
$$(a, o) \text{ and } (b, u), \quad (a_1, o_1) \text{ and } (b_1, u_1)$$

must meet; and they can only meet in a point P of the original line which is the line of all the points common to the two planes in which the two figures are constructed.

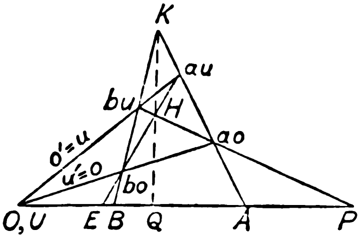
Having proved that the same point P is obtained when we construct figures in two different planes passing through the original line, it follows as before that the same point P is obtained when we construct two figures in the same plane, by varying the lines a, b, o, u, preserving the same method of association of the couples a, b and o, u. It is clear that the two couples A, B and O, U play similar parts in the construction, and that the two points of a couple play similar parts; we may therefore represent the points P, P' obtained, respectively, by

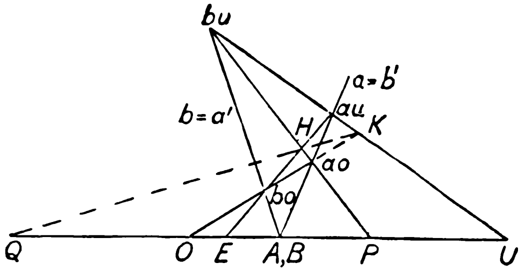
$$P = \begin{pmatrix} A, & B \\ O, & U \end{pmatrix} \Big/ E = \begin{pmatrix} O, & U \\ A, & B \end{pmatrix} \Big/ E, \quad P' = \begin{pmatrix} A, & B \\ U, & O \end{pmatrix} \Big/ E = \begin{pmatrix} U, & O \\ A, & B \end{pmatrix} \Big/ E.$$

Remarks. (*a*) We may make a figure containing both methods of association, using the same lines a, b, u, but two lines o, o' through O.



(*b*) As the two methods of association are distinguished by either the interchange of the points A, B, or the interchange of the points O, U, the points P', P will coincide when either A, B coincide, or O, U coincide. In either case the figures appropriate to the two methods of association may be taken identical. When A, B coincide, taking lines a, b, o, u, e for one association, we may take lines $a'=b$, $b'=a$, o, u, e for the other. When O, U coincide, taking lines a, b, o, u, e





for one association, we may take lines a, b, $o'=u$, $u'=o$, e for the other. By a construction indicated in the diagrams we may prove that when A, B coincide, if $Q=(O, U)/A$, then $P=(A, Q)/E$; and that when O, U coincide, if $Q=(A, B)\ O$, then $P=(O, Q)/E$. Hence also, when A, B coincide, if $U=(E, A)/O$, then P coincides with E, as a diagram at once makes clear.

Further, when E coincides with O, both P and P' coincide with U.

A theorem in regard to a chain of perspectivities; reduction to two links. There is another result of great importance to us in the sequel, which may be deduced from the Propositions of Incidence. Though the proof is somewhat intricate we give it at once; the reader may prefer, when he has understood what is the effect of the theorem, to pass over the details of the proof for the present.

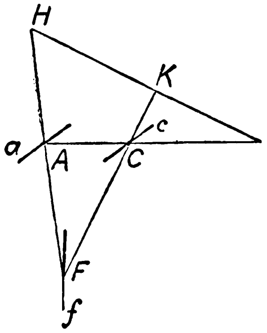
It has been seen that two ranges of points $AA'\ldots$, $BB'\ldots$, lying respectively on two lines a, b, are said to be in perspective when the joins of corresponding points of these ranges, that is the lines AB, $A'B'$,..., all pass through another point. It is clearly necessary that the lines a, b should be in one plane. Suppose now that we have a set of lines a, b, c,..., k, finite in number, arranged in order such that every consecutive two intersect; and that there are ranges of points upon these lines, such that those upon the first and second are in perspective with one another from some point, that the ranges upon the second and third lines are in perspective with one another from some point, and so on, for every consecutive two, to the last. *It can then be proved that the ranges upon the first and last lines, a and k, can be obtained from one another by means of only two perspectivities*, namely that there is a line m, and upon this a range which is in perspective with the given range upon the line a from some point, and is also in perspective with the given range upon the line k from some point. It will appear that the line m, which must intersect both a and k, is by no means unique.

Let us agree to say that two ranges of points upon two different lines, p, q, which may or may not intersect one another, are *related*, when these ranges are both in perspective with the same range upon another line, n, from appropriate centres. Two ranges which are in perspective with one another are then also related, in a very particular way, but the converse is not generally true. The proposition to be proved is then that the ranges on the lines a, k are related. And the proposition will follow if we prove the theorem that *when two ranges are related, any range which is in perspective with one of these is related to the other.* We address ourselves then to proving this last theorem.

It may prevent confusion of thought if we add at once that we shall also be led to speak of two ranges of points on the *same* line as being related; but, for a reason which will appear, the definition will be that two such ranges are related when one of them is in perspective with a range on another line which is related, in the above sense, to the other range of the given line, not being directly in perspective with it.

Proof for the case of ranges on skew lines. Before entering upon a general proof of the theorem, we give a proof, which is very direct, for the case when the two given related ranges are on lines which do not intersect one another, and the range which is given as being in perspective with one of the two ranges lies on a line not intersecting the line containing the other of these. Logically it is unnecessary to give this, the general proof which follows being applicable in all cases.

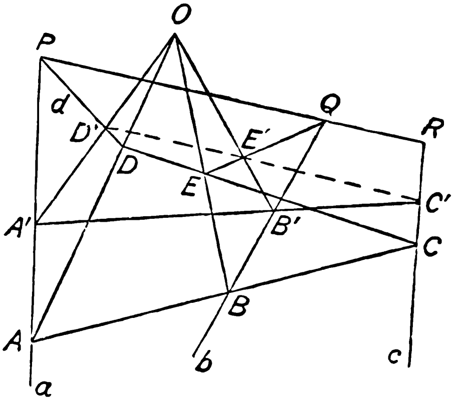
But in this case there is a simple way of describing when the ranges on the two (non-intersecting) lines are related. For if ranges $(A, A', \ldots)$, $(C, C', \ldots)$, on two lines a, c, which do not intersect, be both in perspective with a range $(F, F', \ldots)$, on a line f, so that there is a point H through which the lines AF, $A'F'$, ... all pass, and a point K through which the lines CF, $C'F'$, ... all pass, then the lines AC, $A'C'$, ..., joining corresponding points of the two related ranges on a, c, all intersect the line HK. This line HK will not intersect the lines a, or c; for if it intersected a, the plane Ha, which contains f, would contain the line HK, and the plane Kc, containing f and KH, would coincide with the former plane Ha; so that the lines a and c would intersect. Thus a simple construction by which the range on the line a gives rise to



the related range on the line c is, to draw from the points A, A',..., of the range on a, the transversals which meet both c and the line HK; their intersections with the line c are the points of the related range thereon. Conversely, if we draw from points A, A',... of a line a, the transversals to two other lines, c and m, which do not meet one another, or meet a, and if these transversals meet c in C, C',... respectively, then the ranges (A, A',...), (C, C',...) are related in the sense first defined; for a range with which they are both in perspective is obtained by taking any two points H, K on the line m, remarking that the lines HA, KC meet in a point, F, of the line, f, in which the planes Ha, Kc intersect one another. We may therefore define two ranges on two non-intersecting lines as being related when the joins of corresponding points of these ranges have a common transversal.

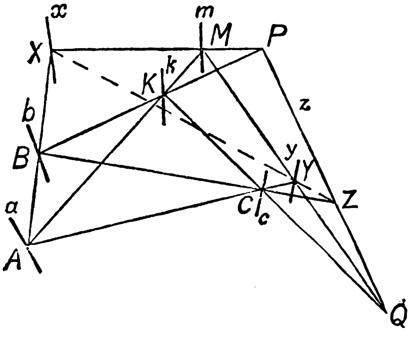
Now consider two related ranges (A, A', ...), (C, C', ...), on two lines a, c which do not intersect one another, the joins AC, $A'C'$,... of corresponding points of these ranges having the common transversal b, which they meet in (B, B',...). Suppose also that the range (D, D',...), on the line d, is in perspective with the range (A, A',...), from the point O, the line d not intersecting the line c. We wish to shew that the range (D, D', ...) is related to the range (C, C', ...).

Let the lines a, d meet in P; from P draw the transversal PQR to the lines b, c, meeting these respectively in Q, R. Let D, C be two points, respectively of the ranges on the lines d, c, which correspond to a point A of the range on a; thus DC is in the plane joining O to AC. Wherefore, if AC meet b in B, then OB meets DC, say in E. Next, let B', D' be the points of the ranges on the lines b, d which similarly arise from *any* point A' of the range on a, so that O, A', D' are in line, and the line $A'B'$ meets c, in C'. The lines OB', QE both lie in the plane Ob; let them meet in E'; we can then shew that D', E', C' are in line. For consider the two tetrads of points A', A, B, B' and D', D, E, E'; as they are in perspective from O any two joins of corresponding pairs of points in the two tetrads meet in a point lying on a plane which contains all such points of meeting, as was remarked above in connexion with Desargues' theorem. Such corresponding joins are AA', DD', meeting in P, and BB', EE', meeting



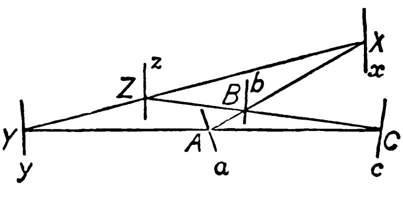
in Q, and AB, DE, meeting in C; whence it follows that $D'E'$ meets $A'B'$ in a point of the plane PQC, and the only point of $A'B'$ lying on this plane is the point C'. Thus $D'E'$ passes through C'. Therefore, as D' is an arbitrary point of the range on d, we see that this range is related to the range on c, the joins of corresponding points of these ranges all meeting a line QE; this proves what is required. The range thus arising on the line QE is in perspective with the range on the line b, from the point O.

Example. It follows from what has just been given that, if a, b, c be three lines, of which no two intersect, and a range of points on the first be related to a particular range on the second, and this in turn be related to a range on the third, then the range on the first is related to the range on the third; regarding ranges on two non-intersecting lines as being related to one another by the fact that the joins of corresponding points of these ranges have a common transversal, we may speak of this transversal as the *supplementary* line, and the range thereon as the supplementary range. A further exercise in the ideas is then obtained by proving the following particular result: Let a, b, c be three skew (non-intersecting) lines, there being ranges on a and b which are related to one another by a supplementary range on a line x, the range on b being related to a range on c by a supplementary range on a line z. Then if, in accordance with the preceding theorem, the ranges on a and c be related to one another by a supplementary range (y), on a line y, it can be shewn that the ranges (x), (z), which arise on the supplementary lines x and z, are also related to one another by the same supplementary range (y). It will be seen that, if the figure formed by four lines in a plane and their six intersections in pairs, or *vertices*, be called a complete plane quadrilateral, the result is the same as that, *if of the six vertices of a complete plane quadrilateral, five move on arbitrary skew lines, then the locus of the remaining vertex is also a line.*



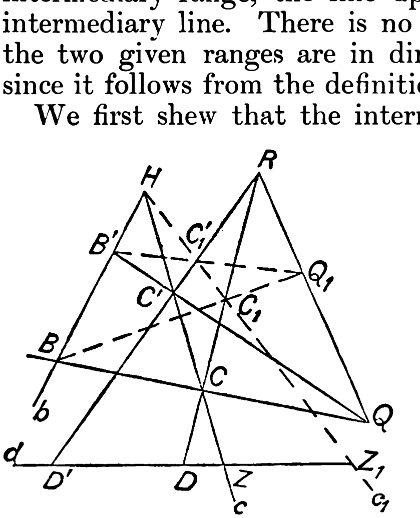
The diagram by which we illustrate the proof of this result will be of a symbolical character, a range being represented by a single general point of the range, except in the case of the range (z). Take any points, P, Q, on the supplementary line, z, of the related ranges (b), (c). Then, as has been remarked above, the joins of P, Q, respectively to corresponding points, B, C, of the ranges (b), (c), meet in the points of a range (k), lying on the intersection of the planes Pb, Qc. As the ranges (a), (b) are related, with (x) as supplementary range, and the range (k) is in perspective with the range (b), from P as centre, it follows, from the result just proved, that the joins of corresponding points, A, K, of the ranges (a), (k), meet the plane Px in the points, M, of a range (m), in perspective with (x) from P, which is the supplementary range of the two related ranges (a) and (k). Then, as the ranges (a), (k) are related, with (m) as supplementary range, and the range (c) is in perspective with (k), from Q, it follows, by the same result, that the joins of corresponding points, A, C, of the ranges (a), (c), meet the plane Qm in the points, Y, of a range (y), in perspective with (m) from Q, which is the supplementary range of the ranges (a), (c). These are therefore related. Considering the triads A, B, C and M, P, Q, we see that the joins of corresponding points, AM, BP and CQ, meet in a point K; wherefore, by Desargues' theorem, the three points of intersection of corresponding sides, namely X, from AB and MP, Y from AC and MQ, and Z, from BC and PQ, are in line. Thus any two of the ranges (x), (y), (z) are related, with the third as supplementary range; as we desired to prove. The diagram does not put in evidence the facts that the line k intersects both b and c, and the line m intersects both x and y.

The result is evidently equivalent to saying that if a, b, c, z, x be any five lines of which no two intersect, and from a variable point, B, of the line b, the transversals, ABX, CBZ, be drawn to meet the lines a, x and c, z, respectively in A, X, C, Z, then the lines AC, ZX meet in a point Y lying on a sixth line. This is another form of the statement above made in regard to a complete plane quadrilateral. More generally, given four fixed lines a, c, x, z, of which no two intersect, if through an arbitrary point B we draw the transversal to one pair of these, say a and x, meeting these in A and X respectively, and also draw the transversal to the other pair, meeting these in C and Z, it is clear that the lines AC, XZ will intersect, say in Y (as will also the lines AZ, XC). Taking all the possibilities of grouping there are thereby six points Y obtainable from B, and from any one of these, when the association of the lines is specified, we can proceed back to B by a similar construction.



General proof of the theorem. We now pass to the general proof of the theorem referred to, that, if two ranges be related, any range in perspective with either is related to the other.

By definition two ranges, on different lines, are related when they are both in perspective with a third range, from appropriate centres. For the sake of clearness let this other range be called the intermediary range, the line upon which it lies being called the intermediary line. There is no need to prove the theorem when the two given ranges are in direct perspective with one another, since it follows from the definition of related ranges.



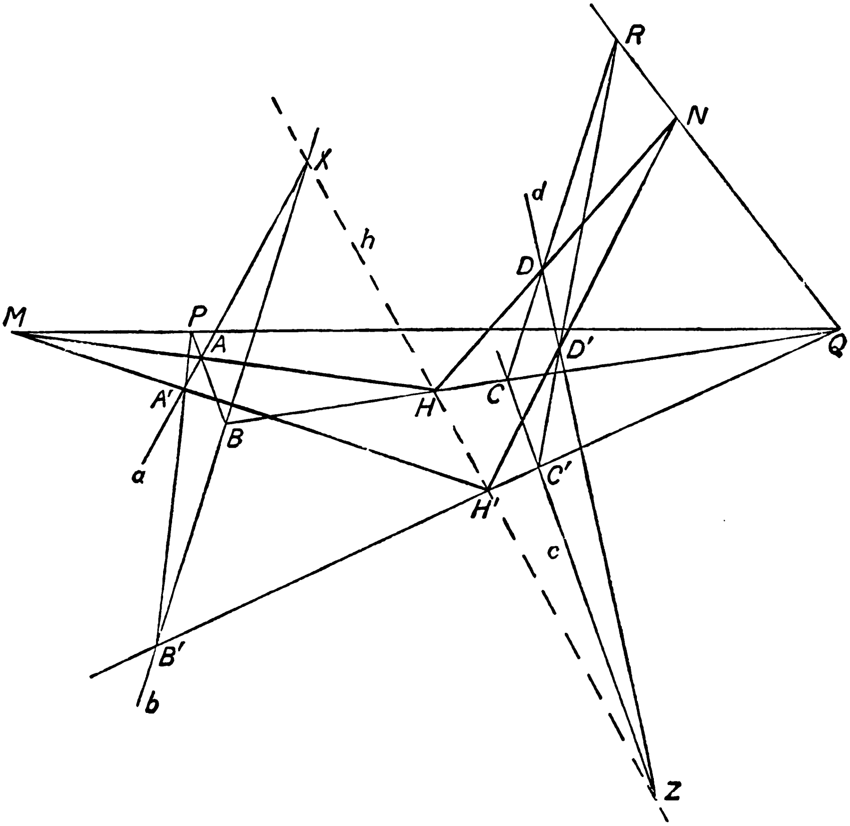
We first shew that the intermediary line, which necessarily intersects both the given lines, can be taken to be any line whatever intersecting these which does not either (*a*) intersect the lines of the related ranges in corresponding points, or (*b*) pass through the point of intersection of these lines in case they intersect. Let b, d be the lines of two related ranges, not in perspective with one another, with an intermediary line c, intersecting both b and d. Through the point H where c intersects b draw a line c_1, meeting d, in a point, Z_1, not corresponding to the point H, or (b, c), of the range (b). The possibility of this requires the assumption that if b and d intersect, the intermediary line c does not pass through their intersection; and this assumption may be made because it is easy to see, from Desargues' theorem, that if the intermediary line c passed through the intersection of b and d, then the ranges on b and d would be in perspective with one another, which we suppose not to be the case. It is also supposed that c_1 does not coincide with b (and therefore does not pass through the intersection of b and d, if they intersect). We shew that c_1 may be used, instead of c, as an intermediary line. From this the general arbitrariness of the intermediary line, asserted above, can be deduced at once. Let the ranges (b) and (c) be in perspective from the centre Q, the points C, C' of c corresponding respectively to the points B, B' of b; also let the ranges (c), (d) be in perspective from the centre R, the points D, D' of d corresponding respectively to the points C, C' of c. The line QR may be called the supplementary line. In the plane $[c, d]$, which contains R, and also contains the line c_1 drawn to meet c and d, let the lines RC, RC' meet c_1 respectively in C_1 and C_1'. The triads B, C, C_1 and B', C', C_1' are in perspective from the point H; thus, by Desargues' theorem, the lines BC, $B'C'$ intersect in a point, Q_1, of the line QR. Whence, taking for B' any point of the range (b), with corresponding positions of C' and C_1', the range (b) is in perspective from Q_1, which is determined by the definite line BC_1, with the range $(C_1, C_1', \ldots)$ lying on the line c_1, while this is in perspective from R with the range (d). Thus c_1 is a new intermediary line for the two given ranges (b), (d). The supplementary line QR is unchanged by the replacement of the line c by c_1, being determined however, now, not by R and Q, but by R and Q_1. When we further, in order to get a general replacement of the intermediary line, replace c_1 by a line c', meeting (b), passing through the point (c_1, d), the point R will be replaced by another point, say R', also on QR; the final supplementary line will be the same as the original supplementary line.

For what follows it is necessary to add the following further remark in regard to the choice of the line c_1. Let c and c_1 meet d in Z and Z_1; as the point Q lies in the plane $[b, c]$, the line QZ meets b, say in X, and X, Z are corresponding points of the ranges (b), (d) respectively. Thus X, Z_1 are not corresponding points of the ranges (b), (d). Hence Q_1, Z_1, X are not in line.

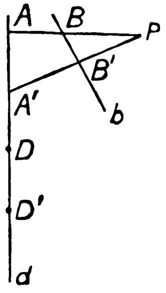
Now suppose the ranges (b), (d), on different lines b, d, to be related, not being in perspective with one another, and (a) to be a range in perspective with (b), the line a not being the same as d. We are to prove that the ranges (a), (d) are related. When (b), (d) are in perspective with one another this is true by definition. As before, let (c) be the intermediary range of (b) and (d), the centre of perspective for (b) and (c) being Q. Let X be the point of intersection of the lines a, b, and Z the intersection of the lines c, d. If Q, Z, X are in line, we can, as we have just proved, suppose c and Q respectively replaced by a line c_1 and a point Q_1 such that, if Z_1 be the point (c_1, d), the points Q_1, Z_1, X are not in line. We may, therefore, without loss of generality, suppose Q, Z, X not to be in line. Let h be the line XZ, joining the points (a, b) and (c, d). [See the diagram on page 24.]

Let A, B, C, D be corresponding points of the ranges (a), (b), (c), and (d), respectively, and A', B', C', D' other corresponding points of these ranges. The line h, joining a point of the line b to a point of the line c, is in the plane $[b, c]$, and therefore intersects the lines BC and $B'C'$, say in H and H' respectively. The triads A, B, H and A', B', H' are in perspective from X; thus, if P be the centre of perspective of the ranges (a), (b), lying at the intersection of BA and $B'A'$, it follows, by Desargues' theorem, that $H'A'$ and HA meet on PQ, say in M; this would fail if Q, Z, X were in line, the points H, H' then coinciding at Q. Again the triads H, C, D and H', C', D' are in perspective from Z; if R be the centre of perspective for the ranges (c), (d), it follows, by Desargues' theorem, that $H'D'$ and HD meet on QR, say in N.

This in effect establishes what is required; for the range on (h) is shewn to be in perspective with the range (a), from M as centre, and in perspective with the range (d), from N as centre, so that the ranges (a), (d) are related; the line h is the intermediary line and the line MN the supplementary line. The points M, N are determined when A, B, C, D are assigned.

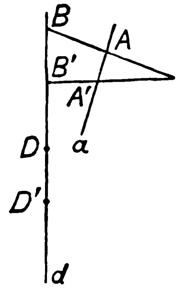


This proof is valid whether the lines a, c intersect or not, and also whether the lines b, d intersect or not. But it is necessary to consider whether the proposition is true when the lines b, d, a are not all different. The proposition has no meaning when a coincides with b; when d coincides either with b or with a, the line h, joining the intersection of a, b with the intersection of c and d, becomes the line d, and the previous construction fails. We must therefore consider the proposition independently. For this purpose it is necessary to define when two ranges on the same line are to be said to be related. If we take the natural course, and define two ranges on the same line as being related when they are both in perspective with the same range from different centres, we cannot at this stage give a proof to enable us to maintain the proposition above when the lines a, d are the same. We cannot in fact prove that if two ranges (b), (d) on different lines be related, then a range (a) on the line d which is in perspective with the range (b) is necessarily related to (d), in the sense that these two ranges (a), (d) are both in perspective with the same range. (The line upon which this last range lies would in fact meet the line d in a point belonging to both the ranges (a), (d); and until we have introduced the so-called complex points it is not necessarily true that the ranges (a), (d) on the line d have any common corresponding points.) Thus we shall define two ranges on the same line as being related when one of them, (a), is in perspective with a range, (b), which is related to the other, (d); it is then at once seen that a range which is in perspective with the other is related to the one. Two ranges on the same line which are both in perspective with another range will then be related, though for not the most general possible reason.



This being understood, the above proposition is true when the lines a, d coincide, namely a range (a) on the line d is related to (d), when (a) is in perspective with a range (b) which is related to (d). And the proposition is also true when the lines b, d coincide, namely if two ranges (b), (d) on the same line are related, a range (a) in perspective with (b) is related to (d).

Thus finally the theorem that if we have a succession of ranges of which any consecutive two are related, then any range in perspective with the first is related to the last, remains true independently of the coincidence of the lines of any two related ranges.



Examples in regard to related ranges.

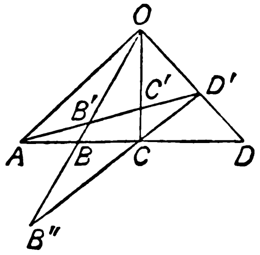
Ex. 1. If A, B, C, D be four points of a line, any two of the four ranges

$$A, B, C, D; \quad D, C, B, A; \quad C, D, A, B; \quad B, A, D, C,$$

which are obtained from the range A, B, C, D by an interchange of two of the points accompanied by an interchange of the other two points, are related.

Take any point O; join OA, OB, OC, OD; let any line through A meet the joins in A, B', C', D' respectively; let the line $D'C$ meet the join $OB'B$ in B''.

The two ranges A, B', C', D' and B, A, D, C are related, being both in perspective with the range B, B', O, B'', respectively from

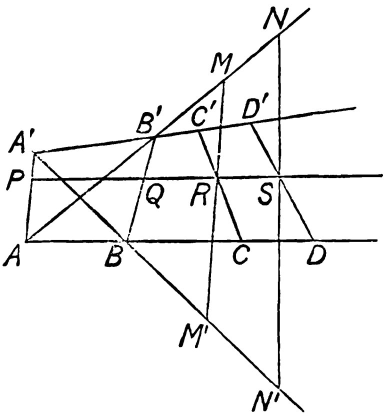


the centres C and D'; and the range A, B', C', D' is in perspective with A, B, C, D from the centre O. Thus (A, B, C, D) and (B, A, D, C) are related. From this the result follows.

Ex. 2. If on two non-intersecting lines there be two ranges A, B, C, D and A', B', C', D' which are related, so also are the ranges A, B, C, D and B', A', D', C', since (by Ex. 1) the latter is related to A', B', C', D'.

Thus if two ranges A, B, C, D and A', B', C', D', on two non-intersecting lines, be such that the four joins AA', BB', CC', DD' have a common transversal, then the four joins AB', BA', CD', DC' have a common transversal. It seems worth while to make a direct proof of this geometrical result, in verification of the foregoing theory.

The fact that the ranges A, B, C, D and A', B', C', D' are related, in accordance with what has been said above, is expressed by the fact that the lines AA', BB', CC', DD' have a common transversal, meeting them respectively, say, in P, Q, R, S. We wish to shew the existence of one or more common transversals of the cross joins AB', BA', CD', DC'. And in fact, if the transversal from R to AB' and $A'B$ meet these respectively in M and M', and the transversal from S, also to AB', $A'B$, meet these respectively in N and N', it can be shewn that the line MN', which is already a transversal of AB' and BA', is equally a transversal of CD' and DC'. The line $M'N$ is also a transversal of these four lines; and other transversals can be found by drawing from P, or from Q, the transversals to CD' and $C'D$. It can also be shewn that the point where the line MN' meets CD' lies on RA' and SA; and similarly the point $(MN', C'D)$ is the same as the point (RB, SB'), the point $(M'N, CD')$ the same as (RB', SB), and the point $(M'N, C'D)$ the same as (RA, SA').



For, first, the lines RA', SA are both in the plane $AA'Q$, and therefore meet, say in the point Y; while the line CD' lies in both the planes RCA' and SDA, and so meets both RA' and SA, but is not in the plane $AA'Q$. Thus CD' contains Y. Again, MN' lies in both the planes $RM'A'$ and SNA, and so meets both RA' and SA, but is not in the plane $AA'Q$. Thus MN' contains Y. Wherefore MN' meets CD' in Y.

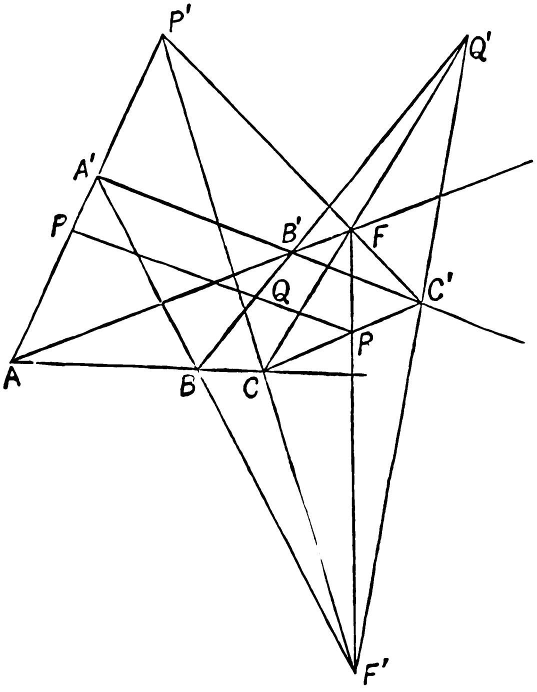
Similarly RB and SB' meet, say in X, and $C'D$ lies in both the planes BRC and $SB'D'$, while MN' lies in both the planes BRM' and $SB'N$. Thus MN' meets $C'D$ in X.

Also, SB and RB' meet, say in T, and CD' lies in both the planes BSD and $B'RC'$, while $M'N$ lies in both the planes BSN' and $B'RM$. Thus $M'N$ meets CD' in T.

Finally RA and SA' meet, say in Z, and $C'D$ lies in both the planes ARC and $A'SD'$, while $M'N$ lies in both the planes ARM and $A'SN$. Thus $M'N$ meets $C'D$ in Z.

The tetrad A, B, B', A' is in perspective with the tetrad Z, X, T, Y, from R, and in perspective with the tetrad Y, T, X, Z, from S. The four lines MC, $M'C'$, ND, $N'D'$ can be shewn to meet BB' in the same point, which is the harmonic conjugate of Q in regard to B and B'. Similarly the lines MC', $M'C$, ND', $N'D$ all meet the line AA' in the harmonic conjugate of P in regard to A and A'.

Ex. 3. It is interesting to shew that, if four skew lines AA', BB', CC', DD' have three common transversals $ABCD$, $A'B'C'D'$, $PQRS$, as in the preceding figure, we can, by the Propositions of Incidence alone, construct other transversals of these four skew lines, in infinite number, equally meeting every line having the three given transversals.



In the first place, if, on the line AA', the point P' be the harmonic conjugate of P in regard to A and A', and, on BB', the point

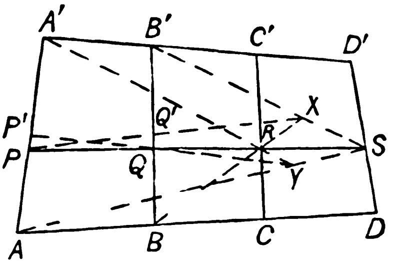
Q' be the harmonic conjugate of Q in regard to B and B', while, similarly, on CC' and DD', the points R', S' are, respectively, the harmonic conjugates of R and S in regard to C, C' and D, D', then the points P', Q', R', S' are in line. And then the line $P'Q'R'S'$ is such a transversal of AA', BB', CC', DD' as was required.

For from R, through which passes the transversal CRC' of AB and $A'B'$, draw the transversal, FRF', of AB' and $A'B$, meeting these respectively in F and F'. Then the lines CF and $F'C'$ intersect one another, and, being respectively in the planes ABB' and $A'BB'$, they meet one another on the line of intersection, BB', of these planes, say at the point Q'. Similarly the lines $F'C$ and $C'F$ meet one another in a point, P', of the line AA'. It can be shewn that Q' and P' are the harmonic conjugates of Q and P respectively in regard to the couples B, B' and A, A'. For, from the construction made, the line $P'R$ meets $F'C'$ in the point harmonically conjugate to Q' in regard to F' and C'; and this point lies on the plane $P'RA'$, which is the plane $A'QA$. Wherefore, by perspective from A', the point Q is the harmonic conjugate of Q' in regard to B and B'. A similar argument is applicable to P and P'. Next, the line $P'Q'$, in the plane of FF' and CC', meets CC', and, by perspective from P', we see that it meets CC' in the point R' which is harmonically conjugate to R in regard to C and C'. If, now, from another point S, of the line PQR, there be drawn the transversal, DSD', to AB and $A'B'$, meeting these in D and D' respectively, and the transversal, GSG', to AB' and $A'B$, meeting these in G and G' respectively, we similarly shew that the lines DG, $D'G'$ meet in Q' and the lines DG', $D'G$ meet in P', and therefore that $P'A'$ meets DD' in the point S' which is the harmonic conjugate of S in regard to D and D'.

The line $P'Q'R'S'$ may be called appropriately the harmonic conjugate of the line $PQRS$ in regard to the lines $ABCD$ and $A'B'C'D'$. We may then similarly draw the harmonic conjugate of the line $A'B'C'D'$ in regard to the lines $ABCD$ and $PQRS$, and continue this process, obtaining from every three transversals of the four lines AA', BB', CC', DD' three others, and so on.

Another method of obtaining a fourth transversal of the four lines AA', BB', CC', DD', when we are given the three transversals $ABCD$, $A'B'C'D'$ and $PQRS$, may be explained, which also leads to an infinite number of transversals. The lines so constructed to meet the four given lines are not, however, shewn to meet any line with the same three transversals.

Let the lines $B'S$ and BR, which are both in the plane SBB', meet in the point X; also the lines $A'R$ and AS, which are both in the plane SAA', meet in the point Y. The line XP, in the former plane, SBB', will meet BB', say in Q'; the line YQ, in the plane SAA', will meet AA', say in P'. It can be shewn that the line $P'Q'$, which already meets AA' and BB', also meets CC' and DD'. In fact the four lines $P'Q'$, CC', XA, YB' meet in one point, as do the lines $P'Q'$, DD', YB, XA'. A simple method of verifying this, and similar results, arises later. For the present we may argue as follows.



The lines XA, YB', in the plane ASB', intersect; the lines XA, $P'Q'$, in the plane XAP, intersect; the lines YB', $P'Q'$, in the plane YQB', also intersect. Hence the three lines $P'Q'$, XA, YB' lie in one plane or meet in one point; the former would involve that $B'Q'$ and AP', that is BB' and AA', were in one plane, and is excluded.

Again, the lines YB' and CC', in the plane $RC'A'$, intersect; and the lines AX, CC', in the plane BCR, intersect; while we have shewn that AX and YB' intersect. Hence the three lines CC', XA, YB' all lie in one plane, or meet in one point; the former would involve that $B'C'$ and AC, and therefore also BB' and CC', were in one plane, and is excluded.

Wherefore, as stated, the four lines $P'Q'$, CC', XA, YB' meet in one point.

A similar proof can be given for $P'Q'$, DD', XA', YB.

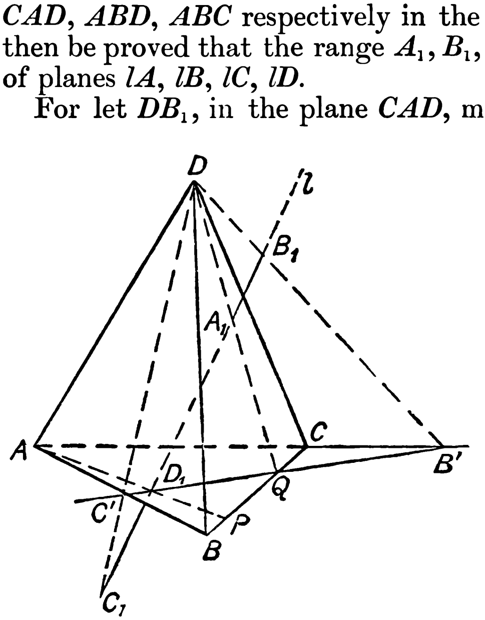
It can also be shewn that X lies on $C'D$, and that Y lies on CD'.

It cannot be proved at present that $P'Q'$ meets any other line meeting the three lines $ABCD$, $PQRS$, $A'B'C'D'$, beside the four AA', BB', CC', DD'; and it is in this respect different from the harmonic conjugate obtained above.

From $P'Q'R'S'$ we can find another line $P''Q''R''S''$ meeting AA', BB', CC', DD', just as we found $P'Q'R'S'$ from $PQRS$; and so on continually.

Ex. 4. Four planes, say α, β, γ, δ, which meet in a line, x, are said to form an axial pencil of planes. If these planes be met by any line, l, which does not meet the line x, respectively in the points A, B, C, D, and by any other line, l', not meeting x, respectively in the points A', B', C', D', then the ranges A, B, C, D and A', B', C', D' are related, since the joins AA', BB', CC', DD' have the common transversal x. We may thus speak of an axial pencil of planes, (ϖ), and a range of points, (m), as being related when the planes of (ϖ) are met by an arbitrary line, not meeting the axis of (ϖ), in a range which is related to (m).

With this definition, consider a tetrad of points A, B, C, D, not lying in a plane, and let any line, l, meet the four planes BCD, *CAD*, *ABD*, *ABC* respectively in the points A_1, B_1, C_1, D_1. It can then be proved that the range A_1, B_1, C_1, D_1 is related to the pencil of planes lA, lB, lC, lD.

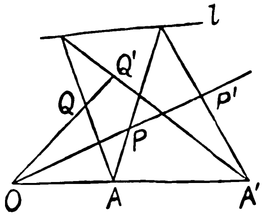


For let DB_1, in the plane *CAD*, meet *AC* in B'; let DC_1, in the plane *ABD*, meet *AB* in C'; and let DA_1, in the plane *BCD*, meet *BC* in *Q*. Then the points C', D_1, Q, B' are in the plane *Dl*, and are thus in line. Let AD_1, in the plane *ABC*, meet *BC* in *P*.

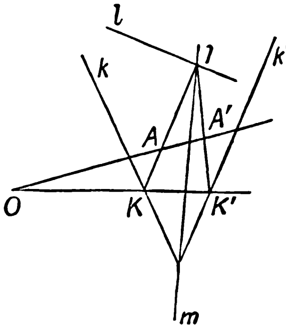
Then the ranges C_1, D_1, A_1, B_1 and B, P, Q, C, lying on lines which do not intersect, are related, because the joining lines of corresponding points, BC_1, PD_1, QA_1, CB_1, all meet the line *AD*. Wherefore, by Ex. 2 above, the ranges C_1, D_1, A_1, B_1 and C, Q, P, B are related. The latter four points lie however, respectively, upon the planes lC, lD, lA, lB. This proves the result stated.

Ex. 5. We have shewn that Desargues' theorem follows by assuming the Propositions of Incidence for space of three dimensions. Conversely it can be shewn that, if Desargues' theorem for triads of points in one plane be assumed, there are aggregates of points and lines in this plane which combine together in accordance with laws corresponding to the Propositions of Incidence of space of three dimensions. Thus, also, beings of only two-dimensional experience might, in effect, be familiar with a three-dimensional geometry.

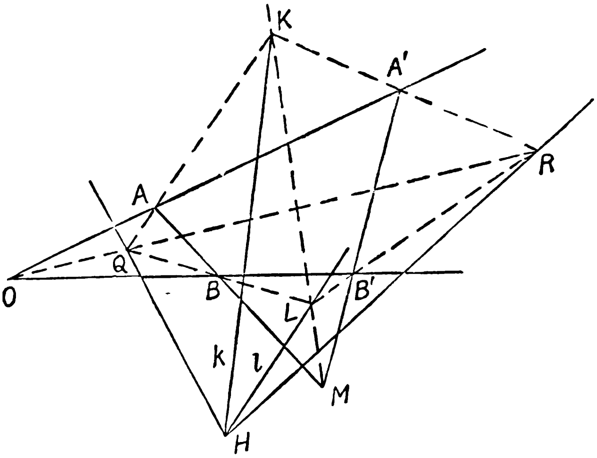
Take an arbitrary fixed point *O* of the plane. Any two points P, P' of the plane which are such that the line PP' passes through O, determine a point couple (P, P'), which, in the scheme we are explaining, plays the part of a point in a three-dimensional space of which the given plane is one plane. The couple (P', P) is to be distinguished from (P, P'). When P' coincides with P, the couple (P, P) represents the point P of the plane, regarded as belonging to the threefold space. When P' is at O, the couple (O, P), regarded as equivalent with (P, O), represents the point O itself, whatever P may be. Any two lines of the plane, taken in a definite order, give a line couple, which represents a line of the threefold space. Thus a line couple $(PQ, P'Q')$ is determined by two point couples (P, P') and (Q, Q'), and contains other point couples in infinite number, of which any two suffice for its determination. The condition that a line couple, (k, k'), should contain a point couple, (P, P'), is that the line k should contain the point P and also the line k' contain the point P'. Lastly, let the aggregate of a point couple (A, A'), and a line, l, of the given plane, represent a plane, any point couple (P, P') being regarded as lying on this plane when the lines PA and $P'A'$ meet on the line l. Thus if (Q, Q') be any other point couple of this plane, it follows, by Desargues' theorem, considering the two triads APQ, $A'P'Q'$, that the lines PQ, $P'Q'$ meet on the line l, so that the plane is equally represented by the point couple (P, P') and the line l; also any line couple $(PQ, P'Q')$ of the plane, determined by the two point couples (P, P') and (Q, Q'), is represented by two lines of the given plane which intersect on the line l. Any three point couples, (A, A'), (P, P'), (Q, Q'), determine the plane, which is given by the point couple (A, A') and a line l of the original plane containing the intersection of AP, $A'P'$, the intersection of AQ, $A'Q'$, and the intersection of PQ, $P'Q'$.



Any line couple, (k, k'), and plane (AA', l), have then a point couple in common. For, in the given plane, with the lines k, k' and the points A, A', by drawing lines through O to meet k, k', we can, in virtue of Desargues' theorem, construct a line, m, passing through the intersection of k and k'. If this line meet the line l in T, the lines TA, TA', by their intersections with k, k' respectively, define a point couple (K, K'). This lies on the line couple (k, k') and also on the plane (AA', l), and is the point couple common to these.



Again, any two planes, (AA', k) and (BB', l), have a line couple in common. For take the line couple containing the two point couples (A, A') and (B, B'), which is represented by the two lines AB, $A'B'$ of the given plane; let these meet in M. Draw from M an arbitrary line in this plane, meeting the two given lines k, l, of this plane respectively in K and L; let KA, LB meet in Q, and KA', LB' meet in R. Then from Desargues' theorem, applied to the two triads A, Q, B and A', R, B', it follows that QR passes through O, so that (Q, R) is a point couple. As QA, RA' meet on k, and QB, RB' meet on l, this point couple belongs to both the planes. If another line ML_1K_1 be drawn through M, and Q_1 be the position thence obtained for Q, the application of Desargues' theorem to the triads L_1, K_1, Q_1 and L, K, Q shews that the line QQ_1 passes through the point *H* where *k* and *l* intersect. Similarly the point ***R*** describes a line passing through *H*. Thus the point couple (*Q*, *R*)



K
A'
R
A
Q
O
B
B'
L
k

couple (P, P') to intersect each of two given lines represented by the line couples (l, l') and (m, m'). By drawing variable lines through O to meet the lines l, l' in L and L' respectively, and joining LP, $L'P'$, we define, by the locus of the intersection of these, a line h. Similarly lines through O meeting m and m' in M and M' respectively define a line k. Let these lines h, k intersect in H. Then let the lines HP, HP' meet l and l' respectively in R and R'; these will lie on a line through O and define a point couple (R, R'). So, let HP, HP' define by their intersections respectively with m and m' a point couple (S, S'). Then (HP, HP') are a line couple, representing a line, containing the given point couple (P, P'), which meets the line couple (l, l') in the point couple (R, R'), and meets the line couple (m, m') in the point couple (S, S'); as was desired.

Propositions of Incidence in space not limited to three dimensions. In general we assume that by means of two *points* a system of points is determined which can equally be determined by any two different points of the system. This system of points is said to lie on a *line*. A point is said *to be dependent upon*, or *to be in syzygy with*, two specified points, when it belongs to the system of points determined by these two. Later on we shall use the word *space* instead of the word *system*.

By means of three points, of which no one is dependent upon the others, a system of points is determined which can equally be determined by any three independent points of the system. The points of the line determined by any two points of the system all belong to the system. The system of points determined by three independent points is said to lie on a plane, or to be a twofold system. A point is said to be dependent upon, or to be in syzygy with, three specified independent points when it belongs to the system of points determined by these three.

By means of four independent points a system of points is determined which can equally be determined by any four independent points of the system. The points of a plane determined by any three independent points of the system, and therefore also the points of a line determined by two points of the system, all belong to the system. A point is said to be dependent upon, or in syzygy with, four independent points when it lies in the system determined by these four. Such a system is called a threefold system, or the points are said to lie on a threefold.

And so on in general, without limit.

Consider now an n-fold system which is determined by $(n+1)$ points, these last being such as to contain three independent points, a fourth point independent of these, a fifth point independent of these four, and so on, and, finally, an $(n+1)$th point independent of the preceding; in such an n-fold system there exist r-fold systems

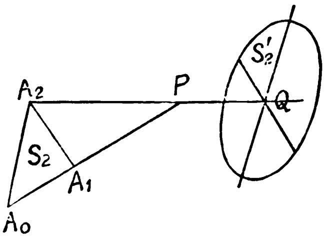
$(r < n)$, each determined by $(r+1)$ independent points, of which, by hypothesis, every point belongs to the n-fold system. Two such contained systems, for the same or different values of r, may have points in common. Denote by S_r a system determined by $(r+1)$ independent points, and in particular by S_0 a single point. The general statement is that, *if r and h be two numbers both less than n but such that their sum is equal to or greater than n, then two systems, S_r and S_h, both contained in S_n, have always common a system S_{r+h-n}, but may have common a system S_k for which k is greater than $r+h-n$. When, as before, $r<n$ and $h<n$, but $r+h<n$, two systems S_r, S_h, both contained in S_n, have not always a system common. In general, with $r<n$, $h<n$, if two systems S_r, S_h, both contained in S_n, have common a system $S_{r+h-n+t}$, then there exists a system S_{n-t}, contained in S_n, which contains both S_r and S_h.*

We shew that these results are a logical consequence of one fundamental proposition, which, like the conception of a system of points determined by given points, we assume. This proposition is that, *if in the system S_n there be contained a system S_{n-1}, determined by n independent points of S_n, and also a system S_1, determined by two points of S_n which do not belong to S_{n-1}, then S_1 and S_{n-1} have one point in common*, so that every S_{n-1} contained in S_n has with every S_1 contained therein at least one common point. For instance we assume that, in a S_2 (or plane), any two S_1, (any two lines), have a point in common; and, in a S_3, any plane has common, with a line determined by two points not in this plane, a single point.

(1) From this proposition it follows that every S_r contained in S_n, where $r<n$, has a point in common with every S_{n-r} contained in S_n.

To prove this we remark that when $r=2$ every S_{r-1} contained in S_n has a point in common with any S_{n-r+1} contained therein. Then we shew that, from the assumption that every S_{r-1} contained in S_n has a point in common with any S_{n-r+1} contained therein, it follows that every S_r contained therein has a point in common with any S_{n-r} so contained. Consider an S_r determined by the $r+1$ independent points $A_0, A_1, \ldots, A_r$, contained in S_n, and an S_{n-r} contained in S_n. It is supposed that S_r is not wholly contained in S_{n-r}; there is therefore at least one of the points $A_0, A_1, \ldots, A_r$ which is not contained in S_{n-r}; we may therefore suppose that the point A_r is not contained in S_{n-r}, and that the points $A_0, A_1, \ldots, A_{r-1}$ are independent points. The S_{n-r} is determined by $n-r+1$ independent points, and we may suppose that A_r is independent of these, since $(n-r+1)+1$, or $n+1-(r-1)$, is less than the greatest possible number, $n+1$, of independent points in S_n (for $r=2, 3, \ldots$). These $n-r+1$ points together with A_r thus determine a Σ_{n-r+1} contained in S_n, which we may speak of as determined by S_{n-r} and A_r. On the other hand the points $A_0, A_1, \ldots, A_{r-1}$ determine a Σ_{r-1} contained in S_r. By what we have supposed, this Σ_{r-1} and the Σ_{n-r+1} have a point in common (one at least), which we may denote by P. This point P, being in Σ_{r-1}, is in S_r, as also is A_r, and we can suppose P and A_r not to coincide; thus the points P and A_r determine a Σ_1 lying in S_r. On the other hand both P and A_r lie in the Σ_{n-r+1} determined by S_{n-r} and A_r, as therefore also does the Σ_1. By the fundamental proposition, therefore, the Σ_1 and S_{n-r} have a point in common, say Q, which, as Σ_1 is contained in S_r, is a point common to S_r and S_{n-r}. This is the point whose existence was to be shewn.

To explain the argument by a particular case suppose $n=4$ and $r=2$. We are to shew that any two planes in a space of four dimensions have a point in common (one at least). Let these be S_2, determined by the independent points A_0, A_1, A_2, and S_2', of which S_2' does not contain A_2. Then A_2 and S_2' determine a Σ_3, while $A_0 A_1$ determine a Σ_1' contained in S_2; this Σ_1' has with Σ_3 a point P common. Both A_2 and P are in S_2, and determine a Σ_1, the line A_2P. But A_2 and P are both in Σ_3, which contains S_2'. Thus the line A_2P meets S_2', in Q, which is then common to S_2 and S_2'. Thus it appears as a consequence of the facts that in an S_3 a line intersects a plane, and in an S_4 a line intersects an S_3, that, in an S_4, an S_2 intersects an S_2'.

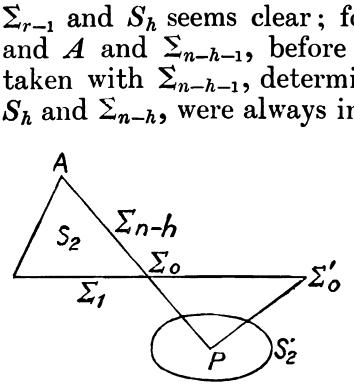


(2) We next deduce, if $r<n$ and $h<n$, but $r+h \geqq n$, that an S_r and an S_h have an S_{r+h-n} in common (at least). It is sufficient, after (1), to prove this when $r+h>n$. For this we suppose that an S_{r-1} and an S_h have an $S_{r+h-n-1}$ in common, which is true, by (1), when $r=n-h+1$.

We can, as in (1), suppose the S_r to be determined by a Σ_{r-1}, lying in S_r, and a point A, also lying therein. Then, because $r \geqq n-h$, we can, in Σ_{r-1}, find a Σ_{n-h-1}; with A this will determine a Σ_{n-h}, lying in S_r; by (1), this Σ_{n-h} will contain a point, P, of S_h; this point P lies then in S_r and S_h. By hypothesis the Σ_{r-1} and S_h have a $\Sigma_{r+h-n-1}$ in common; this, lying in Σ_{r-1}, also lies in S_r. Assuming, for a moment, that P does not lie in the $\Sigma_{r+h-n-1}$, this point P and the $\Sigma_{r+h-n-1}$, together, determine an S_{r+h-n}, and this lies both in S_r and S_h because both P and $\Sigma_{r+h-n-1}$ do so. This establishes the statement made.

That the common point, P, of S_h and the Σ_{n-h} determined by Σ_{n-h-1} and A, does not necessarily lie in the $\Sigma_{r+h-n-1}$ common to

Σ_{r-1} and S_h seems clear; for we can suppose P determined by S_h and A and Σ_{n-h-1}, before we specify the $r+h-n$ points which, taken with Σ_{n-h-1}, determine the Σ_{r-1}; if P, which is common to S_h and Σ_{n-h}, were always in Σ_{r-1}, it would be in Σ_{n-h-1}; this however has, in general, no point common with S_h.



For an illustrative example, let $n=3$, $r=2$, $h=2$; the theorem will be that in an S_3, a space of three dimensions, an S_2 has with an S_2' a line common. We suppose the S_2 determined by a line Σ_1 and a point A. In this line Σ_1 take a point Σ_0; this point, with A, determines a line Σ_{n-h}, lying in S_2. This line, Σ_{n-h}, contains a point P of S_2', lying in S_2. The line Σ_1 has, with S_2', a common point Σ_0', also in S_2. As P and Σ_0' are different, they determine a line, $P\Sigma_0'$, lying both in S_2 and S_2'. Thus the hypothesis that a line and an S_2', lying in an S_3, have a point in common, involves that two planes in S_3 have a line in common.

(3) Lastly, if in a system S_n, an S_r and S_h have common a system $S_{r+h-n+t}$, then there exists a system S_{n-t}, contained in S_n, which contains both S_r and S_h. It is not assumed that $r+h$ is as great as n.

By the hypothesis we must have

$$r+h-n+t \leqq r, \quad \text{and} \quad r+h-n+t \leqq h,$$

so that $h \leqq n-t$ and $r \leqq n-t$. We can take, in $S_{r+h-n+t}$, independent points in number $r+h-n+t+1$; these, with $n-t-h$ points, independent of the former, taken in S_r, will furnish $r+1$ independent points by which S_r may be determined; the same $r+h-n+t+1$ points in $S_{r+h-n+t}$, with $n-t-r$ points independent of those already taken in S_h, will furnish $h+1$ points by which S_h may be determined. The total number of independent points thus employed is, however, only

$$(r+h-n+t+1)+(n-t-h)+(n-t-r)$$

or $n-t+1$. The system determined by these, which is a S_{n-t}, contains then both S_r and S_h.

For example, for $n=4$, $r=h=2$, two planes in a fourfold space have not a line in common unless they both lie in the same space of three dimensions.

Examples of the Propositions of Incidence in space of four and five dimensions.

Ex. 1. In space of four dimensions, two lines which have no point in common, being each determined by two points, determine together a space of three dimensions, defined by four points two on each line. This threefold space has in common with any arbitrary third line of the fourfold space a single point; from this point can be drawn, in this threefold space, a single transversal line of the two former lines. Thus we can shew that three general lines in space of four dimensions are all met by one other definite line. If the three lines lie in a threefold space they have, of course, an infinite number of common transversals.

Ex. 2. In general a line and plane in a fourfold space have no point in common. If they have a point O in common, this with another point P of the line, and two other points A, B of the plane not lying in line with O, make four points, which determine a threefold space containing both the given line and plane.

But through one of three lines in fourfold space, having one common transversal, can be drawn a single plane to meet each of the other two lines in a point, that namely containing the chosen line and the common transversal line of the three given lines.

It follows that, in space of four dimensions, ∞^1 planes can be drawn through an arbitrary point O to meet each of three given lines of general position. For a plane can be drawn containing the line joining O to an arbitrary point of one of the three given lines which shall meet each of the other two. We can further specify three other lines each of which is met by every one of these planes. For consider one of these planes, meeting the three given lines a, b, c, respectively in A, B, C. In this plane the lines AB and OC intersect one another, say in the point P. And this point P is clearly on the line which is the intersection of the threefold defined by the lines a, b and the plane Oc. There are two other lines which arise by replacing c, in this description, by a or by b.

Ex. 3. It has already been remarked above that the necessary condition for two planes in fourfold space to have a line in common is that these planes should lie in a threefold space. This space will be determined by two points of the line and two further points, one on each plane.

Ex. 4. Three lines in most general position, being determined by six points, two on each line, lie in at most five dimensions; if the lines have a single common transversal line, they lie in the fourfold space determined by two points of this and a further point on each of the lines; if they have two common non-intersecting transversal lines they lie in the threefold space determined by these. Similarly a line and a plane, determined by two points of the line and three points of the plane, lie in a fourfold space, unless the line and plane have a common point. Further, two planes are determined by three points on each, and lie in at most five dimensions; if the planes have one common point they lie in four dimensions; if they have two common points they lie in three dimensions.

three points $(BC, B'C')$, $(CA, C'A')$, $(AB, A'B')$, which, as the planes ABC, $A'B'C'$ are distinct, must be in line. The six points of intersection of corresponding lines are then on four lines of the plane ϖ. (Cf. the tetrads A, B, C, P; A', B', C', P' in the Frontispiece.)

Ex. 7. The results of Examples 2 and 5 may be generalised—and the conclusions will be of interest for an application to the theory of related ranges of points.

We prove that in space of an odd number of dimensions, S_{2n-1}, a definite S_{n-1} can be drawn through a point, O, to meet n lines of general position, each in one point. And hence, that there are ∞^1 spaces S_{n-1} meeting $(n+1)$ lines of general position; and further, when $n > 2$, that each of these S_{n-1} meets the line which is the intersection of the S_3, containing any two of the $(n+1)$ given lines, with the S_{2n-3} containing the remaining $(n-1)$ of the given lines. There are $\frac{1}{2}n(n+1)$ lines of this description.

We prove, also, that in space of an even number of dimensions, S_{2n}, a definite S_{n-1} can be drawn to meet $(n+1)$ lines of general position. And hence, that there are ∞^1 spaces S_n passing through a point, O, which meet $(n+1)$ lines of general position; and further, when $n > 1$, that each of these S_n meets the line which is the intersection, of the S_3 containing two of the $(n+1)$ given lines, with the S_{2n-2} containing O and the remaining $(n-1)$ of the given lines. There are $\frac{1}{2}n(n+1)$ lines of this description.

Consider a space S_{2n-1}, and therein a point, O, and n lines of general position. Let a be one of the lines; the remaining $(n-1)$ lines, each determined by two of its points, together with O, depend upon $(2n-1)$ points, which, as we provisionally assume, may be regarded as independent. These determine then a S_{2n-2} containing O and these $(n-1)$ lines, which we speak of as determined by O and these lines. In the S_{2n-1}, this S_{2n-2} meets the line a in a point, say A. There are other $(n-1)$ spaces, also of dimension $(2n-2)$, each of which contains the point O, the line a, and all of the remaining given lines except one. The n spaces, S_{2n-2}, thus defined, meet in a S_{n-1}, which contains the point A, this being on every one of the spaces. By symmetry this S_{n-1} contains a point of each of the n given lines; and it passes through O. Conversely a S_{n-1} through O, which meets each of the n given lines, has n points in common with a S_{2n-2} containing O and any $(n-1)$ of these lines; such S_{n-1} thus coincides with that found, which is therefore unique.

It follows that there are ∞^1 spaces S_{n-1} meeting $(n+1)$ lines of general position in S_{2n-1}, namely one such through every point of a selected one of the $(n+1)$ given lines. Let one such S_{n-1} meet two of these given lines, say a_1 and a_2, respectively in A_1 and A_2. The $(n-1)$ intersections of this S_{n-1} with the other $(n-1)$ given lines determine a S_{n-2} lying in the chosen S_{n-1}; and the line A_1A_2, lying in the S_{n-1}, meets this S_{n-2} in a point, say P. This is a point of the S_{n-1}. The line A_1A_2, however, lies in the S_3 determined by the lines a_1 and a_2; and the S_{n-2} contains $(n-1)$ points of the S_{2n-3} containing the other $(n-1)$ given lines, and so lies in this S_{2n-3}. Thus the point P is in the space common to the S_3 and S_{2n-3}; this common space is of dimension $(2n-1)-(2n-4+2)$ or 1, namely it is a line. This proves the result stated for a space S_{2n-1}. The method of proof is provisional, since we have, for simplicity, assumed without examination various sets to consist of independent points. The same remark applies to the case of a space S_{2n}, which we now consider.

In a space S_{2n} suppose $(n+1)$ lines of general position to be given. Let a be one of these lines. The remaining n lines determine a S_{2n-1}, which will meet the line a in a point, say A. The space common to this S_{2n-1} and to the other n spaces of dimension $2n-1$, each determined by the line a and $(n-1)$ of the remaining lines, is of dimension $2n-(n+1), = n-1$. This S_{n-1} contains the point A, which is on each of the $(n+1)$ spaces S_{2n-1}; and thus, by symmetry, this S_{n-1} meets every one of the $(n+1)$ given lines. Conversely, any existing S_{n-1} meeting these lines, as it contains n points of each S_{2n-1} containing n of these lines, lies in all the $(n+1)$ spaces S_{2n-1}; the S_{n-1} found is therefore unique. Hence we deduce that a single space S_n exists containing an arbitrary line, b, which meets n other lines of general position. For this line, b, and these n others, are all met by a certain S_{n-1}, as we have shewn; this S_{n-1} is determined by n points which, with a point of the line b not lying on the S_{n-1}, give $(n+1)$ points determining a S_n containing b and the S_{n-1}; this S_n therefore meets these n other lines each in a point.

It follows that ∞^1 spaces S_n can be drawn through an arbitrary point O to meet $(n+1)$ lines of general position. Take one of these S_n; let a_1, a_2 be two of the $(n+1)$ lines, the aggregate of the remaining $(n-1)$ lines being denoted by (c). On these lines (c) there are the $(n-1)$ points in which they are met by this S_n, and this also contains the point O. These n points determine a S_{n-1} lying in this S_n, and this is intersected in a point by the line, say t, also lying in this S_n, joining the two points where this S_n meets a_1 and a_2. Thus we have a point, say P, of S_n not on any of the $(n+1)$ given lines. The S_{n-1} contains n points of the S_{2n-2} determined by the $(n-1)$ lines (c) and the point O, and the line t lies in the S_3 determined by the two lines a_1, a_2. The point P therefore lies on the intersection of this S_{2n-2} and S_3, and these, in S_{2n}, meet in a space of $2n-(2+2n-3)$ dimensions, that is in a line. The ∞^1 spaces S_n thus meet the line which is the intersection of the S_3, containing two of the $(n+1)$ given lines, and the S_{2n-2} determined by O and the $(n-1)$ remaining lines. There are $\frac{1}{2}n(n+1)$ lines of this description.

Ex. 8. We have said that two ranges of points on two lines in threefold space are related when they are both in perspective with the same range on another, intermediary, line, from two appropriate centres. The threefold space may be determined by the two centres of perspective and two points of the intermediary line. As a particular case the two ranges may lie on lines which are in a plane. When this is not so the ranges are related if the joining lines of corresponding points of the ranges all meet another line. The definition gives a geometrical construction by which we may pass from a point of either range to the corresponding point of the other range *depending only on the Propositions of Incidence.* Suppose that, in a space which is of higher than three dimensions, we have a set of lines arranged in order, say a, b, c,..., k, each containing a range of points, and that the ranges (a), (b) are related by the preceding construction, which will be confined to the threefold (or twofold) space determined by the lines a, b, also the ranges (b), (c) related by this construction, in the threefold space (b, c), and so on for every consecutive two. Then we may enquire whether the ranges (a), (k) are related by the preceding construction. Next suppose that in a space of more than three dimensions we have two ranges (a), (k) for which we have a geometrical construction, only depending on the Propositions of Incidence, defining uniquely the point of either range from a corresponding point of the other. We may then enquire whether two such ranges are related according to the preceding definition. If the answer to this query be affirmative, that to the former will also be.

We do not enter into this enquiry now. But the preceding example gives a case which is illustrative. In four dimensions a geometrical correspondence is effected between the points, P, Q, of two lines, a, b, by means of planes containing these points drawn through a point O to meet a third line, c. We have shewn that then the joining line PQ meets the plane Oc in the points of a line lying in the threefold determined by a and b. In five dimensions a geometrical correspondence is effected between the points, P, Q, of two lines, a, b, by means of planes containing these points which meet two other lines, c, d. We have shewn that then the joining line PQ meets the threefold space determined by c, d in the points of a line lying in the threefold space determined by a and b. And we have shewn that this can be generalised to space of higher dimension. (See Note I, at the end of the Volume.)

Ex. 9. Another example interesting to consider in connexion with the enquiry suggested in the last example arises for the planes which meet four lines of general position in space of four dimensions. One such plane can be drawn passing through two arbitrary points one on each of two of the four given lines; so that we may say there are ∞^2 such planes. It will be proved subsequently, with the help of an assumption in addition to the Propositions of Incidence, that all these planes meet another line. (See p. 92, below.)

Let the given lines be denoted by a, b, c, d, and the line which meets a, b, c be denoted by d', the lines meeting the other sets of three of the four given lines being denoted respectively by a', b', c'; then it can be shewn from the Propositions of Incidence only that the four threefolds determined respectively by the pairs of lines (a, a'), (b, b'), (c, c') and (d, d') do not meet in a point merely, but in a line. It is this line which is shewn to be met by any plane meeting the lines a, b, c, d.

On the Principle of Duality in general. We have remarked that in three dimensions the Propositions of Incidence establish a duality whereby, to every geometrical result involving points, lines and planes, there corresponds a result involving respectively planes, lines and points. A similar duality arises from the Propositions of Incidence in space of any number of dimensions. If the space be of n dimensions the correspondence between spaces contained therein is between a space of dimension r and a space of dimension $n-r-1$. Thus to a point corresponds a S_{n-1}; to the line determined by two points corresponds the S_{n-2} which is the intersection of two spaces S_{n-1}, and so on. To our fundamental proposition that a line meets a S_{n-1} in a point corresponds then the statement that a S_{n-2} and a point together determine a S_{n-1}, which was a more fundamental part of our description of what is a space, or system.

Thus, in four dimensions, to a point corresponds a threefold and to a line corresponds a plane; and conversely in each case. For example, as two planes in four dimensions have in general a point in common, so two lines determine a threefold; the fact that when the planes have a line in common they lie in a threefold, becomes the fact that when two lines lie in a plane they have a point in common. The fact that a line and a plane which meet in a point lie in a threefold is evidently dual to its converse. Again as there is a line meeting each of three general lines in a point, so there is a plane meeting each of three given planes in a line; the fact that three lines lying in a threefold are met, each in a point, by an infinite number of lines lying in this threefold, becomes the fact that if three planes have a point in common an infinite number of planes can be drawn through this point each meeting each of the three given planes in a line. The result we have discussed above, that there is an infinite number of planes through a given point meeting each of three given lines, of general position, in a point, becomes the statement that of the lines meeting three given planes of general position there is an infinite number lying in an assigned threefold; these are evidently the common transversals of the lines in which the three given planes meet the threefold.

In five dimensions a line is dual to a threefold and a plane is dual to a plane. For example, the fact that two lines in a plane have a point in common is dual to the fact that if two threefolds, instead of meeting in a line, meet in a plane, then they lie in a fourfold space.

On projection from one space to another. It is frequently possible to make a correspondence by geometrical construction between the points of one space, α, and the points of another space, β, a single arbitrary point of either space being thus related uniquely to a single point of the other space. When through certain fixed points, or spaces, γ, variable spaces, ϖ, can be drawn, each of which intersects the space α in one point, and is made unique by the assignment of this point, and then intersects the space β in one point, and if the same is true when instead of α, β we say respectively β, α, then such a correspondence may be called a projection. The process will have so many applications that it seems unnecessary to do more at this stage than to refer to it as one of the fundamental things.

SECTION II. THE CORRESPONDENCE OF THE POINTS OF TWO LINES. PAPPUS' THEOREM

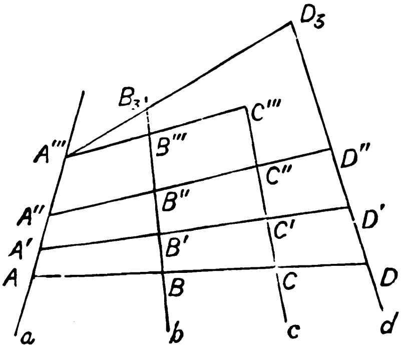
Preliminary remarks. In using the words point, line, plane, for the entities of our theory, it is clearly intended that the properties obtained shall not be widely different from those ordinarily supposed to belong to the entities, given or suggested by experience, to which these familiar names are attached. In particular, the fullness, or multiplicity, of the points that are possible on a line must not be widely different in the two cases. As will appear quite adequately in the sequel, this condition is not secured by the Propositions of Incidence alone; these leave us free to regard as distinct, because differently obtained, points which, from the suggestions of our experience, we should regard as coincident. This experience takes account in fact of other ideas than those we have embodied in the Propositions of Incidence, in particular of the idea of one point of the line being *between* two others. This idea is considered in Chapter II. As has been stated in the Introductory Remarks to this volume, we do not finally adopt this idea as fundamental; the present Section is intended to lead up to the adoption of another assumption which will enable us to avoid this.

The question of the identification of points upon a line we merge in the question of the identity of the points of two ranges of points on the line; and this we regard as a particular case of the question when two ranges of points on two different lines can be regarded as being in unambiguous correspondence, so that the specification of a point of either line leads to a definite point of the other. One way in which such a correspondence arises is suggested by our preceding work; the points of two ranges which are in perspective from a point are evidently in such unambiguous correspondence. It is natural then to make the condition that a method of correspondence adopted shall be such that ranges in perspective are a particular case; and hence that ranges which are in correspondence by means of a succession of any number of perspectivities shall also be in correspondence in virtue of the definition which we adopt. In a phraseology we have used, and by a result obtained in Section I, this comes to saying that two ranges which are *related*, in particular in perspective, shall correspond with one another. A particular consequence of this condition is that if four points of one range be in the harmonic relation to one another, this shall be true also of the four corresponding points of the other range. But, of four points in this harmonic relation, three can be taken arbitrarily. Thus the method of correspondence which we adopt must be of such generality that, having taken any three points upon one of two lines, a correspondence is possible in which any three arbitrarily chosen points of the other line correspond respectively to these; and the same must be true of two ranges upon the same line which correspond to one another. Now, we can find upon any line, b, a range which is related, in the sense used in Section I, to a given range upon another line, a, so that three arbitrary points of b shall correspond to three specified points of the given range (a); if the Propositions of Incidence were sufficient to secure an unique point of b to correspond then to an arbitrary point of the given range (a), these Propositions might be a sufficient basis for such a theory of correspondence. Unfortunately this is not so. On the other hand a range on one line, related to a given range on another line, cannot be constructed so that four arbitrary points of the constructed range shall correspond to four given arbitrary points of the original range.

Hence either we must give up the suggestion that the method of correspondence adopted, ultimately with a view to the identification of the points of a line, shall lead us to regard related ranges as being in correspondence; or else a statement that two ranges are in correspondence because they are related must always be accompanied by a statement of a particular construction rendering the method of relation unambiguous; or else finally we must add to the Propositions of Incidence some further general Proposition which, probably by acting as a restriction of what points we regard as possible on a line, shall secure that the correspondence of the points of two related ranges is unique when three points of the one are given as corresponding to three points of the other. It is the last alternative which we adopt. As will be seen, a geometrical theory can thus be framed which, avoiding many particular assumptions, obtains results exactly corresponding to those usually based on these assumptions. The merit of pointing out, in part, the very remarkable fact that such a course should be possible belongs originally to H. Wiener, *Jahresbericht d. Deutschen Math.-Verein*, Erster Bd., 1890–91, p. 47. His statement relates to geometry in a plane. For subsequent development cf. F. Schur, *Math. Annal.* LI, 1899, p. 402 and Hilbert, *Gauss-Weber Festschrift*, *Grundlagen der Geometrie*, 1899.

Conditions that the correspondence of two related ranges should be of freedom three. Consider, in space of three dimensions until the contrary is said, two lines, a, b, which do not intersect. Upon the former take three arbitrary points, A, A', A'', and upon the latter three arbitrary points, B, B', B''. Join AB; upon this take any point C. From C draw the transversal, $CC'C''$, to meet the join $A'B'$ in the point C', and the join $A''B''$ in the point C''; denote this transversal by c. Then, if A''' be any fourth point on the line a, the transversal, $A'''B'''C'''$, drawn from A''', to meet the line b in B''' and the line c in C''', makes correspond to the arbitrary point A''' of a the definite point B''' of b. Namely the assignment of three points, B, B', B'', of b, to correspond respectively to three given points, A, A', A'', of a, *with the additional assignment of a definite point* C *of the line* AB, makes correspond to any range $(AA'A''A'''\ldots)$ of the line a, a definite range $(BB'B''B'''\ldots)$ of the line b.

But it does not follow that this correspondence is independent of the position of C upon the line AB, when A, A', A'' and B, B', B'' remain the same. Let D be any other point of the line AB, and draw the transversal d to meet the line $A'B'$ in the point D', and $A''B''$ in D''; then denote by B_3 the point in which the transversal $A'''B_3D_3$, drawn from A''' to meet the lines b and d, meets the line b. It does not follow from the Propositions of Incidence alone that the point B_3 coincides with B'''.

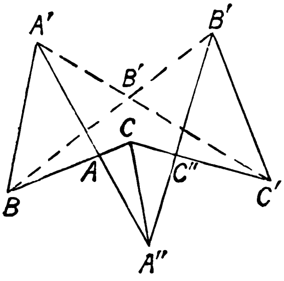


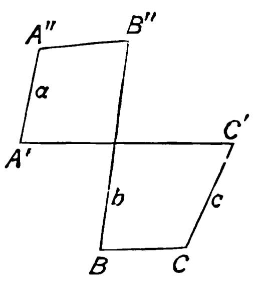
If B_3 do coincide with B''', then the line $A'''B'''C'''$ coincides with the line $A'''B_3D_3$ and meets all of a, b, c, d. If such coincidence holds for all positions of A''' upon a, the four lines a, b, c, d, simply in virtue of having three transversals, $ABCD$, $A'B'C'D'$, $A''B''C''D''$, will have an infinite number of transversals, namely, what is important, one passing through every point of the line a. And, if it be true generally that any four lines, of which no two intersect, (lying in a threefold space), which have three transversals meeting all of them, have also a common transversal passing through any point of one of them, then, in the figure just considered, the four lines ABC, $A'B'C'$, $A''B''C''$, $A'''B'''C'''$ will be intersected by the transversal drawn to the first three of them from *any* point, D, of the first.

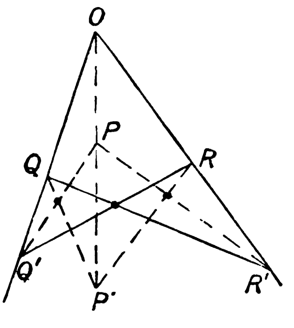
We thus have two equivalent conditions which are necessary, and are also sufficient, in order to secure that the correspondence of two related ranges, on two non-intersecting lines a, b, may be uniquely determined by the assignment of three points of one of these lines to correspond respectively to three assigned points of the other, namely:

1. That if four skew lines have three common transversals, they should possess a common transversal through any point of each of the four lines.
2. That if three lines, a, b, c, of which no two intersect, be each met by three other lines, ABC, $A'B'C'$, $A''B''C''$, then every transversal of the first three lines, a, b, c, should meet every transversal of the second set of three lines.

Brianchon hexagons and another form of the conditions. This last can be replaced by another equivalent condition. Consider six points, not lying in a plane, joined in a definite order, P, Q', R, P', Q, R', to form what we describe as a skew hexagon. It is easy to see that, if the three lines PP', QQ', RR', joining opposite angular points of the hexagon, meet in a point, say O, then any two opposite sides of the hexagon, such as PQ', $P'Q$, or $Q'R$, QR', or RP', $R'P$, intersect one another. And conversely that, if every







pair of opposite sides is in a plane, the three diagonals meet in a point. A hexagon with this particularity we may distinguish by calling it a *Brianchon* hexagon. Such a hexagon is constituted by six points of the figure we were discussing, namely, in order, A', A'', B'', B, C, C'. The three pairs of opposite sides of this hexagon, namely ($A'A''$, BC), ($A''B''$, CC'), ($B''B$, $C'A'$), meet, respectively, in the points A, C'', B'. The condition (2) above can then be stated in the form

3. That any transversal of one set of alternate sides (here the lines a, b, c) of a Brianchon hexagon should intersect every transversal of the other set of alternate sides (here the lines BC, $C'A'$, $A''B''$).

Pappus' Theorem. Is true if the conditions are satisfied. These three conditions are, in virtue of the Propositions of Incidence, equivalent to one another. We proceed to shew that they are also equivalent to a certain proposition of geometry in a plane; that is, that this proposition follows if any one of the three conditions is supposed always to be satisfied, while, conversely, the truth of this proposition would secure that every one of these conditions is satisfied. The proposition in question is

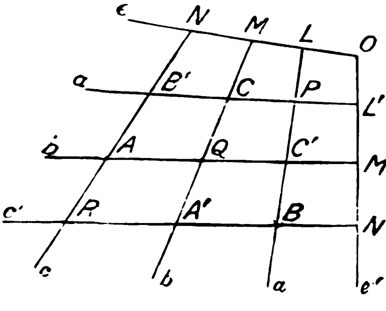
4. If L, M, N be any three points of a line, and L', M', N' be any three points of another line, intersecting the former, then the three points of intersection of cross joins

$$(MN', M'N), \quad (NL', N'L), \quad (LM', L'M)$$

are in line.

This proposition is stated in the συναγωγή of Pappus (? 340 A.D. See Ch. Taylor, *Ancient and Modern Geometry of Conics*, Cambridge, 1881, p. liii, and the works of T. L. Heath on the geometry of the Greeks referred to in the Bibliography at the end of this volume). We shall refer to it as Pappus' Theorem.

We shew, first, that Pappus' theorem follows if the condition (2) above be satisfied.



Let O be the point of intersection of the lines LMN and $L'M'N'$, which we may denote respectively by e and e'. Through the points L and L' draw two lines, respectively a and a', intersecting in a point P, not lying in the plane of the lines e and e', but otherwise arbitrary. Through the point M draw any line, b, intersecting the line a', say in the point C. This line b will not intersect the line a, or the line $L'M'N'$, since, otherwise, a' would intersect the line LMN and be in the plane of e and e'. Then through the point M' draw the transversal to the lines a and b, say the line b', meeting the lines a, b respectively in C' and Q. This line b' will not meet the line a', or the line LMN, since, otherwise, the line a would intersect the line $L'M'N'$ and be in the plane of e and e'. Lastly, draw from the point N the transversal to the lines a' and b', say the line c, meeting a' and b', respectively, in the points B' and A. This line c will not meet any one of the lines b, a, $L'M'N'$, since, otherwise, the line a' would meet the line LMN. And draw from the point N' the transversal to the lines a, b, say the line c', meeting these, respectively, in B and A'. This line c' will not meet any one of the lines b', a', LMN, since, otherwise, the line a would meet $L'M'N'$. The fact that no two of the four lines a', b', c', LMN intersect, and no two of the four lines a, b, c, $L'M'N'$ intersect, is thus a consequence of taking P to be any point not lying in the plane of the two lines e and e'.

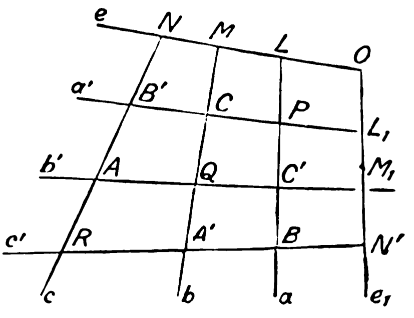
If now we assume the condition (2) above to be satisfied, it follows that the two lines c, c' intersect one another, say in the point R. Let this be so.

The line QR does not meet either the line e or the line e'; since, in the former case, b and c would intersect, and, in the latter case, b' and c' would intersect; thus QR does not lie in the plane $[e, e']$, which contains the two lines MN' and $M'N$. But QR intersects the line MN', these two lines, QR, MN', being both in the plane $[b, c']$; and QR intersects $M'N$, these two being both in the plane $[b', c]$. Therefore the line QR must pass through the point of intersection of the lines MN' and $M'N$; this intersection may thus be defined as the point of intersection of the line QR with the plane $[e, e']$. The points $(NL', N'L)$ and $(LM', L'M)$ are, similarly, the intersections, respectively, of the lines RP and PQ with the plane $[e, e']$. The points P, Q, R are not in line, since the points L, M, N, L', M', N' are supposed to be of such general positions that the three points $(MN', M'N)$, $(NL', N'L)$, $(LM', L'M)$ are different. These three points are therefore in line, namely in the line in which the plane PQR meets the plane $[e, e']$.

Thus Pappus' theorem is shewn to follow if the condition (2) is satisfied, and therefore follows equally if either of the equivalent conditions, (1) or (3), is satisfied.

Pappus' Theorem. The conditions follow if Pappus' Theorem be assumed. Conversely we now shew that if Pappus' theorem be assumed, then condition (2) is satisfied.

Let a, b, c be any three lines, of which no two intersect, and a', b', c' any other three lines of which, equally, no two intersect; let every one of the lines a', b', c' intersect every one of a, b, c, the respective intersections being P, C, B' on a', and C', Q, A on b',



and B, A', R on c'. Draw any further transversal of the lines a, b, c, say the line e, meeting these respectively in L, M, N, this line not meeting the lines a', b', or c'. Then, from any point, N', of the line c', draw the transversal, say e_1, of the lines e and a', meeting these in O and L_1, respectively. As c' does not meet e, this line e_1 will not meet a, or b, or c. As before, the line RP does not lie in the plane $[e, e_1]$, but meets both the lines $N'L$ and NL_1, lying with these, respectively, in the planes $[a, c']$ and $[a', c]$; so that the lines $N'L$ and NL_1 meet in the point where RP meets the plane $[e, e_1]$. The transversal e_1 does not lie in the plane $[a, b']$, since it does not meet the line a; let it meet this plane in the point M_1. The line PQ does not lie in the plane $[e, e_1]$, but meets the lines LM_1 and L_1M, lying with these, respectively, in the planes $[a, b']$ and $[a', b]$. Thus LM_1 and L_1M meet in the point in which the line PQ meets the plane $[e, e_1]$. The points P, Q, R do not lie in line, since the lines $N'L$, NL_1, L_1M do not meet in a point, unless N' be taken at B. There is thus a line in which the plane PQR meets the plane $[e, e_1]$. The application of Pappus' theorem to the two triads L, M, N and L_1, M_1, N' would lead to a line in the plane $[e, e_1]$ containing the three points

$$(LM_1, L_1M), \quad (MN', M_1N), \quad (NL_1, N'L);$$

of these the first and third have been shewn to lie, respectively, on PQ and PR; thus the second, the point (MN', M_1N), lies in the plane PQR. The line MN' does not lie in this plane; for, if so, it would intersect PQ, in a point other than Q, and, then, PQ, having two points in the plane $[b, c']$, would lie in this plane, so that PB, that is the line a, would intersect the line b. But MN', in the plane $[b, c']$, meets QR; therefore, as the point (MN', M_1N) lies in the plane PQR, it follows that M_1N intersects QR. Hence M_1 lies in the plane NQR, or $[b', c]$. And M_1 was constructed to be in the plane $[a, b']$. Thus, M_1 is on the line b', and the transversal e_1, drawn from N' to meet e and a', is the same as the transversal which can be drawn from N' to meet a' and b'; this last transversal therefore meets e. And this is the same as that the condition (2) is satisfied.

Alternative proof of the equivalence of Pappus' theorem with the conditions. The six points $AB'CA'BC'$ constitute a Brianchon hexagon, the pairs of opposite sides

$$(AB', A'B), \quad (B'C, BC'), \quad (CA', C'A)$$

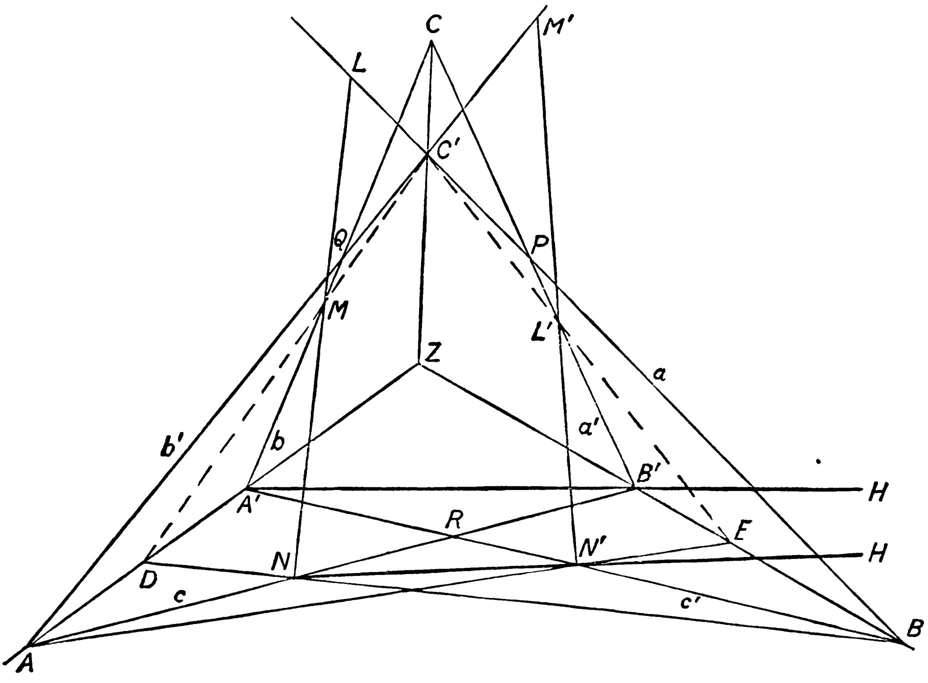
being intersecting lines, meeting, respectively, in R, P, Q. The joins of opposite angular points, namely the lines AA', BB', CC', therefore meet in a point. Taking account of this, we may substitute for the proof which has just been given, that condition (2) is satisfied if Pappus' theorem be assumed, and conversely, the following proof.

Let a, b, c be three skew lines, that is, lines of which no two intersect, and a', b', c' be three other skew lines, all intersecting every one of a, b, c. Denote the nine points

$$(a, a'),\ (a, b'),\ (a, c'),\ (b, a'),\ (b, b'),\ (b, c'),\ (c, a'),\ (c, b'),\ (c, c'),$$

respectively, by

$$P,\ C',\ B,\ C,\ Q,\ A',\ B',\ A,\ R.$$



The three planes $[a, a']$, $[b, b']$, $[c, c']$ then meet in pairs in the three lines AA', BB', CC', which thus meet in one point, say Z. Let LMN be a line, meeting the lines a, b, c, respectively, in L, M and N, but not intersecting any of the lines a', b', c'. In the plane $[c, c']$ draw the line BN, meeting the line AA' in the point D. Take N', an arbitrary point on the line c'; in the plane $[c, c']$ draw the line AN', meeting the line BB' in the point E. Let H be the intersection of the lines $A'B'$ and NN', both lying in the plane $[c, c']$. Draw from N' the transversal to meet the lines a' and b', respectively, in L' and M'.

The points D, M, C' are in the plane $[b, b']$, and are also in the plane LBN, and are therefore in line. The points C', L', E are in the plane $[a, a']$, and are also in the plane $M'AN'$, and are therefore in line. Thus the line $L'M$ lies in the two planes $CA'B'$ and $C'DE$, and, therefore, passes through the intersection of the two lines $A'B'$ and DE of the plane $[c, c']$.

Wherefore, the necessary and sufficient condition that the two transversals LMN and $L'M'N'$ should intersect one another, which is the condition that the lines $L'M$ and NN' should intersect, is that DE should pass through the intersection, H, of $A'B'$ and NN'.

If we assume Pappus' theorem, and apply it to the two triads A, N, B' and B, A', N', lying, respectively, on two lines of the plane $[c, c']$, the consequence is precisely that DE passes through H; for AA', BN meet in D, while NN', $A'B'$ meet in H, and AN', BB' meet in E.

Thus condition (2) is satisfied if Pappus' theorem be assumed.

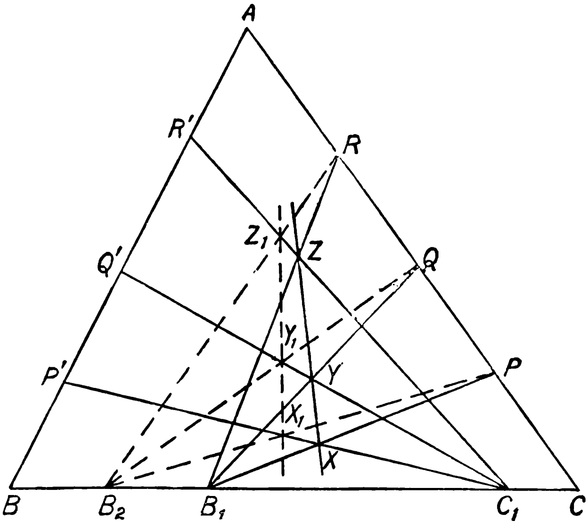
Conversely, from the assumption that the transversals LMN and $L'M'N'$ intersect one another, the truth of Pappus' theorem follows for the two triads A, N, B' and B, A', N'. Thus it will be proved that Pappus' theorem follows when condition (2) is satisfied, if we shew that the figure can be constructed when A, N, B' and B, A', N' are any two sets of three points, each in line, in a plane. For this, take Z, the intersection of the lines AA' and BB'; from Z draw the arbitrary line $ZC'C$, not in the plane of the two given triads; join the points A and B to the arbitrary point, C', of this line, and join the points A' and B' to the other arbitrary point, C, of this line. Then, from the point N, draw the transversal NML to meet $A'C$ in M and BC' in L, and, from the point N', draw the transversal $N'L'M'$ to meet $B'C$ in L' and AC' in M'. The construction of the points D, E, H then follows as before.

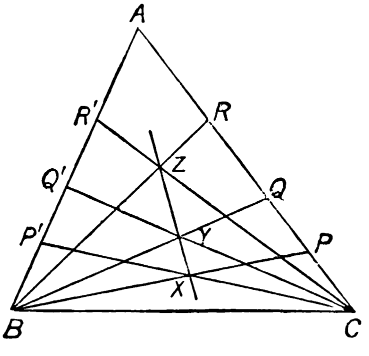
The identification of the two results is thus completed.

It is thus shewn that the adjunction of Pappus' theorem to the Propositions of Incidence enables us to regard the assignment of three points of one line, to correspond to three points of another line, not intersecting the former, as leading to a unique correspondence for all points of two related ranges upon these lines.

Equivalence of Pappus' theorem with the conditions; case of ranges in one plane. We proceed now to shew that the same is true for two related ranges upon lines which intersect one another. That this must be so is evident from what has preceded; for, of two ranges upon intersecting lines, one may be regarded, in an infinite number of ways, as being in perspective with a range lying on a line which does not intersect the other. But an independent proof is interesting, and, incidentally, will furnish information in regard to related ranges in one plane.

Suppose that the ranges $(PQR\ldots)$, $(P'Q'R'\ldots)$, respectively on the intersecting lines AC, AB, are related, being both in perspective with the range $(XYZ\ldots)$, respectively from B_1 and C_1. The line $XYZ\ldots$ must intersect both AC and AB, so that B_1C_1 lies in the plane of the lines AB, AC, meeting them, respectively, say, in B and C. It can then be shewn that these ranges are related by perspectivities whose centres are any two points on the line BC, as has indeed already appeared in Section i. For take any point, B_2, of BC; let B_2P, B_2Q, B_2R, ... respectively meet C_1P', C_1Q', C_1R', ... in X_1, Y_1, Z_1, ...; then, by Desargues' theorem applied to the two triads PXX_1, QYY_1, since corresponding joins of points of these triads meet in the points B_1, C_1, B_2, which are in line, it follows that X_1Y_1 passes through the point common to XY and AC. The same is true for X_1Z_1; and so on; so that X_1, Y_1, Z_1 are in line. In the same way, if C_2 be another point of BC, and C_2P', C_2Q', C_2R' meet B_2P, B_2Q, B_2R respectively in X_2, Y_2, Z_2, we see, from the triads $P'X_1X_2$, $Q'Y_1Y_2$, $R'Z_1Z_2$, that $X_2Y_2Z_2$ are in line.





We may thus suppose the ranges $(PQR\ldots)$ and $(P'Q'R'\ldots)$ to be in perspective with a range $XYZ\ldots$ respectively from the centres B and C.

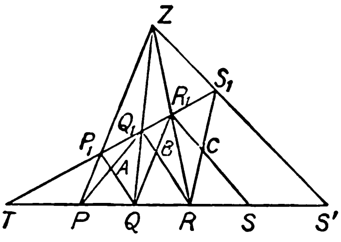
We first shew that when, of the two related ranges $(PQ\ldots)$, $(P'Q'\ldots)$, the three points P', Q', R' of one are given as corresponding to the three given points P, Q, R of the other, then the point, S', of one range which corresponds to any assigned point, S, of the other, is without ambiguity if we assume Pappus' theorem to be true.

By Pappus' theorem the two triads, P, Q, R and P', Q', R', each of points on a line, give rise to another line containing the three points of intersection $(QR', Q'R)$, $(RP', R'P)$, $(PQ', P'Q)$; and this line is without ambiguity when the two triads are given. But, also by Pappus' theorem, this line in fact is the same as the intermediary line XYZ, arising when the two ranges are related by perspectivities having B, C for centres; for, by applying Pappus' theorem to the two triads P, C, Q and P', B, Q', we infer that the point $(PQ', P'Q)$ lies on the line XY. And we can similarly infer that the points $(QR', Q'R)$ and $(RP', R'P)$ lie on the line XY. But then, if S' be the point of the range $(P'Q'R' \ldots)$ which corresponds to a point S of the range $(PQR \ldots)$, so that BS and CS' meet on XY, a similar proof shews that RS' and $R'S$ meet on XY.

Thus, the rule for the construction of S', when P, Q, R, P', Q', R', and S, are given, is, to find the Pappus line of the two triads P, Q, R and P', Q', R', take the intersection of $R'S$ with this, and draw RS' through this intersection. This construction necessarily gives a unique point, independent of the method whereby the ranges $(PQR \ldots)$, $(P'Q'R' \ldots)$ are related.

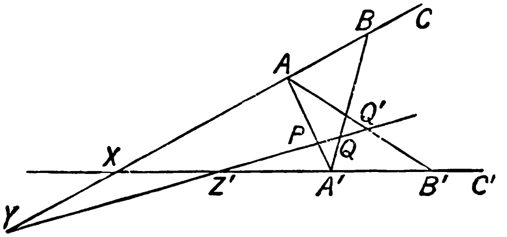
The proof of the converse theorem, that the uniqueness of S', when P, Q, R, P', Q', R', and S, are given, requires Pappus' theorem, may be omitted, in view of what has been said above.

Related ranges on the same line. Now consider two ranges on the same line which are related; by definition, this means that one of these ranges is in perspective with a range, on another line, which is related to the remaining range of the given line. Suppose that the two ranges, $(PQRS \ldots)$, $(PQRS' \ldots)$, of the given line have three corresponding points, P, Q, R, in common; and let $(PQRS' \ldots)$ be in perspective, from a centre Z, with a range $(P_1Q_1R_1S_1 \ldots)$, related to $(PQRS \ldots)$, lying on another line, which meets the former in T. Then, by the above, the ranges $(PQRS \ldots)$, $(P_1Q_1R_1S_1 \ldots)$ being related, the joins, RS_1 and R_1S, intersect on the Pappus line of the two triads P, Q, R and P_1, Q_1, R_1, if we assume Pappus' theorem. Denote the points (PQ_1, P_1Q), (QR_1, Q_1R), (RS_1, R_1S), respectively, by A, B, C. By Desargues' theorem, applied to the triads P, A, P_1 and R, B, R_1, the point T lies on AB, which is also the Pappus line of the two triads P, Q, R and P_1, Q_1, R_1. The fact that C lies on this line, involves then, by Desargues' theorem applied



to the triads Q, B, Q_1 and S, C, S_1, that the line SS_1 passes through Z. Thus S coincides with S'.

Thus it is a consequence of Pappus' theorem that two related ranges on the same line coincide entirely if they have three corresponding points in common.



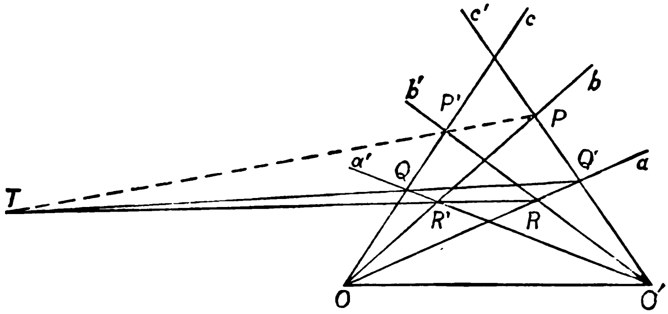
Conversely, if two related ranges on the same line coincide entirely when they have three points in common, then Pappus' theorem follows. For, let A, B, C and A', B', C' be any two triads of points respectively on two lines which intersect in X. Consider two related ranges on these lines, so constructed that the points A, B, C, of one of these, correspond respectively to the points A', B', C' of the other; it follows from preceding work that such a construction is possible. Let the point X, of intersection of the lines of the ranges, regarded as a point of the range $(ABC\ldots)$, correspond to the point Z' of the second line $A'B'C'\ldots$, in virtue of the perspectivities by which the ranges are related; similarly, let the point X, regarded as belonging to the range $(A'B'C'\ldots)$, give rise to the point Y of the line $ABC\ldots$. Join YZ', and let this joining line be met by AA', $A'B$, AB', respectively, in the points P, Q, Q'. The points Y, X, A, B, of the first range, correspond, respectively, to the points X, Z', A', B' of the second range; and, from the centre A', the former range is in perspective with Y, Z', P, Q. Therefore, by what we have proved, the last range is related to the range X, Z', A', B'; this, however, from the centre A, is in perspective with the range Y, Z', P, Q', which is then related to the range Y, Z', P, Q. If, then, we assume that two related ranges on the same line which have three points in common entirely coincide, we can infer that the points Q and Q' coincide, so that the joins AB' and $A'B$ intersect on the line YZ'. By a similar proof the joins AC' and $A'C$ intersect on this line as do the joins BC' and $B'C$. This shews that Pappus' theorem holds for the two triads A, B, C and A', B', C'.

Pappus' theorem and the Principle of Duality. It was seen that the Propositions of Incidence lead to a duality, in virtue of which, in space of three dimensions, points correspond to planes and conversely, and lines to lines. And the conditions (1), (2), (3) above are of self-reciprocal character, since two lines with a common point lie in a plane. As so far stated, Pappus' theorem has not this character, and we must enquire whether its adjunction to the Propositions of Incidence would destroy the validity of the duality of space. We shew that this is not so by deducing the reciprocal of Pappus' theorem from itself and the Propositions of Incidence. In three dimensions this reciprocal would be that, if three planes, α, β, γ, have a line, l, in common, and three planes, α', β', γ', have a line, l', in common, the lines l, l' being in one plane, and we take the lines (α, β'), and (α', β), and the plane containing these, the three planes so obtained have a line in common. By taking a section of the figure by an arbitrary plane, we see that this is equivalent to the statement that, if three lines, a, b, c, lying in a plane, meet in a point, O, and three other lines, a', b', c', of this plane, meet in a point, O', and we denote the points of intersection

$$(b, c'),\ (b', c),\ (c, a'),\ (c', a),\ (a, b'),\ (a', b)$$

respectively by $\quad P,\ P',\ Q,\ Q',\ R,\ R'$,

then the three lines PP', QQ', RR' meet in a point.



In fact, if T be the point of intersection of the lines QQ' and RR', the application of Pappus' theorem to the two triads, O, Q', R and O', R', Q, shews that the line PP' passes through T.

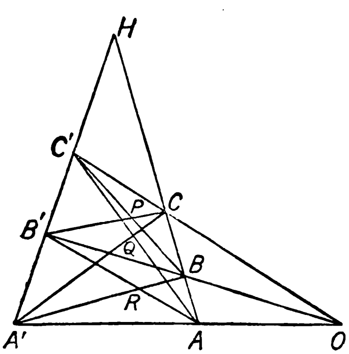
Related ranges in space of more than three dimensions. If in space of n dimensions we have a succession of ranges of which every consecutive two (which will both lie in a threefold space) are related by the definition applied before, the proof given in Section I of this Chapter avails to shew that the first and last are related, and assuming Pappus' theorem to hold generally, it follows as here that three points are sufficient to identify a range related to a given one. This leaves open the question, suggested in the examples in Section I, whether a more compendious method of relating two ranges in space of higher dimensions may not be possible than by a succession of perspectivities by lines drawn from a centre. The next Section (III) throws some light on the general question here touched. For the present we shall only add the further remark that, as in space of three dimensions, the adjunction of Pappus' theorem leads to no abandonment of the Principle of Duality, the reciprocal of Pappus' theorem in space of n dimensions being, as in that case, reducible to the theorem itself. The reciprocal in question would be as follows: In space of n dimensions we are given two spaces, each of $n-2$ dimensions, which we shall denote by λ and λ', both containing the same space S_{n-3}, say ϖ (this being the reciprocal of the plane in which the lines l, l' of the original theorem both lie). Through the S_{n-2} called λ there pass then three spaces S_{n-1}, say U, V, W, and, similarly, three spaces S_{n-1}, say U', V', W', through λ'. Then the spaces U, V' intersect in a space S_{n-2}, as do also the spaces U', V; and the two S_{n-2} so obtained both lie in a S_{n-1}, which we call w. The pairs U, W' and U', W similarly determine a S_{n-1}, which we call v; and the pairs V, W' and V', W determine a S_{n-1}, which we call u. The spaces U, V, W, U', V', W', u, v, w all contain the S_{n-3} which we call ϖ. The theorem is that the spaces u, v, w have a space S_{n-2} in common.

To see that this is true, take a general plane, σ, in the space of n dimensions, not intersecting the space S_{n-3} which we have called ϖ. This plane, σ, will be met by λ, λ' each in a point, say in the points O, O', respectively; it will be met by U, V, W in lines through O, say a, b, c respectively, and by U', V', W' in lines, a', b', c', through O'. The space w then meets the plane σ in the line joining the points (a, b') and (a', b), and similarly with the spaces u and v. We therefore have the same figure in the plane σ as was obtained in three dimensions by reciprocating the figure of Pappus' theorem. Thus the lines in the plane σ arising from the spaces u, v, w meet in a point. This point with the space ϖ, of $n-3$ dimensions, which is contained in each of the spaces u, v, w, determine a space S_{n-2} contained in all of these. This constitutes the space which proves the theorem.

Examples in connexion with Pappus' theorem.

Ex. 1. Pappus' theorem can be *proved* for the case of two triads which are in perspective.

For if AA', BB', CC' meet in O, the points of intersection $(BC', B'C)$, $(CA', C'A)$, $(AB', A'B)$ lie on the line joining the point H, where the lines of the two triads intersect, to the point which is the harmonic conjugate of O in regard to A and A'.

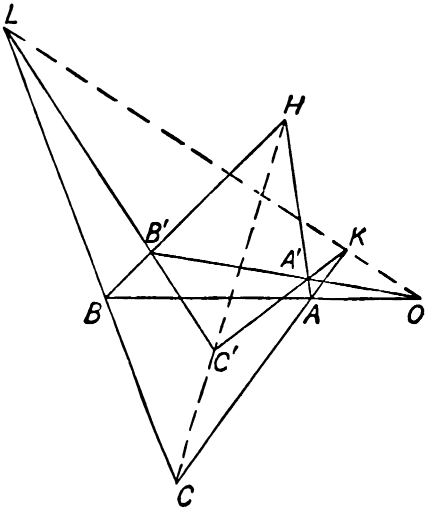


Ex. 2. We have so far regarded two ranges in perspective as being a particular case of two related ranges, of which the two centres of perspective coincide, and the intermediary line is any line through the point of intersection of the lines of the two ranges.

There are however other more definite ways in which two ranges in perspective may be related, with two distinct centres of perspective.

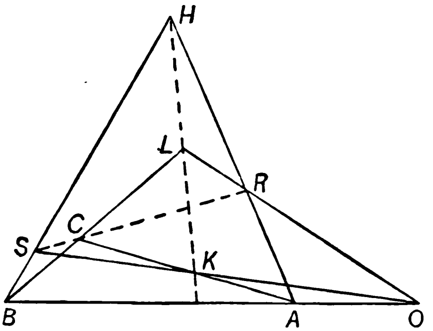
(*a*) Two ranges in perspective may be related with the intermediary line passing through the point of intersection of the lines of the ranges and the supplementary line, that is the line joining the two centres of perspective, passing through the original centre of perspective.

For if the ranges $(AA' \ldots)$, $(BB' \ldots)$ be in perspective from O, and K, L be any two points on a line through O, the lines KA, LB meeting in C, and the lines KA', LB' meeting in C', it follows, by Desargues' theorem, that C' lies on the line joining C to the point H, the point of intersection of the lines of the ranges. The original ranges are thus related with CH as intermediary line and KL as supplementary line.



(*b*) If we assume Pappus' theorem we can relate the ranges in perspective in such a way that, not the intermediary line, CH, but, the supplementary line, KL, passes through the intersection H of the lines of the ranges.

For let the ranges $(A \ldots)$, $(B \ldots)$, on lines intersecting in H, be in perspective from O, and HLK be an arbitrary line through H, while RS is an arbitrary line meeting HA, HB, respectively, in R and S, not passing through O or H; let OR, OS meet the line HLK respectively in L and K. Then, using Pappus' theorem for the two triads A, O, B and L, H, K, we see that AK and BL meet on RS. Thus the two ranges are in perspective with a range on RS, respectively from the centres K and L; the line RS is now the intermediary line, and the line KL the supplementary line.

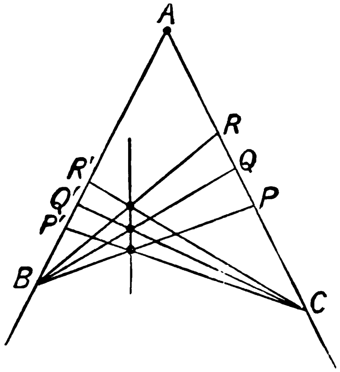


(*c*) Conversely, two related ranges are in perspective with one another when the intermediary line passes through the point of intersection of the lines of the ranges; and the new centre of perspective is on the supplementary line of the ranges. This follows by Desargues' theorem. The diagram in (*a*) may be used.

(*d*) And two related ranges are also in perspective with one another when the supplementary line passes through the point of intersection of the lines of the ranges. This follows from Pappus' theorem. The diagram in (*b*) may be used.

(*e*) It is clear that if, of two related ranges, the point of intersection of the lines of the ranges corresponds to itself regarded as belonging to both lines, then either the intermediary line or the supplementary line passes through this point. Hence, with the assumption of Pappus' theorem, it follows, from what has been said, that the two ranges are in perspective with one another.

Ex. 3. We have seen, assuming Pappus' theorem, that, in the case of two related ranges on intersecting lines for which the supplementary line does not pass through the point of intersection of the lines of the ranges, the two centres of perspective, by means of which the ranges are related, can be taken to be any two points on the supplementary line. In particular if these centres, B and C, be respectively on the lines, (P', Q', ...) and (P, Q, ...), of the two ranges, then the two triads B, P', Q' and C, P, Q have the same Pappus line as have the two triads P, Q, R and P', Q', R', this being the intermediary line for the two related ranges.



Thus the centres of perspective, B and C, are corresponding points of the two ranges.

More generally a line joining any point, S', of the range (P', Q', ...), to the corresponding point, S, of the range (P, Q, ...), is a possible supplementary line. And it will appear later (in Volume II) that, through an arbitrary point of the plane of the two ranges, two lines can be drawn either of which may serve as supplementary line; and further that any possible supplementary line for the two ranges is intersected, by the joins PP', QQ', ..., of corresponding points of the two ranges, in a range of points which is related to either of the two given ranges. This last is the same result as was found for related ranges on two lines which do not intersect, before the introduction of Pappus' theorem.

Ex. 4. Consider two related ranges (A, B, C, D, ...) and (A', B', C', D', ...), on two lines which do not intersect one another. For each pair of corresponding points of these ranges, such as A, B and

A', B', consider the cross joins (not joining corresponding points), such as AB' and $A'B$. Let O be any point of the threefold space of the two ranges; from this point a transversal can be drawn to the cross joins AB' and $A'B$. It can be shewn that all such transversals lie in a plane through O; such a plane is then determined, by the two given ranges, passing through every point O. Further, if the transversal from O to the lines of the two given ranges meet them, respectively, in P and Q', and P', Q be the points of the ranges $(A'B' \ldots)$, $(AB \ldots)$ respectively corresponding to P, Q', this plane is that joining O to the line $P'Q$.

This result, which is of subsequent interest, is a consequence of Pappus' theorem. Taking an arbitrary plane, not passing through O, the given ranges are projected from O upon this plane into two ranges, $(A_1, B_1, C_1, \ldots)$ and $(A_1', B_1', C_1', \ldots)$, related to one another, for which, as we have shewn to follow from Pappus' theorem, the points of intersection $(A_1B_1', A_1'B_1)$, $(A_1C_1', A_1'C_1)$, $(B_1C_1', B_1'C_1)$, ..., are in line.

In particular, when P, Q' and P', Q are constructed, as in the enunciation, instead of one there is an infinite number of transversals from O to the cross joins PQ', $P'Q$, namely any line in the plane $OP'Q$ is such a transversal.

Ex. 5. The reciprocal theorem is that, if $(A, B, C, \ldots)$ and $(A', B', C', \ldots)$ be related ranges on two lines, l and l', which do not intersect one another, and if an arbitrary plane, ϖ, meet these lines, l and l', respectively in P and Q', to which there correspond, on the other lines, l' and l, respectively, the points P' and Q, then the point O, in which the plane ϖ is met by the line $P'Q$, lies on the line joining the intersections of the plane ϖ with any pair of cross joins, such as AB' and $A'B$. By the two given ranges there is thus determined a point, O, upon any plane, ϖ.

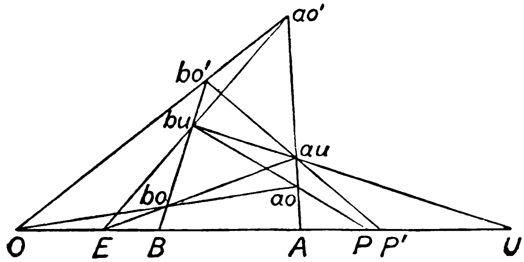
Ex. 6. If A, B, C, A', B', C' be six general points in threefold space, and O be any point on the line of intersection of the planes ABC and $A'B'C'$, and we draw from O the transversal to the pair of joins BC' and $B'C$, as also the transversal to CA' and $C'A$, and the transversal to AB' and $A'B$, these three transversals are in one plane.

Ex. 7. If, in fourfold space, the four points A, B, C, D be in one plane, and the four points A', B', C', D' be in another plane, the three transversals, respectively, of the triplets of lines $(BC', B'C, DD')$, $(CA', C'A, DD')$, $(AB', A'B, DD')$, are in one threefold space. This space then contains the line DD'; if we project the figure on to an arbitrary plane by means of planes passing through the line DD', we obtain Pappus' theorem.

Ex. 8. In Pappus' theorem for two triads, A, B, C and A', B', C', there are six ways of arranging the triad A', B', C' in association with A, B, C. Consider the figure of the six Pappus lines thus found. And reciprocate the figure.

Ex. 9. The following result is of great importance for the development of the theory.

We have seen that if five arbitrary points be taken on a line, consisting of two couples, O, U and A, B, and a determining point E, and there be drawn, in an arbitrary plane passing through this line, lines o, u, a, b respectively through the points O, U, A, B, subject to the condition that the intersections, (a, u) and (b, o), lie on a line through the point E, then the join of the points, (a, o) and (b, u), meets the original line in a point, P, independent of the lines o, u, a, b. Similarly, if the lines o, u, a, b be subject to the condition that the intersections, (a, o) and (b, u), lie on a line through E, then the join of the points, (a, u) and (b, o), meets the original line in a point, P', also independent of the lines o, u, a, b.



It was said (p. 15) that the Propositions of Incidence are insufficient to determine whether P and P' coincide. It is important to notice that, if Pappus' theorem be assumed, these points must be regarded as identical.

For we can have a figure containing both constructions, the lines a, b, u being the same in both, the line drawn through O for the second construction being o'. If then, on the lines a, b, we consider the two triads of points, respectively

$$(a, u),\quad (a, o'),\quad (a, o),$$

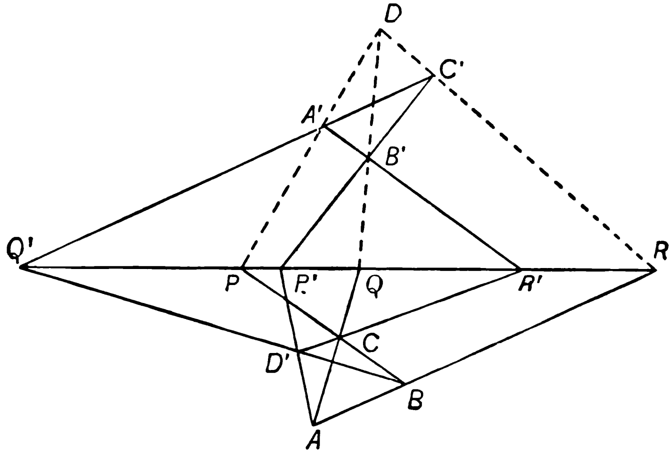
and

$$(b, u),\quad (b, o),\quad (b, o'),$$

then the first and second of these three pairs of corresponding points, by the joins of the points, (a, u) to (b, o) and (a, o') to (b, u), give the point E; the second and third, by the joins of (a, o) to (b, o) and of (a, o') to (b, o'), give the point O; but the first and third, of (a, o) to (b, u) and of (a, u) to (b, o'), are the lines respectively containing P and P'. These lines thus meet the original line, EO, in the same point.

In the original figure, before the consideration of Pappus' theorem, the points O, U, of a couple, were symmetrical, as were also the points A, B of the other couple. The introduction of Pappus' theorem renders the points E, P symmetrical in regard to one another. This is brought out well by a diagram illustrating the two cases in which lines o, u, a, b are drawn in one plane, and other lines o', u', a', b', through the same points, are drawn in another plane through the original line. The diagram so obtained is precisely that which, with different lettering, is used to illustrate the following example.

Ex. 10. Let A, B, C, D be any four points not in one plane; let A', B', C', D' be further points lying, respectively, in the planes BCD, CAD, ABD, ABC; suppose that the line $B'C'$ meets AD', the line $C'A'$ meets BD' and the line $A'B'$ meets CD'. Thus the planes $B'C'D'$, $C'A'D'$, $A'B'D'$ contain, respectively, the points A, B, C. It is supposed that the points A', B', C' are not in the plane



ABC (respectively on the lines BC, CA, AB), so that the points A', B', C', D' are not in one plane.

We can then shew, assuming Pappus' theorem, that the plane $A'B'C'$ contains the point D.

Consider the line of intersection of the two planes ABC and $A'B'C'$. As $B'C'$, AD' meet, their intersection, P', must be on this line; as must similarly be the point of intersection, Q', of $C'A'$, BD', and the intersection, R', of $A'B'$, CD'. Let BC, CA, AB meet this line, respectively, in P, Q, R.

Then we have a figure such as that spoken of in the last example. Considering the plane of the points A, B, C, D', and denoting by p, p' and r, r' the lines drawn in that plane respectively through the points P, P', R, R', the join of the points (p, r') and (p', r) passes through the point Q, and the join of the points (p, r) and (p', r') passes through the point Q'. In the other plane, consider the lines PA' and RC', denoting these, respectively, by p_1 and r_1, the lines drawn in this plane through P' and R' being respectively denoted by p_1' and r_1'. It follows then, from the fact that the join of the points (p_1, r_1') and (p_1', r_1) passes through Q', that the join of the points (p_1, r_1) and (p_1', r_1') passes through Q. Thus the lines PA', QB', RC' meet in one point. This point is evidently on each of the planes $A'BC$, $B'CA$, $C'AB$, and is therefore the point D. It is thus proved that the plane $A'B'C'$ contains the point D.

It is thus shewn that it is possible to have two tetrads of points A, B, C, D and A', B', C' D' with the relation that the plane containing any three points of either tetrad contains a point of the other tetrad. This remark was first made by Moebius, and we shall therefore sometimes refer to the tetrads as Moebius tetrads.

It is also shewn incidentally that the three pairs of opposite joins of four points in a plane meet an arbitrary line of that plane in six points of which one is to be regarded as determined uniquely by the other five. It is usually said that the three couples, of which the six points are composed, are three couples in *involution*. The relation was recognised by Pappus (cf. Ch. Taylor, *Ancient and Modern Geometry of Conics*, Cambridge, 1881, p. lii). It is important for our purpose to notice that it does not follow from the Propositions of Incidence, without what we have called Pappus' theorem.

The theorem of Moebius tetrads may be stated thus: Let P_1, P_2, P_3, P_4 be four arbitrary points in a plane; through each of the six joins of two of these let an arbitrary plane be drawn, the plane through P_iP_j being denoted by α_{ij}. The set of three of these planes, passing through the pairs from three of the original points, meet in a point; for instance the planes α_{23}, α_{31}, α_{12} meet in a point which we may call P_{123}. The theorem is then that the four points P_{234}, P_{314}, P_{124}, P_{123} lie in one plane.

The reciprocal theorem, of which the generalisation to space of higher dimensions will be of interest later, is as follows: Let four planes α_1, α_2, α_3, α_4 be drawn through a point O; on the line of intersection of any two of these planes take an arbitrary point, say, the point P_{ij} on the line (α_i, α_j); through the three such points arising from three of the planes there passes a plane, for instance the plane α_{123} through the points P_{23}, P_{31}, P_{12}. The four planes α_{234}, α_{314}, α_{124}, α_{123} meet in a point, say O'. In all we have eight points and eight planes; through each point pass four of the planes, and in each plane lie four of the points.

SECTION III. INTRODUCTION OF ALGEBRAIC SYMBOLS

The laws of operation of the symbols employed. We have considered in the two preceding Sections, respectively, the Propositions of Incidence, and the consequences of supposing Pappus' theorem to hold. It will add greatly to clearness, and, finally, will amply justify itself as a means of investigation, to accompany the preceding work by an algebraic symbolism. And as an example of one kind of usefulness which this may have, it may be as well to cite at once the following, which signalises an important step in the logical development. It may perhaps be supposed that as Desargues' theorem in a plane was deduced in consequence of the Propositions of Incidence for space of three dimensions, so it may be possible to obtain Pappus' theorem as a consequence of Propositions of Incidence assumed for higher space. It will appear however that there is an algebraic symbolism corresponding in every detail with the geometry deducible from the Propositions of Incidence alone, in space of however high dimensions, which is sharply and definitely distinguished from the symbolism which is appropriate if Pappus' theorem is true. This theorem requires a precise limitation, in the character of the symbols adequate when only the Propositions of Incidence are assumed; thus Pappus' theorem cannot be a consequence of Propositions of Incidence in however high dimensions.

The symbols which we first introduce are, speaking in general terms, subject to all the laws of ordinary algebra, except the commutative law of multiplication. They are not necessarily, and will not be finally, arranged in order of magnitude, so that, in their entirety, they are wider than the real numbers of arithmetic. In order to emphasize this, we give here a formal statement of the properties assumed for them, and some examples.

We use the symbol $=$ to mean "may be replaced by." Thus if a, b be two of the symbols, the statement $a=b$ is the same as $b=a$.

From any two of the symbols, say a and b, another symbol can be formed, represented by $a+b$, or by $b+a$, independent of the order in which a, b are taken. Further, if $a=b$ and $x=y$, then also $a+x=b+y$. Also, if a, b, c be any three of the symbols, the symbol thus formed from a and $b+c$ is equivalent with that so formed from $a+b$ and c; that is

$$a+(b+c)=(a+b)+c.$$

We speak of the process of forming $a+b$ as *addition*, and of $a+b$ as the *sum* of a and b; and we may say that the addition of two symbols is *commutative*, and the addition of three symbols is *associative*. It follows that the symbol

$$a+b+c+\ldots+k,$$

formed from any number of the symbols, has a definite meaning independent of the order, and of the partial associations, of the symbols.

Among the symbols however there is one, and only one, which we denote by 0, whose addition to any other symbol leaves that unaltered, so that

$$a+0=0+a=a.$$

To every symbol, say a, there corresponds another, which we denote by $-a$, whose addition to the original gives 0 for sum, so that

$$a+(-a)=0=(-a)+a.$$

The symbols so corresponding to any two equivalent symbols are themselves equivalent, so that if $a=b$, then also $-a=-b$. Thus the symbol so corresponding to 0 is itself 0; for -0 is, by the definition of 0, equal to $0+(-0)$, and this, by the definition of -0, is itself 0. Conversely, if a be such that

$$a=-a,$$

it follows that $a+a=0$; it will be a consequence of subsequent prescriptions that thence $a=0$. We denote the sum of two symbols a and $-b$, namely $-b+a$, or $a+(-b)$, also by $a-b$. Thus if $a=b$ and $x=y$ we also have $a-x=b-y$. And, by the associative law, whatever symbols a and b may be, we have

$$(a-b)+b=a+(-b)+b=a+(-b+b)=a+0=a,$$
$$a-(a-b)=[(a-b)+b]-(a-b)=b+(a-b)-(a-b)=b.$$

Thus also, if $b=-a$, then $-b=a$, for

$$-b=0-b=a+(-a)-b=a+b-b=a,$$

and either of these follows from $a+b=0$. We may speak of $-a$ as the negative of a.

From any two symbols, a, b, can be formed, beside the sum $a+b, =b+a$, two further combinations, different from this, dependent on the order in which a, b are considered, denoted, respectively, by

$$a\,.\,b \text{ or } ab, \quad \text{and} \quad b\,.\,a \text{ or } ba.$$

It may happen that these symbols are equivalent, but this is not to be assumed in general. In particular, for the symbol 0, whatever a may be, we have $0\,.\,a=a\,.\,0=0$.

If $a=b$ and $x=y$, then $ax=by$, and $xa=yb$. Also, if three symbols a, b, c be taken, the consequence of combining, in this way, the symbol ab, taken first, with c, is the same as of combining a, taken first, with bc; namely

$$(ab)c=a(bc).$$

We may speak of ab as obtained by *multiplication* of a and b, and of ab as their *product*, and say that multiplication is *associative*. Thus if a, b, ..., k be any symbols, the symbol

$$ab\ldots k$$

is in general dependent upon the order of the component symbols, but not dependent upon their association to form partial products, being the same, for instance, as

$$(ab)(c\ldots k), \text{ or } a(bc\ldots k).$$

We may also have multiplications $(a+b)c$, or $c(a+b)$, defined respectively by

$$(a+b)c = ac + bc, \quad c(a+b) = ca + cb.$$

This leads, if a, b be any symbols, to the result

$$(-a)b = -(ab) = a(-b);$$

for

$$(-a)b + ab = (-a+a)b = 0 \,.\, b = 0,$$
$$a(-b) + ab = a(-b+b) = a \,.\, 0 = 0.$$

Beside the special symbol 0, with the two properties

$$a + 0 = 0 + a = a, \quad a \,.\, 0 = 0 \,.\, a = 0,$$

there is another special symbol, denoted by 1, with the property that, whatever symbol a may be,

$$a \,.\, 1 = 1 \,.\, a = a.$$

For reasons which will appear, the symbol 0 is said to be *singular*. There may be other singular symbols. The product of two non-singular symbols is not singular.

To every symbol, a, which is not singular, there corresponds another symbol, denoted by a^{-1}, having the property that

$$a^{-1} \,.\, a = a \,.\, a^{-1} = 1,$$

and such that, if $a = b$, then $a^{-1} = b^{-1}$. Thus

$$ab^{-1} \,.\, b = a \,.\, b^{-1}b = a \,.\, 1 = a, \quad a \,.\, a^{-1}b = aa^{-1} \,.\, b = 1 \,.\, b = b,$$

while, if a, b be symbols such that $ab = 1$, and a be not singular,

$$a^{-1} = a^{-1} \,.\, 1 = a^{-1}(ab) = a^{-1}a \,.\, b = b,$$

from which, if also b be not singular,

$$b^{-1} = 1 \,.\, b^{-1} = aa^{-1} \,.\, b^{-1} = ab \,.\, b^{-1} = a \,.\, bb^{-1} = a.$$

Further, if $x = ab$, then $x^{-1} = b^{-1}a^{-1}$; for, if $y = b^{-1}a^{-1}$,

$$xb^{-1} = a, \quad xb^{-1}a^{-1} = 1, \quad xy = 1, \quad y = x^{-1}.$$

Also, if a is not singular, there is one and only one symbol, x, such that $ax = b$, and one and only one symbol y such that $ya = b$, where b is an arbitrary symbol. For $ax = b$, $ya = b$ lead, respectively, to

$$x = a^{-1}a \,.\, x = a^{-1} \,.\, ax = a^{-1}b, \quad y = y \,.\, aa^{-1} = ya \,.\, a^{-1} = ba^{-1}.$$

This involves that the statement $ax = az$ requires $x = z$, the symbol a not being singular.

It is to be remarked that the symbol 1 is by no means necessarily identical with that so denoted in ordinary arithmetic, as subsequent examples will illustrate. But no confusion need arise, since the laws of combination agree. Similarly we may use the symbol 2 for the sum $1+1$, and 3 for the sum $1+1+1$, and so on. It may then be shewn, as in ordinary arithmetic, that these combine together just as do the symbols of ordinary arithmetic—and in particular that they are commutative in multiplication. For distinctness we shall speak of them as the *iterative* symbols. None of these symbols is singular, and to any one of them, for instance for 2, or for 3, there is a symbol 2^{-1}, or 3^{-1}, of which 1^{-1} is equivalent to 1; if m, n be any two of these symbols, we have $m^{-1}n = nm^{-1}$, this being equivalent to $nm = mn$. As regards combinations with other of our symbols, we have

$$\begin{aligned} 2\,.\,a &= (1+1)\,a = a + a = a\,(1+1) = a\,.\,2, \\ 2a\,.\,b &= (a+a)\,b = ab + ab = 2\,.\,ab = a\,(b+b) \\ &= a\,.\,2b = a2\,.\,b = a\,.\,b\,.\,2 = ab\,.\,2, \end{aligned}$$

and so on; so that if, in a product $abc\ldots k$, any of the symbols a, b, ..., k be those denoted by 1, 2, 3, ..., the places where they occur in the product are indifferent, so long as the order of the other symbols is preserved.

Examples of symbols obeying these laws. Simple examples of such symbols may be formed with aggregates of the numbers of ordinary arithmetic, the addition and multiplication of the symbols being defined by arithmetical operations carried out, according to a prescribed rule, with the numbers of the aggregate. If α, α', β, β', ... be numbers of ordinary arithmetic, including negative and fractional numbers, the numbers zero and unity being, for distinctness, denoted by $\bar{0}$, $\bar{1}$, we may, for example, have symbols formed with two such numbers, taken in a definite order,

$$a = (\alpha, \alpha'), \quad b = (\beta, \beta'), \ldots,$$

defining the fundamental symbols and operations by

$$0 = (\bar{0}, \bar{0}), \quad 1 = (\bar{1}, \bar{0}), \quad a + b = (\alpha+\beta, \alpha'+\beta'), \quad -a = (-\alpha, -\alpha'),$$
$$ab = (\alpha\beta - \alpha'\beta', \ \alpha\beta' + \alpha'\beta),$$
$$a^{-1} = \left(\frac{\alpha}{\alpha^2+\alpha'^2}, \ \frac{-\alpha'}{\alpha^2+\alpha'^2}\right).$$

Here 0 is the only singular symbol, and every two symbols are commutative in multiplication.

Another example is furnished by symbols which are aggregates of three ordinary numbers, taken in a definite order, say

$$a = (\alpha, \alpha', \alpha''), \quad b = (\beta, \beta', \beta''), \ldots,$$

with
$$0 = (\bar{0}, \bar{0}, \bar{0}), \quad 1 = (\bar{1}, \bar{0}, \bar{1}), \quad a + b = (\alpha+\beta, \alpha'+\beta', \alpha''+\beta''),$$
$$-a = (-\alpha, -\alpha', -\alpha''), \quad ab = (\alpha\beta, \ \alpha\beta' + \alpha'\beta'', \ \alpha''\beta''),$$
$$a^{-1} = \left(\frac{1}{\alpha}, \ -\frac{\alpha'}{\alpha\alpha''}, \ \frac{1}{\alpha''}\right).$$

Here every symbol (a, a', a'') for which either a or a'' vanishes is a singular symbol; and the equation $ab=ba$ is not generally true.

A very general example of such symbols as we have described is furnished by those aggregates of n^2 ordinary numbers which are called matrices; here n may be two, or three, or any positive integer number. The n^2 component numbers are thought of as arranged in n rows and n columns, so that it is convenient to denote the number in the rth row and sth column by $a_{r,s}$. Two such symbols are considered equivalent only when they have the same number of component numbers, and these are separately the same. The sum of two such symbols, a, b, of the same number of components, generally denoted by $a_{r,s}$ and $\beta_{r,s}$, is the symbol whose general component is $a_{r,s}+\beta_{r,s}$; the symbol 0 is that of which every component vanishes; the symbol $-a$ is that of which the general component is $-a_{r,s}$. The symbol ab is that of which the general component, $\gamma_{r,s}$, is formed, from the rth row of a, and the sth column of b, according to the rule

$$\gamma_{r,s}=a_{r,1}\beta_{1,s}+a_{r,2}\beta_{2,s}+\dots+a_{r,n}\beta_{n,s},$$

where, in the suffixes, the numbers 1, 2, ... are those of ordinary arithmetic. It is easy to prove from this definition that, for three such symbols a, b, c, with each n^2 components, we have

$$ab\,.\,c=a\,.\,bc$$

$$(a+b)c=ac+bc,\quad c(a+b)=ca+cb,$$

but not in general $ab=ba$. The symbol 1, when the number n^2 is specified, denotes the matrix in which every component $a_{r,s}$ is zero except the diagonal components $a_{r,r}$, of which each is unity. The symbol 2 may then denote that formed by an equal number of components, of which $a_{r,s}=0$, except $a_{r,r}$, which is the number 2 of ordinary arithmetic, and so on. It will easily be seen that this is in accordance with the general specifications above, this description being still applicable when 2 is replaced by any number of ordinary arithmetic. In particular, if h be any number of ordinary arithmetic, and a be a matrix symbol, say of n^2 components $a_{r,s}$, it will be legitimate to regard the matrix whose general component is $ha_{r,s}$ as the product of h and the matrix denoted by a. To define the symbol a^{-1}, denote by $|a|$ the determinant formed with the n^2 components, and by $A_{r,s}$ the cofactor of $a_{r,s}$ therein, with its proper sign. Then a^{-1} is the matrix of n^2 components of which the component in the rth row and sth column is given by

$$a'_{r,s}=A_{s,r}/|a|.$$

When the components are such that the determinant $|a|$ is zero, there is no symbol a^{-1}. In this case a is a singular symbol; and there may evidently, for specified n, be an infinite number of such symbols.

Particular examples of such matrix symbols may be referred to:

(1) For $n=2$, if a, a' be numbers of ordinary arithmetic, of which the numbers zero and one are denoted by $\bar{0}$, $\bar{1}$, and we put

$$1=\begin{pmatrix}1, & \bar{0}\\ \bar{0}, & \bar{1}\end{pmatrix},\quad i=\begin{pmatrix}\bar{0}, & -\bar{1}\\ \bar{1}, & \bar{0}\end{pmatrix},$$

then the symbol $$a=\begin{pmatrix}a, & -a'\\ a', & a\end{pmatrix},$$

may be replaced by

$$a\begin{pmatrix}\bar{1}, & \bar{0}\\ \bar{0}, & \bar{1}\end{pmatrix}+a'\begin{pmatrix}\bar{0}, & -\bar{1}\\ \bar{1}, & \bar{0}\end{pmatrix},\quad =a\,.\,1+a'\,.\,i;$$

we find $$1\,.\,1=1,\quad 1\,.\,i=i\,.\,1,\quad i\,.\,i=-1,$$

and hence

$$ab=(\alpha\,.\,1+\alpha'\,.\,i)(\beta\,.\,1+\beta'\,.\,i)=(\alpha\beta-\alpha'\beta')1+(\alpha\beta'+\alpha'\beta)i$$
$$=\begin{pmatrix}\alpha\beta-\alpha'\beta', & -(\alpha\beta'+\alpha'\beta)\\ \alpha\beta'+\alpha'\beta, & \alpha\beta-\alpha'\beta'\end{pmatrix},$$

so that

$$ab=ba.$$

If, for brevity, m stand for $\alpha^2+\alpha'^2$, the symbol a^{-1} is given by

$$a^{-1}=\begin{pmatrix}\dfrac{\alpha}{m}, & \dfrac{\alpha'}{m}\\ -\dfrac{\alpha'}{m}, & \dfrac{\alpha}{m}\end{pmatrix},$$

which is impossible if $\alpha=0$, $\alpha'=0$.

The symbols here described have precisely the same behaviour as the independent variables of ordinary analysis. They are therefore of the highest importance.

(2) If we similarly consider symbols given by

$$a=\begin{pmatrix}\alpha, & \alpha'\\ \bar{0}, & \alpha''\end{pmatrix},\quad b=\begin{pmatrix}\beta, & \beta'\\ \bar{0}, & \beta''\end{pmatrix},\ \ldots$$

where $\bar{0}$ is the zero and $\alpha, \alpha', \ldots, \beta, \ldots$ are numbers of ordinary arithmetic, we find

$$ab=\begin{pmatrix}\alpha\beta, & \alpha\beta'+\alpha'\beta''\\ \bar{0}, & \alpha''\beta''\end{pmatrix},\quad a^{-1}=\begin{pmatrix}\dfrac{1}{\alpha}, & -\dfrac{\alpha'}{\alpha\alpha''}\\ \bar{0}, & \dfrac{1}{\alpha''}\end{pmatrix},$$

so that ab is different from ba in general, and a^{-1} is impossible if either α or α'' be zero.

(3) As the symbols considered in Ex. (1) obey all the laws of combination of the numbers of ordinary arithmetic, they may themselves be used as components to define other symbols. Using 0, 1, i for the particular symbols of this kind defined in Ex. (1), let us consider then the four symbols

$$U=\begin{pmatrix}1, & 0\\ 0, & 1\end{pmatrix},\quad I=\begin{pmatrix}0, & -1\\ 1, & 0\end{pmatrix},\quad J=\begin{pmatrix}0, & i\\ i, & 0\end{pmatrix},\quad K=\begin{pmatrix}-i, & 0\\ 0, & i\end{pmatrix};$$

it is then easy to compute that

$$JK=-KJ=I,\quad KI=-IK=J,\quad IJ=-JI=K,$$
$$I^2=J^2=K^2=-U.$$

Hence, if $\alpha, \beta, \gamma, \delta$ be iterative symbols, that is, here, matrices of two rows and columns with components zero except in the diagonal where there are equal numbers of ordinary arithmetic—so that, in brief, $\alpha, \beta, \gamma, \delta$ behave like numbers of ordinary arithmetic—, the symbol

$$a=\delta+\alpha I+\beta J+\gamma K$$

is the same as

$$a=\begin{pmatrix}\delta-\gamma i, & -\alpha+\beta i\\ \alpha+\beta i, & \delta+\gamma i\end{pmatrix}.$$

Replacing $\alpha, \beta, \gamma, \delta$ respectively by $\alpha', \beta', \gamma', \delta'$, to form a symbol a', we easily find that aa' is generally different from $a'a$. In particular, the symbol a^{-1} is obtained by replacing $\alpha, \beta, \gamma, \delta$ respectively by

$$\alpha'=-m^{-1}\alpha,\quad \beta'=-m^{-1}\beta,\quad \gamma'=-m^{-1}\gamma,\quad \delta'=m^{-1}\delta,$$

where m denotes $\alpha^2+\beta^2+\gamma^2+\delta^2$ Thus a^{-1} is impossible when $\alpha=0$, $\beta=0$, $\gamma=0$, $\delta=0$, in which case $a=0$.

Another symbol with the same laws of combination as a may be represented by

$$\begin{pmatrix} \delta, & \gamma, & -\alpha, & -\beta \\ -\gamma, & \delta, & \beta, & -\alpha \\ \alpha, & -\beta, & \delta, & -\gamma \\ \beta, & \alpha, & \gamma, & \delta \end{pmatrix}.$$

Beside the symbols formed with aggregates of ordinary numbers, there are other symbols obeying the laws of combination which we have enunciated. Of such those introduced by Grassman are probably the most important. For a definite positive integer number n, consider symbols $e_1, e_2, \ldots, e_n$ such that

$$e_i^2=\bar{0}, \quad e_ie_j=-e_je_i, \qquad (i, j=1, 2, \ldots, n).$$

With these we can form a symbol

$$a=a+a_1e_1+\ldots+a_ne_n,$$

where $a, a_1, \ldots, a_n$ are (in the first instance) numbers of ordinary arithmetic. The symbols 0, 1 are obtained then by putting, respectively,

$$a=a_1=\ldots=a_n=\bar{0}, \text{ and } a-\bar{1}=a_1=\ldots=a_n=\bar{0};$$

while a^{-1} is given by $$a^{-1}=\frac{1}{a}-\frac{a_1}{a^2}e_1-\ldots-\frac{a_n}{a^2}e_n,$$

and is impossible, whatever $a_1, \ldots, a_n$ may be, when $a=0$.

Preliminary remarks in regard to the use of the symbols in geometry. Some brief remarks seem necessary to make clear the point of view taken at this stage in introducing the symbols into geometrical discussions. It appears to be more interesting, as well as more satisfactory, to regard this introduction at present as provisional, and illustrative, and to require, for every geometrical result, a geometrical proof independent of the symbols. In the first place we shew that the Propositions of Incidence, and the consequences of these, can be well represented by the symbols. It is more difficult to be sure that every result obtainable from the symbolism, when interpreted as a geometrical theorem, is demonstrable by geometrical reasoning; but we give in detail a geometrical representation of every one of the fundamental laws of combination of the symbols, in accordance with the Propositions of Incidence.

We then shew that the introduction of Pappus' theorem corresponds to a definite additional limiting law of combination for the symbols, namely that their multiplication is commutative. If the correspondence between the geometry and the symbols be exact, it will then follow that a geometrical result is a consequence of the Propositions of Incidence only, when its representation and deduction by means of the symbols does not require this commutative property. In attempting to construct a geometrical proof of a suspected theorem, this remark is of value, and we give several examples of its application.

Two kinds of symbols are employed in what follows: Symbols for geometrical elements, generally points, which we may call element-symbols; and symbols subject to laws of computation, which we may call algebraic symbols. It is of these last we have so far spoken in what precedes. In dealing with any geometrical figure we have as many fundamental element-symbols as is necessary to fix the symbols belonging to all the points, or elements, of the figure, together with a certain number of algebraic symbols. From the manner in which the symbols are introduced it will appear to be without doubt that two points which are identical in virtue of their geometrical construction must then have, as a consequence of computation, the same element-symbol. If we are to employ the symbolism with confidence the converse must also be established, the identity of two element-symbols, arrived at by computation, must imply the possibility of proving the identity of the elements by geometrical reasoning; we seek to induce the conviction that this is so in the present Section, reserving a final consideration for Chapter III.

The use of algebraic symbols for geometrical reasoning dates from very early times (? Apollonius B.C. 230; Ptolemy A.D. 130), and has prompted much in the development of Abstract Geometry. To some writers, therefore, it has seemed to need no justification. But first, it seems evident that a geometry prompted by an algebra must necessarily run parallel to the laws of combination of the symbols of that algebra; and, as we have sought to indicate, there is a good deal of arbitrariness in such laws. And, second, it would seem that a geometry, properly so called, must necessarily be based upon an analysis of our intuition, or experience, of geometrical relations; and that it is necessary to shew that the ideas we adopt from this experience, are properly represented by the symbols. It does not seem likely that a purely analytical geometry can convey any geometrical ideas; there must be constant appeal to geometrical conceptions to give it a meaning; it is surely proper that these conceptions should receive consideration before the symbols are introduced. And, while it would be foolish not to employ the symbols for purposes of discovery, the view taken in the present volumes is, that the object of a geometrical theory is to reach such a comprehensive scheme of conceptions, that every geometrical result may be obvious on geometrical grounds alone.

The symbolical representation of the Propositions of Incidence. In the symbolical scheme which we now proceed to construct to accompany the geometry, we represent a point by a symbol, generally indicated by the same capital letter as that by which we name the point. But we suppose that, if P is the symbol which represents a point, precisely the same point is equally represented by a symbol mP, where m is any one, other than 0, of the system of algebraical symbols which we are employing. It is supposed that this system has no singular symbol other than 0, so that m^{-1} is also a symbol of the system. If P, Q represent any two points, we regard the symbol $mP+nQ$, where m and n are any two algebraical symbols of the system employed, as equally representing a point; and regard all points so represented, for different values of m and n, as being points of the line determined by the points P and Q, making the further assumption that all points of this line can be so represented[1]. Thus a symbol $mP+nQ$ can be replaced by a symbol $-kR$, where R represents a point of the line PQ and k is an algebraic symbol of our system; and, conversely, if P, Q, R be points of a line, there is a relation between them which we may express by writing

$$mP+nQ+kR=0,$$

speaking of this expression as a *syzygy*. Here m, n, k are algebraic symbols of the system employed; in general, when such a syzygy arises, it is in the course of work in which a precise symbol, not further susceptible of being multiplied by an algebraic symbol, has been introduced for each of the points P, Q, R; when this is so, the symbols m, n, k in the syzygy are definite when the points P, Q, R are given, save for a common multiplier prefixed to each. Such syzygies we suppose capable of being combined together, by addition and subtraction, in the manner of linear algebraic equations, the order of the terms in any syzygy being indifferent. To this end it is necessary to understand that a symbol $mP+nP$ may be replaced by $(m+n)P$, and, more generally, that a symbol $m(nP)$ may be replaced by $mn\,.\,P$. This last assumption requires the associative law in multiplication for the algebraic symbols; for, in virtue of this,

$$m[n(kP)]=m[nk\,.\,P]=m(nk)\,.\,P,$$

and

$$m[n(kP)]=mn(kP)=(mn)k\,.\,P.$$

Similarly the associative law in addition is involved in the former assumption. For $[(m+n)+k]P$ is thence $(m+n)P+kP$, and this is $mP+nP+kP$, which again is $[m+(n+k)]P$.

These various suppositions receive their justification by the exact correspondence they set up between the Propositions of Incidence and their symbolical representation.

In general when a point is, in the phraseology already employed in formulating the Propositions of Incidence, *dependent* upon other points, there is a syzygy connecting its symbol with those of these other points; and, conversely, points whose symbols are connected by a syzygy are not independent. For instance, three points which are not in line determine a plane, but for any four points of a plane, represented by symbols A, B, C, D, there is a syzygy

---

[1] See Note I, at the end of the Volume.

$$aA + bB + cC + dD = 0,$$

in which a, b, c, d are algebraic symbols of the system employed; and any point, D, of the plane determined by the points A, B, C, has a symbol capable of the form

$$D = -d^{-1}aA - d^{-1}bB - d^{-1}cC,$$

or, say, $$D = mA + nB + kC.$$

Such a statement may be expressed also by saying that the point D is a *derivative* of the points A, B, C.

The formulation is applicable to space of any number of dimensions. Any $r+1$ independent points, having symbols unconnected by a syzygy, determine a space of r dimensions, in which any $r+2$ points have symbols which are so connected, and conversely. If such $(r+2)$ points be $A_1, A_2, \ldots, A_{r+2}$, this syzygy, written in the form

$$m_1A_1 + m_2A_2 = m_3A_3 + \ldots + m_{r+2}A_{r+2},$$

expresses that the line determined by the two points A_1, A_2, has a point in common with the $(r-1)$ fold determined by the r points $A_3, A_4, \ldots, A_{r+2}$.

Examples of the application of the symbolism. Particular examples may be more illustrative than any further general statement:

(*a*) That two planes in a threefold space have a line in common may be formulated thus: let the planes be respectively determined by the points A, B, C, and the points A', B', C'. As, in three dimensions, any five points are connected by a syzygy, there is such a syzygy connecting the points A', B' and A, B, C; by this is determined a point of the line $A'B'$ which also lies on the plane ABC; this point is then on both planes. Another such point is determined by the syzygy connecting the five points B', C' and A, B, C. The line joining these two points is then that common to the two planes.

(*b*) That, in threefold space, a definite transversal can be drawn through an arbitrary point to meet two lines which have no point in common, is clear because, if the point be P, and the lines be, respectively, determined by the pairs of points A, B and C, D, the syzygy connecting these five points, of the form

$$pP + aA + bB + cC + dD = 0,$$

expresses that the three points P, $aA + bB$, $cC + dD$, being connected by a syzygy, are in line. The points $aA + bB$, $cC + dD$ are upon the two lines, respectively.

(c) Desargues' theorem, that, if two triads of points, A, B, C and A', B', C', be in perspective, the joins of corresponding points, of B, C and of B', C', of C, A and of C', A', of A, B and of A', B', meet in three points which are in line, also follows easily. For, if the lines AA', BB', CC' meet in O, the symbols for A', B', C' must be, respectively, of the forms

$$A' = \alpha A + \lambda O, \quad B' = \beta B + \mu O, \quad C' = \gamma C + \nu O,$$

where α, λ, β, μ, γ, ν are algebraic symbols. There will then, in accordance with what has been said, be no loss of generality in using A', B', C' instead of $\lambda^{-1}A'$, $\mu^{-1}B'$, $\nu^{-1}C'$, respectively, so that, if a, b, c be used for $\lambda^{-1}\alpha$, $\mu^{-1}\beta$, $\nu^{-1}\gamma$, respectively, these syzygies become

$$A' = aA + O, \quad B' = bB + O, \quad C' = cC + O.$$

These give however

$$B' - C' = bB - cC, \quad C' - A' = cC - aA, \quad A' - B' = aA - bB,$$

which, respectively, determine the three points of intersection of corresponding joins, and shew, in virtue of the syzygy

$$(B' - C') + (C' - A') + (A' - B') = 0,$$

that these three intersections are in line.

This example is instructive because the proof is applicable whether the two triads A, B, C and A', B', C' are in one plane or not; in the former case there is a syzygy connecting O with A, B, C, but the proof does not need to utilise this. It has been remarked however, and a formal proof will be given in Chapter II, that Desargues' theorem is incapable of proof from the Propositions of Incidence applicable to a plane only. The symbolism we are using thus implies more than these, even when applied only to a plane. Evidently it implies that any plane through two points contains every point of the line joining these points.

(d) In space of four dimensions two planes have a point in common; for if these planes be respectively determined by the points A, B, C and A', B', C', the two members of the syzygy which necessarily connects these six points in four dimensions,

$$aA + bB + cC = a'A' + b'B' + c'C',$$

represent points lying respectively, in these planes, which, by virtue of the syzygy, are identical.

Or again, if three lines in fourfold space be respectively given by the pairs of points P and P', Q and Q', R and R', the syzygy connecting these six points,

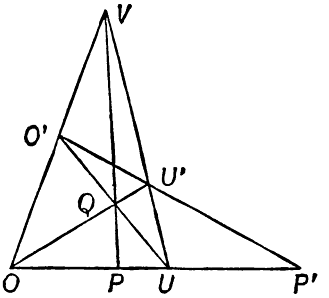
$$pP + p'P' + qQ + q'Q' + rR + r'R' = 0,$$

itself expresses that the three points $pP + p'P'$, $qQ + q'Q'$, $rR + r'R'$, lying respectively on these lines, are in syzygy. So that three lines of general position in fourfold space have a common transversal.

Interpretation of the fundamental laws of the algebraic symbols. After these illustrative examples, which could be indefinitely multiplied, we pass now to give a geometric interpretation of the laws of operation of the algebraic symbols which have been formulated.

(1) The symbol $-a$.

Let O, U be any two points, and P, represented by $O+aU$, be any point on the line joining these. As has been remarked, incidentally, in the above consideration of Desargues' theorem, there would be no gain in representing P in the form $mO+aU$. In any plane through the line OU take the points U', V, on a line passing through U; let OU', VP meet in Q, then QU and OV meet in O', and lastly $O'U'$ meets OU in P'. Thus P' is the harmonic conjugate of P in regard to O and U. We may regard the points of the plane as dependent upon O, U and V. The symbol for the point U' is of the form $U+mV$, and by putting V for mV, in accordance with our original convention, we may suppose this symbol to be $U'=U+V$. Then the point Q is in syzygy with O and U', and also in syzygy with P and V, and the symbol for Q is determined by the fact that it expresses both these circumstances; absorbing an immaterial multiplier, we thence have $Q=O+a(U+V)$, which is both $O+aU'$ and $P+aV$. Similarly, the symbol for O', which is in syzygy both with O and V, and with U and Q, is given by $O'=O+aV$, which is the same as $Q-aU$. Thence the point P', which is in syzygy as well with O' and U', as with O and U, is given by $P'=O-aU$, this being the same as $O+aV-a(U+V)$, or $O'-aU'$. Thus the point $O-aU$ is P'; and the symbols imply that P, P' are distinct.



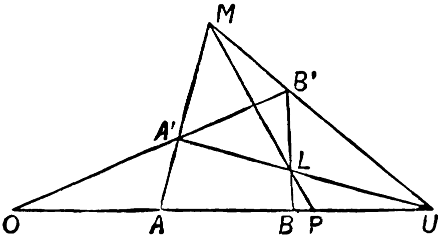
(2) The symbol $a+b$.

Let the points A, B of the line joining the points O and U, when referred to O and U, be, respectively, represented by symbols

$$A=O+aU,\quad B=O+bU.$$

We desire to construct the point $O+(a+b)U$.

In an arbitrary plane drawn through the line AB, draw two lines respectively through

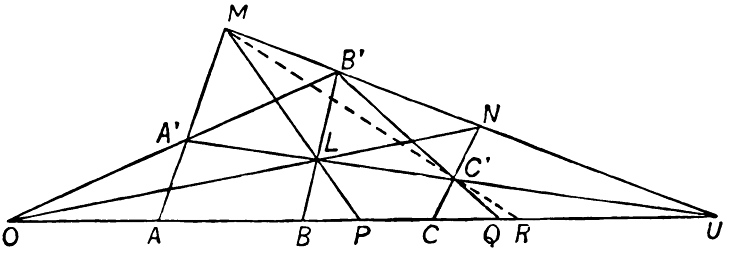


A and B, and let any line through O, in this plane, meet these respectively in A' and B'. Let UA' meet BB' in L, and UB' meet AA' in M, and let LM meet the original line OU in P.

The figure is evidently determinate when, beside O, U, A, B, the points M and A' are given. For the symbol of M we may take $M = A + mA'$, or $M = O + aU + mA'$, which gives $M - aU = O + mA'$; in this syzygy the two members are the symbols, respectively, of a point on the line MU and of a point on the line OA'; this point must then be B', and we may write, for the symbol of this, $B' = O + mA'$. As, however, we have $B = O + bU$, we thence obtain $B' - B = mA' - bU$, which states the equivalence of a point of the line $B'B$ with a point of the line $A'U$. We can, therefore, write, for the symbol of the point L the form $L = mA' - bU$. Thus, as $M = A + mA'$, and, therefore, $M - L = A + bU$, we can, similarly, infer that the point P is given by $P = A + bU$, or $P = O + (a+b)U$.

The construction of P is clearly symmetrical in regard to the points A, B, in accordance with the equation $a + b = b + a$, and, as in earlier cases considered in Section I, is independent of the lines drawn through A, B, O, U when these points are given. Further, when b is $-a$, the figure at once gives $P = O$, in accordance with $a + (-a) = 0$.

(3) The equation $(a+b)+c = a+(b+c)$.



Let p, q denote $a+b$ and $b+c$, respectively. Let A, B, C, referred to the points O, U be, respectively,

$$A = O + aU, \quad B = O + bU, \quad C = O + cU.$$

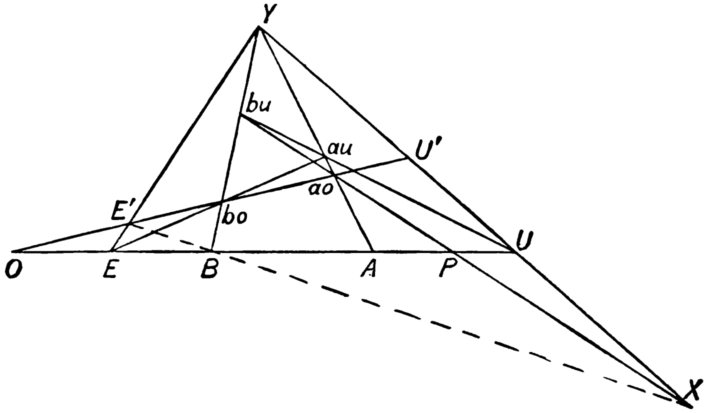
Make the same construction as in the preceding case for A and B, so obtaining the point P given by $P = O + pU$. Now let OL meet the line $MB'U$ in N; join CN meeting the line $A'LU$ in C'; join $B'C'$ meeting OU in Q; also join MC', meeting OU in R. Then as the points L, N, on BB', CC', respectively, are in line with O, it follows, as in the preceding case, that Q is $O + qU$.

Further, as the points A', B', on the lines AM, QC', are in line with O, it follows, also as in the preceding case, that $R = O + (a+q)U$. And, as the points L, N, on the lines PM, CC', are in line with O, it follows, as in the preceding case, that $R = O + (p + c)U$. Thus $p + c = a + q$, as was desired.

(4) The interpretation of the product ab.

For the interpretation of the product ab we go back to a figure which we have already been twice concerned with, first as an immediate application of the Propositions of Incidence (p. 16 above), and then as an example of the consequences of Pappus' theorem (p. 60 above).

Upon the line OU let the points A, B be respectively $O + aU$ and $O + bU$, and let E be the point $O + U$. In an arbitrary plane through this line, draw lines o, u, a, b, respectively through the points O, U, A, B, subject only to the condition that the intersections (a, u), (b, o) are in line with E. Let the joining line of the points (a, o), (b, u) meet the line OU in P. We proceed to shew that the symbol of the point P is given by $P = O + abU$. It has already been shewn that the same point P is obtained for all lines o, u, a, b.



Let the lines a, b meet in the point Y, and the line o meet YU in the point U', and meet the line YE in the point E'. The two triads of points E', E, B and (a, o), (a, u), (b, u) are in perspective from the point (b, o); and the corresponding joins, of E' to E and (a, o) to (a, u), meet in Y, while the corresponding joins, of B to E and (b, u) to (a, u), meet in U. Wherefore, by Desargues' theorem, the line $E'B$ meets the join of (a, o) to (b, u) in a point of the line UY, say X.

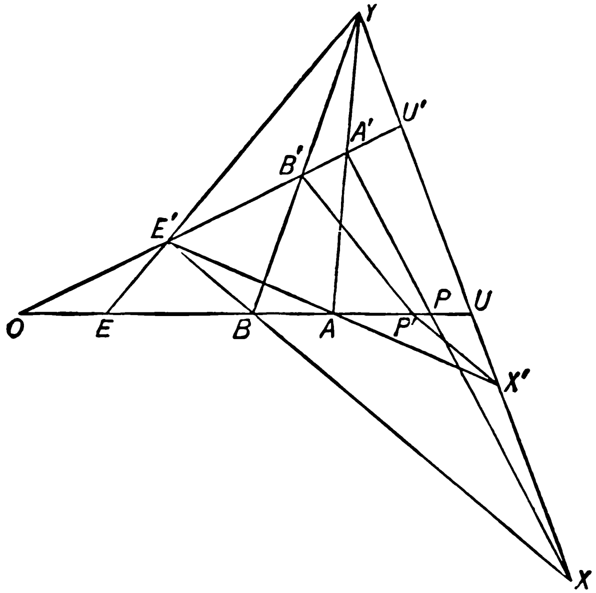
The symbol of U', by absorption of a multiplier in the symbol of Y, may be taken to be $U' = U + Y$. Then E', being both on the join of O to $U + Y$, and on the join of E, or $O + U$, to Y, is given by $E' = O + U + Y$. In a similar way, the point (a, o), being on the join of O to U', or $U + Y$, and also on the join of A, or $O + aU$, to Y, has a symbol $O + aU'$, which is $O + aU + aY$. We find, likewise, for the symbol of the point (b, o), the form $O+bU'$. Thence, the point X, being on the line $U'U$, and also on the join of B to E', that is of $O+bU$ to $O+U'$, has the symbol $U'-bU$. Thence, finally, the point P, being on the line OU, and also on the join of X to (a, o), that is of $U'-bU$ to $O+aU'$, has a symbol

$$O+aU'-a(U'-bU), \text{ or } O+abU.$$

If a line, o', be drawn through O to meet the line a in a point (a, o') which is in line with E and (b, u), and the point (b, o') in which this meets the line b, be joined to the point (a, u) by a line meeting OU in the point P', it can be similarly shewn that the line $E'A$ meets the join of (a, u) and (b, o') in a point of the line YU, and that the point P' has a symbol $O+baU$.

(5) The possibility of the equation $ab=ba$.

We have seen above that the points P, P' coincide if we assume Pappus' theorem (pp. 60, 61). In the present description of the derivation of the points P and P', we have slightly added to the original figure of p. 16, using Desargues' theorem, in order to simplify the proof of the symbols for the points P, P'. In the figure thus reached, arbitrary lines are drawn from E, B, A, U to meet in Y; an arbitrary line is drawn from O to meet these, respectively, in E', B', A', U'; then P is found by drawing $E'B$ to meet YU in X, and taking the intersection of $A'X$ with OU, while P' is found by drawing $E'A$ to meet YU in X', and taking the intersection of $B'X'$ with OU. The identity of P and P' as a consequence of Pappus' theorem can then be seen, differently from



before, by considering the two triads Y, X, X' and E', B', A'; as $YA', E'X'$ meet in A, while $YB', E'X$ meet in B, it follows then that XA' and $X'B'$, or $A'P$ and $B'P'$, meet on AB.

A direct deduction from the figure of p. 16 of the symbols for P and P' may be given, which has a value as an exhibition of the self-consistency of the non-commutative symbolism.

A further construction of P is obtainable by remarking that, in virtue of Desargues' theorem, the lines UE', UA' meet YB, YP, respectively, in two points lying in line with O.

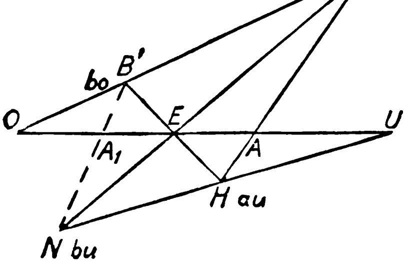
We have seen above (p. 46) that Pappus' theorem, though a theorem of geometry in a plane, is equivalent with a theorem in regard to lines in space. We shall see below (p. 82) that the corresponding expression in symbols, of this theorem in regard to lines in space, also requires that the symbols should be commutative in multiplication.

We have remarked above (p. 66) that, in the case of the iterative symbols, the commutative equation $mn = nm$ is a consequence of their definition. The question whether the geometrical representation of this identity involves Pappus' theorem, and the question whether von Staudt's introduction of numbers in Geometry involves the assumption of Pappus' theorem, are considered below (p. 87 and p. 93).

Provisionally, we may infer that *the assumption of Pappus' theorem, and the restriction of the algebraic symbols to such as are commutative in multiplication, are, subject to the other assumptions made, equivalent.*

(6) The symbol a^{-1}.

This may be represented by the same figure as that used for the representation of ab, if this be specialised so that P coincides with E.



On the line OU let A be $O+aU$; let A', H be any two points in line with A; let B', on OA', be in line with E and H, and N, on UH, be in line with E and A'. Then NB' meets OU in $O+a^{-1}U$.

For, if H have the symbol $A+\lambda A'$, or $H = O + aU + \lambda A'$, we first have

$$(1-a)\,O + \lambda A' = O + aU + \lambda A' - a\,(O+U),$$

as the symbol of a point lying both on OA' and on HE, the point B'; and then we have

$$O + U + \lambda A' = O + aU + \lambda A' + (1-a)\,U$$

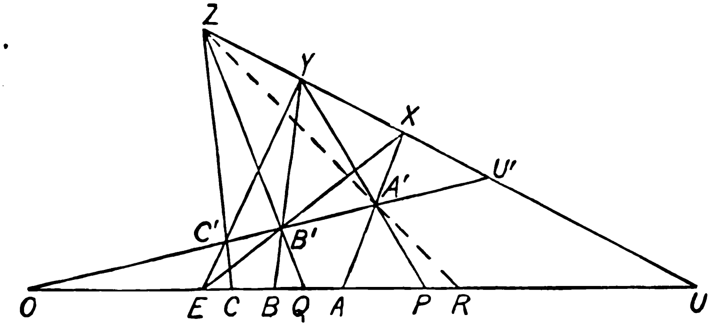
as the symbol of a point lying on EA' and also on HU, the point N. Thence we have $aO + U$ as the symbol of a point lying on $B'N$ which lies on OU; and this gives the same point, A_1, as $O + a^{-1}U$.

Evidently, by the construction, if $b = a^{-1}$, then $a = b^{-1}$, and $ab = 1$. Also when $a = 1$, then also $a^{-1} = 1$.

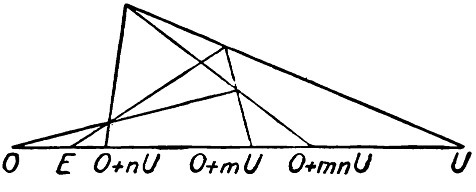
(7) The equation $(ab)c = a(bc)$.

Let p denote ab, and q denote bc.

Let the points A, B, C and E, on the line OU be respectively $O + aU$, $O + bU$, $O + cU$, and $O + U$. Draw, in an arbitrary plane through OU, two lines through O and U, intersecting in U', and let a line through B, in this plane, intersect these, respectively, in B' and Y. Let the lines joining the point E, respectively to Y and B', meet these lines, OU', UU', respectively in C' and X. Let AX meet OU' in A', and CC' meet UU' in Z. Lastly, draw YA', ZB', ZA', meeting OU respectively in P, Q, R.



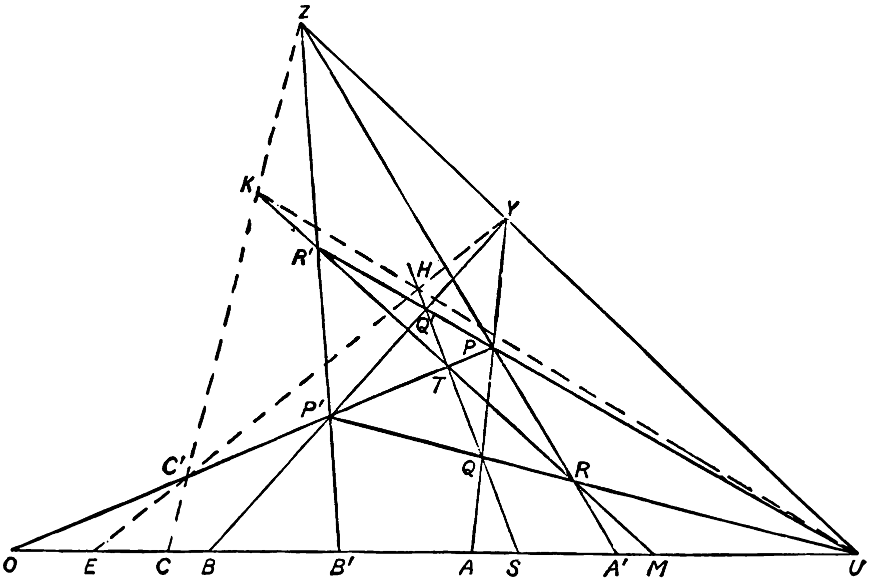
Then, recalling once more the construction for $O + mnU$ from the points $O + mU$, $O + nU$, we see (*a*) that P is $O + abU$, or $O + pU$; (*b*) that Q is $O + bcU$, or $O + qU$; (*c*) that R is $O + aqU$; (*d*) that R is also $O + pcU$. Wherefore $aq = pc$, as we desired to see.



(8) The equation $(a + b)c = ac + bc$.

First remark the following figure: let ZPR, $ZR'P'$, UPR', URP' be any four lines in a plane, with intersections indicated by the lettering, the joins PP', RR' meeting in T; take an arbitrary point, Y, upon ZU, and an arbitrary point, C', upon PP'; let the joins YP, YP' meet $P'R$, $R'P$ respectively in the points Q and Q', so that, by Desargues' theorem, as corresponding joins of the two triads P, Q, R and P', Q', R' meet, respectively, in the three points U, Z, Y, which are in line, it follows that QQ' passes through the point of intersection, T, of PP' and RR'; next, let the joins $C'Y$, $C'Z$ meet QQ'

and RR', respectively, in H and K. Then, as the corresponding joins of the two triads Y, H, Q' and Z, K, R' meet, respectively,



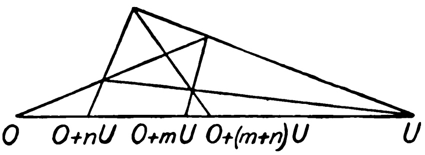
in the points T, P', C', which are in line, it follows that the line KH passes through the intersection, U, of ZY and $R'Q'$. We are concerned now with the intersections of all the lines of this figure with a line drawn through U, in the plane of the figure.

Let O, U be any two points, and E, A, B, C be points upon the line OU, whose symbols, referred to O and U, are respectively

$$E = O + U, \quad A = O + aU, \quad B = O + bU, \quad C = O + cU.$$

In an arbitrary plane through the line OU take a point, Z, and then a point, Y, upon the line ZU. Join YB and YA, and also ZC. Let YE meet ZC in C', and, then, let OC' meet YB and YA, respectively, in P' and P. Let ZP' and ZP, respectively, meet OU in B' and A'; and let UP and UP' meet ZP' and ZP, respectively, in R' and R, these same lines meeting YP' and YP, respectively, in Q' and Q. Then, by what has been remarked, the line QQ' passes through the intersection, T, of PP' and RR', and if this line QQ' meet $YC'E$ in H, while RR' meets $ZC'C$ in K, then KH passes through U. Denote the intersections of QQ' and RR', respectively, with OU by S and M.

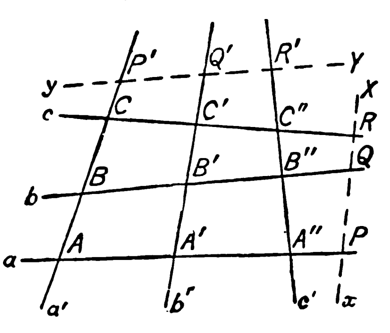
We have just recalled (in No. 7) the construction for finding the point $O + mnU$ from the points $O + mU$ and $O + nU$; if we recall also the construction for finding $O + (m+n)U$ from $O + mU$ and $O + nU$, we see that, in the figure we have constructed, the symbol of the point S is $O + (a + b) U$, and, thence, that the symbol of the point M is $O + (a + b) cU$. On the other hand, we see also that the symbol of the point A' is $O + acU$, and, similarly, of B' is $O + bcU$, and, thence, that the symbol of the point M is $O + (ac + bc) U$. Comparing these two forms for the symbol of the point M, we have the identity $(a + b) c = ac + bc$, which we desired to interpret.



A similar representation of the identity $c (a + b) = ca + cb$ may be constructed.

Representation of the algebraic effect of Pappus' Theorem in three dimensions. We have now shewn that all the fundamental laws of operation for the algebraic symbols are in accord with geometrical facts in one plane deducible from the Propositions of Incidence with the help of Desargues' theorem, which is itself deducible, as we have seen, from these Propositions, assumed not limited to two dimensions. But we have shewn that the commutative law of multiplication for the algebraic symbols involves Pappus' theorem, and conversely. We shewed however, in Section II, that Pappus' theorem, is equivalent, in virtue of the Propositions of Incidence, to a theorem of intersection of two lines in three dimensions. It is interesting to verify directly that this theorem again involves the commutative property of the symbols. The geometrical theorem is that, if we have two triads, each of non-intersecting lines, in three dimensions, every line of either triad meeting all those of the other, then any transversal of the lines of one triad intersects any transversal of the lines of the other.

Let the lines of the two triads be respectively a, b, c and a', b', c', their intersections being, A, A', A'' on a, B, B', B'' on b, and C, C', C'' on c. Let x be any transversal of a, b, c, meeting them, respectively, in P, Q, R, any point of this transversal being X; so, let y be any transversal of a', b', c', meeting them, respectively, in P', Q', R', any point of this transversal being Y.



The points A, A', B, B' are not supposed to be in a plane, and may be taken as fundamental for the threefold space in which the figure lies. Using A, A', B, B' as the symbols for these points, we may, by absorption of algebraic multiples in these symbols, suppose that the symbol of the point C'' is

$$C'' = A + A' + B + B'.$$

This expresses, however, that C'' is a derivative of the two points represented, respectively, by $A + A'$ and $B + B'$, of which the former is on the line a and the latter on the line b. For the symbols of the points A'' and B'' we thus infer

$$A'' = A + A', \quad B'' = B + B'.$$

For the symbols of the points C and C' we similarly infer

$$C = A + B, \quad C' = A' + B'.$$

The points P and Q are, respectively, derivatives of A, A' and of B, B'; thus proper symbols for these are, respectively,

$$P = A + \rho A', \quad Q = B + \lambda B',$$

with suitable values for the algebraic symbols ρ and λ. Then the point R, a derivative of P and Q, must have a symbol of the form

$$R = mP + nQ, \quad = mA + nB + m\rho A' + n\lambda B';$$

on the other hand, as R is a derivative of C and C', its symbol must be of the form

$$R = h(A + B) + h'(A' + B');$$

comparing these two forms, we infer that $m = n$ and $m\rho = n\lambda$, and hence $\rho = \lambda$. Thus the symbols of P, Q involve the same algebraic symbol, being $P = A + \rho A'$, $Q = B + \rho B'$.

Thence the point X, a derivative of P and Q, is given by a symbol

$$X = P + \sigma Q, \quad = A + \rho A' + \sigma B + \sigma\rho B'.$$

Again, the points P' and Q', respectively derivatives of A, B and of A', B', have symbols of the forms

$$P' = A + \kappa B \quad \text{and} \quad Q' = A' + \mu B';$$

and the point R', a derivative of P' and Q', is equally a derivative of A'' and B''. There exists, therefore, a syzygy of the form

$$p(A + \kappa B) + q(A' + \mu B') = r(A + A') + s(B + B');$$

hence we infer that $p = q$ and $p\kappa = q\mu$, and therefore that $\kappa = \mu$.

Thus the point Y, any point of the line $P'Q'$, has a symbol

$$Y = P' + \tau Q', \quad = A + \tau A' + \kappa B + \tau\kappa B'.$$

Comparing the symbols for the points X and Y, we see that the conditions for the lines x and y to have a common point are that, when ρ and κ have been taken, corresponding to the positions of P and P' respectively on AA' and AB, it must be possible to take σ and τ, corresponding to the positions of X and Y respectively on x and y, so that

$$\tau = \rho, \quad \kappa = \sigma, \quad \tau\kappa = \sigma\rho.$$

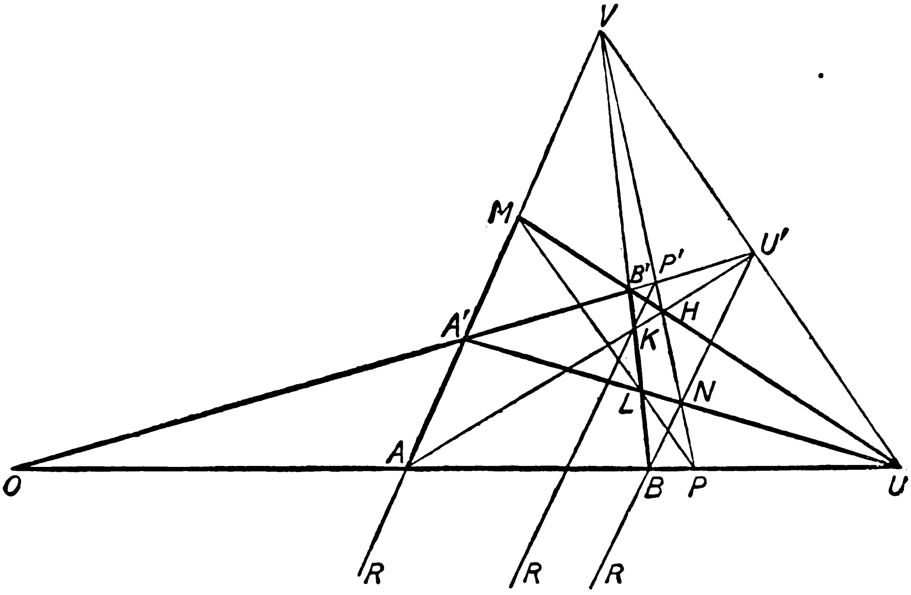
These can be satisfied if, and only if, we have

$$\rho\kappa = \kappa\rho,$$

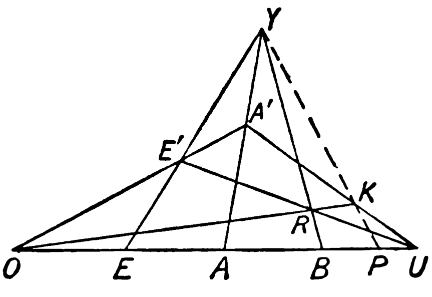
and therefore, $\sigma\tau = \tau\sigma$, $\rho\sigma = \sigma\rho$, $\kappa\tau = \tau\kappa$. The point X is determined by ρ and σ alone; only when these are such that $\rho\sigma = \sigma\rho$ is there a line y, transversal to a', b', c', which meets the line x. The condition of commutative multiplication, for every two of the algebraic symbols employed, is the necessary and sufficient condition that every line x should intersect every line y.

Examples in regard to the use of the symbols, in particular in regard to the commutative law of multiplication. A vast number of applications can be given of the symbolism explained in this Section. We limit ourselves mainly to such as seem to carry the explanation of general principles somewhat further.

Ex. 1. In the construction above given for the point $O + (a+b)U$ from the points O, U, $O + aU$ and $O + bU$, the constructed point P may be differently defined. If AA', BB' meet in V, also $A'B'$ meets VU in U', and meets VP in P', while $U'A$, $U'B$ meet VP, respectively, in H and N, and $U'A$ meets VB in K, then H and N lie, respectively, on UB' and UA', and the lines $P'K$, NB, VA meet in one point, R.

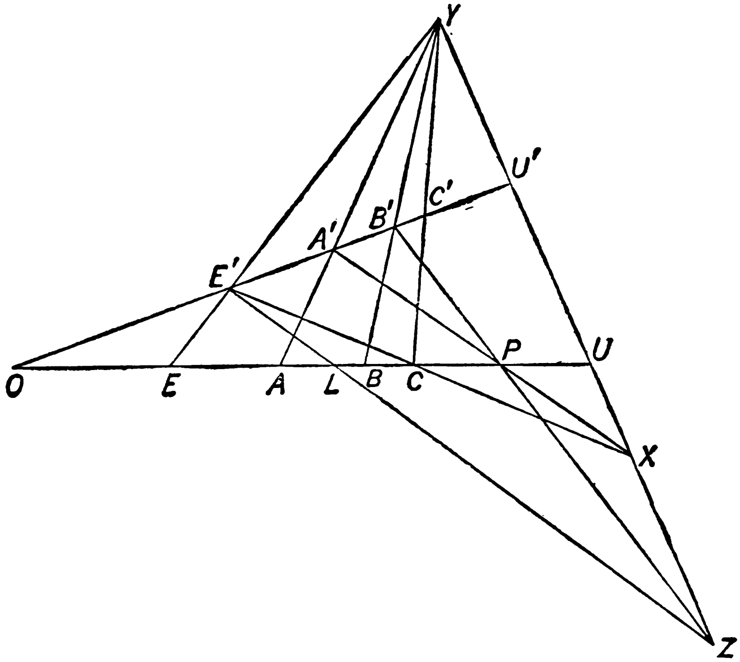


These follow by applying Desargues' theorem.



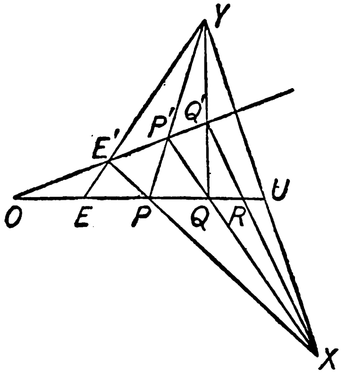
Ex. 2. The construction of the

point $O+abU$, from the points $O, U, E, O+aU, O+bU$, above given, may be stated thus: Let $OE'A'$ be any line through O meeting YE, YA, respectively, in E' and A', where Y itself is arbitrary; let UE' meet YB in R, and OR meet UA' in K; then YK gives the required point P. To reduce this to what is given above we apply Desargues' theorem to the two triads E', R, B and A', K, P.



Ex. 3. If O, U, E, A, B, C represent O, U, $O+U$, $O+aU$, $O+bU$, $O+cU$, and an arbitrary line through O meet the joins of the arbitrary point, Y, to E, A, B, C, respectively, in E', A', B', C', also $E'C$ meet YU in X, and XA' meet OU in P, and $B'P$ meet YU in Z, and lastly ZE' meet OU in L, shew that the symbol of this point is $O+b^{-1}acU$. Then construct a geometrical representation of the equation

$$b^{-1}ac+b^{-1}dc=b^{-1}(a+d)c.$$



Ex. 4. If relatively to the points O, U, the points

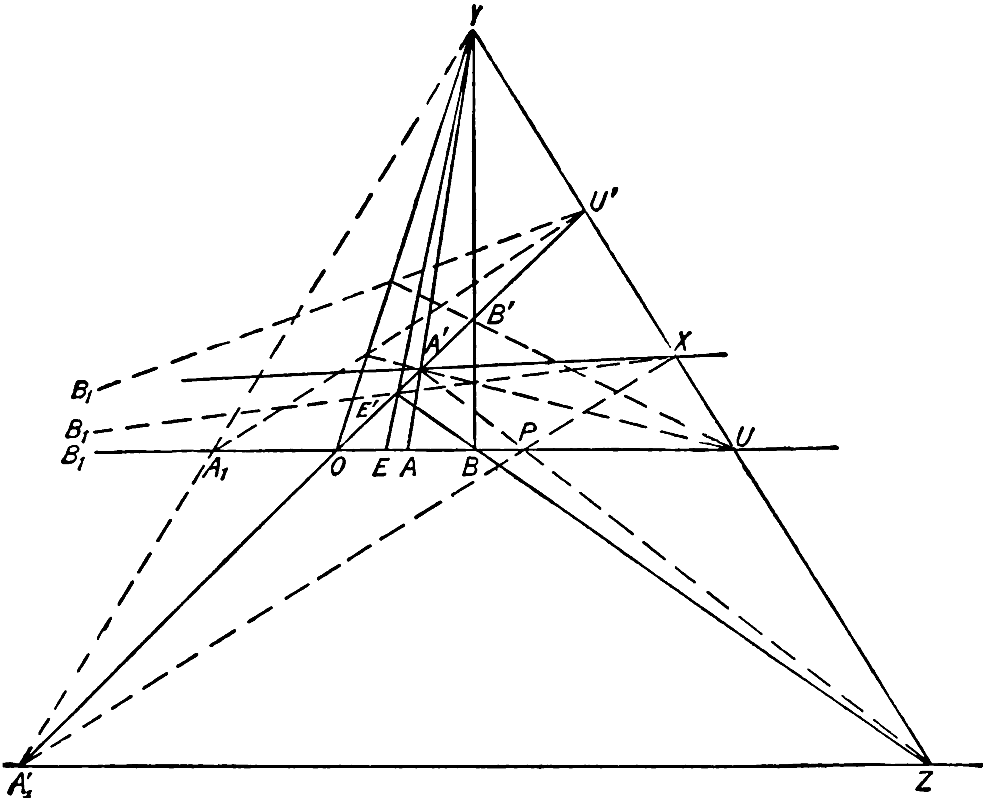
$$E=O+U, \quad P=O+aU$$

be given, and a^2, a^3, ... as usual denote $a.a$, $a^2.a$, ..., construct the points

$$Q=O+a^2U, \quad R=O+a^3U, \quad S=O+a^4U, \text{ etc.}$$

Ex. 5. To represent the equations

$$(-a)(-b) = ab,$$
$$(-a)b = a(-b) = -ab.$$



Let $\quad E = O + U, \quad A = O + aU, \quad B = O + bU.$

Let Y be any point, not on OU, and U' be any point on YU. Let the line OU' meet YE, YA, YB, respectively, in E', A', B'; let $E'B$ meet YU in Z, and $A'Z$ meet OU in P. Join the intersection of YO and UA' to U', the join meeting OU in A_1; join the intersection of YO and UB' to U', the join meeting OU in B_1. Let YA_1 meet OU' in A_1'; let B_1E' meet YU in X.

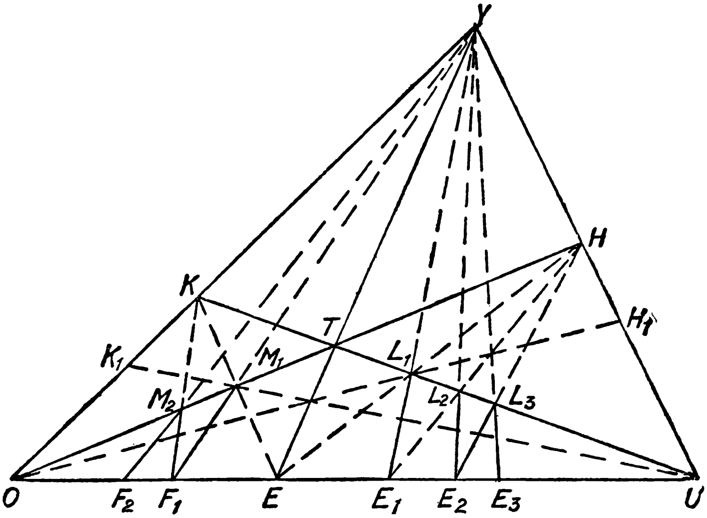
Prove that $A_1'X$ passes through P, and hence represent the equation $(-a)(-b) = ab$. Also prove that $A'X$ and $A_1'Z$ meet on OU, and hence represent the equation $(-a)b = a(-b)$.

Ex. 6. The iterative symbols.

(*a*) Let m, n be any iterative symbols formed, respectively, by $\bar{m}$ and by $\bar{n}$ repetitions of the symbol 1, where $\bar{m}$, $\bar{n}$ are positive integers of ordinary arithmetic. In the first place, given the points O, U

and $E = O + U$, we seek to represent the points $O + mU$, $mO + U$, $mO + nU$.

Take any point Y, not on OU, and any point T on YE, for which the symbol, with proper choice of the symbol Y, may be written $T = Y + E$. Let OT meet YU in H, and UT meet OY in K; the point H, on the join of U and Y, and on the join of O and $Y+O+U$, has symbol $H = U + Y$; so the point K has symbol $K = O + Y$. Let HE and KE meet UT and OT, respectively, in L_1 and M_1; and let YL_1 and YM_1 meet OU in E_1 and F_1, respectively. Let HE_1 and KF_1 meet UT and OT, respectively, in L_2 and M_2; and let YL_2 and YM_2 meet OU in E_2 and F_2, respectively. And let the process thus suggested be continued indefinitely.



It can then be seen at once that the symbols for $E_1, E_2, \ldots$ are $E_1 = O + 2U$, $E_2 = O + 3U$, ..., in general $E_{r-1} = O + rU$. So we have $F_1 = 2O + U$, $F_2 = 3O + U$, ... Then, if the join of O and L_1 meet YU in H_1, the join of K to H_1 meets OU in $O - 2U$; and, in general, if the join of O and L_{r-1} meet YU in H_{r-1}, the join of K to H_{r-1} meets OU in $O - rU$. Similarly if the join of U and M_1 meet YO in K_1, the join of H to K_1 meets OU in $2O - U$, and so on. We thus easily construct all the points $O + mU$, $mO + U$, $O - mU$, $mO - U$.

In fact these points arise by successive applications of the construction for determining the harmonic conjugate of a point P in regard to a given pair of points A, B. For, denoting this fourth harmonic point by $(A, B)/P$, we clearly have

$$E_1 = (E, U)/O, \quad E_2 = (E_1, U)/E, \ldots,$$

$$F_1 = (E, O)/U, \quad F_2 = (F_1, O)/E, \ldots,$$

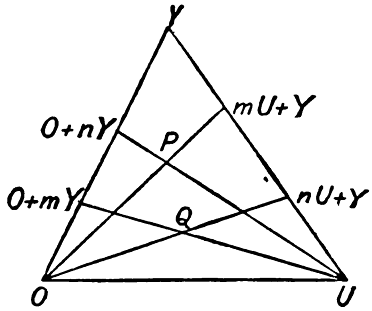
and in general

$$E_{r+1} = (E_r, U)/E_{r-1}, \quad F_{r+1} = (F_r, O)/F_{r-1}.$$

More generally, recalling that the harmonic conjugate of a point $A + \lambda B$, in regard to the points A, B, is $A - \lambda B$, we see that the point $mO + nU$, being $mO + (n-1)U + U$, is the harmonic conjugate of $mO + (n-2)U$ in regard to $mO + (n-1)U$ and U, or, say,

$$E_{m,n} = (E_{m,n-1}, U)/E_{m,n-2}.$$

Every one of the points $mO \pm nU$ can thus be constructed by a succession of processes of finding the fourth harmonic, given the points O, U, $O + U$; the m, n being any iterative symbols.



Consider next the representation of the equation $nm = mn$; we shew that this is independent of Pappus' theorem. In the first place, from the points O, U, E, and Y, we can construct, as above, the points $mU + Y$, $nU + Y$, upon the line YU, and the points $O + nY$, $O + mY$, upon the line YO. The intersection, P, of the joins of O to $mU + Y$ and of U to $O + nY$, evidently has a symbol

$$P = O + nmU + nY,$$

and the intersection, Q, of the joins of O to $nU + Y$ and of U to $O + mY$, evidently has a symbol

$$Q = O + mnU + mY.$$

A representation of $nm = mn$ is, thus, that the points P, Q are in line with Y.

If, however, we consider the three points, P, so arising, for the same value of n, and the three values $m - 1$, m, $m + 1$ in place of m, and at the same time the three points, Q, so arising, for this value of n and the same values for m, the harmonic relation shews that the assumption that two of the three triads Y, P, Q so arising are in line, involves that the third is also. For the initial values of m, n the theorem that Y, P, Q are in line is easy to prove. Thus, by induction, it is always true.

Ex. 7. As examples of the fact that a geometrical result obtainable without Pappus' theorem should be representable symbolically without use of the commutative law for multiplication, and the converse statement that, if we can obtain a symbolical deduction of a result without use of this commutative law, we should be able to construct a geometrical proof from the Propositions of Incidence only, we may reconsider some of the work of Section I.

A simple result was that, if p, a, b, c, d be five arbitrary lines of which no two intersect, lying in three dimensions, and, from an arbitrary point, P, of the first line, p, there be drawn the transversal to two of these lines, say a and c, to meet these respectively in A and C, and also from P the transversal to the other two given lines b, d meeting these in B and D, then the intersection, say Q, of the joins of A and C respectively to B and D, that is of AB and CD, also describes a line. The intersection of AD and CB equally describes a line.

Choosing the symbols of A, B, C, D suitably, we can suppose, these points being in a plane, that the syzygy connecting them is $A+B+C+D=0$. Then the point represented equally by $A+C$ and $-(B+D)$ is necessarily P; and, similarly, for the symbol of Q, we have either $A+B$ or $-(C+D)$. If a second point, P', be taken on the line p, and a similar construction, with a like convention, be made, we can equally write

$$P' = A' + C', \; = -(B' + D'), \quad Q' = A' + B', \; = -(C' + D').$$

A third point, P'', upon p, has a symbol given by

$$\begin{aligned} P'' = mP + m'P' &= m(A + C) + m'(A' + C') \\ &= mA + m'A' + mC + m'C', \end{aligned}$$

which is also $\qquad -(mB + m'B') - (mD + m'D')$.

Thus P'' is in line with the points $mA + m'A'$ and $mC + m'C'$, lying, respectively, on the lines a and c, and is also in line with the points $mB + m'B'$ and $mD + m'D'$, lying, respectively, on the lines b and d. These are then the points obtainable by the original construction from the point P''. If we denote them, respectively, by A'', C'', B'', D'', we see that

$$A'' + B'' = m(A + B) + m'(A' + B') = -(C'' + D''),$$

and the lines $A''B''$, $C''D''$ meet in a point, Q'', given by

$$Q'' = mQ + m'Q',$$

lying on the join of Q and Q'. This establishes the result stated.

Ex. 8. In Section I (p. 27) we gave a construction, when four, or more, non-intersecting lines AA', BB', CC', DD' ..., have three common transversals $ABCD$ ..., $A'B'C'D'$ ..., $PQRS$ ..., for finding a fourth transversal $P'Q'R'S'$.... The point P' was the harmonic conjugate of P in regard to A and A', say $P' = (A, A')/P$; and, similarly, $Q' = (B, B')/Q$, $R' = (C, C')/R$, ...

The figure being in three dimensions we can regard A, A', B, B' as fundamental points, and write the symbols of P and Q in the forms $P = A + \rho A'$ and $Q = B + \sigma B'$; and then the symbols of R and S in the forms $R = P + mQ$ and $S = P + nQ$. By properly choosing the symbols A', B', Q, we can, if we wish, suppose $\rho = 1$,

$\sigma = 1$, $m = 1$; but n is not 1, save for a particular position of S. The form of R,

$$R = A + \rho A' + m(B + \sigma B'),$$

enables us then to infer, for the symbols of C and C', respectively,

$$C = A + mB, \quad C' = \rho A' + m\sigma B';$$

also if, as before (p. 27 above), the transversal from R to the cross lines AB' and $A'B$ meet these respectively in F, F', this form of R shews that, for F and F',

$$F = A + m\sigma B', \quad F' = \rho A' + mB.$$

Hence

$$C - F' = A - \rho A', \; = F - C', \text{ and } C - F = m(B - \sigma B'), \; = F' - C';$$

thus the lines $F'C$ and FC' meet in a point P' of AA' given by $P' = A - \rho A'$, and the lines FC and $F'C'$ meet in a point Q' of BB' given by $Q' = B - \sigma B'$. These are such that $P' = (A, A')/P$ and $Q' = (B, B')/Q$; and they give

$$P' + mQ' = C - C',$$

which shews that $P'Q'$ meets CC' in a point R' such that $R' = (C, C')/R$. From $S = P + nQ$, we can, similarly, shew that the line $P'Q'$ contains a point S' for which $S' = (D, D')/S$.

Ex. 9. Another construction was given (p. 29 above) for a fourth transversal of the four lines AA', BB', CC', DD' of Ex. 8. If BR, $B'S$ meet in X, and XP meets BB' in Q'; while $A'R$, AS meet in Y, and YQ meets AA' in P', then $P'Q'$, which meets AA' and BB', also meets CC' and DD'. Further XA, YB', CC', $P'Q'$ meet in a point, as do YB, XA', DD', $P'Q'$.

With the notation of the previous Example we find, in fact,

$$X = R - (m - n)B = S + (m - n)\sigma B' = A + \rho A' + nB + m\sigma B', \; = D + C',$$

so that
$$nQ' = nB + m\sigma B', \quad Q' = B + n^{-1}m\sigma B'.$$

Also we find

$$Y = m^{-1}R - (m^{-1} - n^{-1})\rho A' = n^{-1}S + (m^{-1} - n^{-1})A$$
$$= m^{-1}A + n^{-1}\rho A' + B + \sigma B', \; = m^{-1}C + n^{-1}D',$$

so that
$$m^{-1}P' = m^{-1}A + n^{-1}\rho A', \quad P' = A + mn^{-1}\rho A'.$$

These lead to

$$P' + mQ' = C + mn^{-1}C', \quad P' + nQ' = D + mn^{-1}D',$$

which we may denote, respectively, by R' and S'. These express that $P'Q'$ meets CC' and DD'.

But, unless we assume a relation, in multiplication, for the symbols, which would follow if we assumed Pappus' theorem, this line $P'Q'$ does not meet any other general transversal of the three given lines $ABCD$, $A'B'C'D'$, $PQRS$. For if, from a point, T, of the line *PQRS*, there be drawn *ETE'* to meet *ABCD* and *A'B'C'D'*, respectively, in *E* and *E'*, taking the symbol of *T* to be $T = P + tQ$, we obtain

$$E = A + tB, \quad E' = \rho A' + t\sigma B',$$

and $$P' + tQ' = E + mn^{-1}E' + mn^{-1}(nm^{-1}tn^{-1}m - t)\,\sigma B'.$$

This shews that the point in which the line *P'Q'* meets the plane *EE'B'* is not on *EE'*, that is, that *P'Q'* does not intersect *EE'*, unless

$$tn^{-1}m = mn^{-1}t,$$

a relation which, if we suppose $m = 1$, as we may do without loss of generality, becomes $tn^{-1} = n^{-1}t$, or $nt = tn$. It would follow if Pappus' theorem were assumed, and it is true, independently of this, when t, m, n are iterative symbols.

The other results stated to be true follow from the syzygies

$$X + (nm^{-1} - 1)\,A = nY + (m - n)\,\sigma B' = nm^{-1}C + C' = nQ' + nm^{-1}P',$$

these combinations being all identical with

$$nm^{-1}A + \rho A' + nB + m\sigma B',$$

together with

$$mY - (m - n)\,B = X + (mn^{-1} - 1)\,\rho A' = D + mn^{-1}D' = nQ' + P',$$

these being all equivalent with

$$A + mn^{-1}\rho A' + nB + m\sigma B'.$$

The facts that *X* lies on *C'D*, and *Y* lies on *CD'*, have already appeared.

If we proceed by the same rule to deduce *P''*, *Q''* from *P'*, *Q'*, just as we have deduced *P'*, *Q'* from *P*, *Q*, we find that

$$P'' = A + mn^{-1}mn^{-1}\rho A', \quad Q'' = B + n^{-1}mn^{-1}m\sigma B',$$
$$P'' + mQ'' = C + mn^{-1}mn^{-1}C', \quad P'' + nQ'' = D + mn^{-1}mn^{-1}D',$$

the last two giving the points where *P''Q''* meets *CC'* and *DD'*.

Ex. 10. We gave in Section I (p. 26) a process for finding a transversal, in the figure of Ex. 8, for the two pairs of cross joins *AB'*, *A'B*, *CD'*, *C'D*. With the notation of Ex. 8, we find for the symbols of the points *M*, *M'*, *N*, *N'*, occurring in that construction

$$M = A + m\sigma B', \quad M' = \rho A' + mB, \quad N = A + n\sigma B', \quad N' = \rho A' + nB,$$

from which follow

$$M + N' = C' + D, \quad M + mn^{-1}N' = C + mn^{-1}D',$$
$$M' + N = C + D', \quad M' + mn^{-1}N = C' + mn^{-1}D,$$

in agreement with the fact that the lines *MN'* and *M'N* both meet the lines *CD'* and *C'D*.

Ex. 11. Consider now the question of two Moebius tetrads of points, *A*, *B*, *C*, *D* and *A'*, *B'*, *C'*, *D'*, such that each of the latter is on the plane determined by three of the former, and each of the former on the corresponding plane determined by three of the latter. We have, in Section I (p. 61), deduced the possibility of this by help of Pappus' theorem; it is to be expected that the symbolical representation will require the commutative restriction.

The points A, B, C, D being regarded as fundamental, the fact that the points D', A', B', C' are, respectively, on the planes ABC, BCD, CAD, ABD, can be expressed, by properly choosing the symbols of A, B, C, A', B', C', by the syzygies

$$D' = A + B + C,$$
$$A' = mC - n_1B - D, \quad B' = nA - l_1C - D, \quad C' = lB - m_1A - D,$$

as is easily seen, l, m, n and l_1, m_1, n_1 being suitable algebraic symbols. Then, the line $B'C'$ meets the plane ABC in a point which is represented by either of the symbols

$$B' - C', \quad (m_1 + n) A - lB - l_1C;$$

if this point is to be on the line $D'A$, remembering $D' = A + B + C$, this point must be a derivative of A and $B + C$. Thus $l = l_1$. So we get $m = m_1$ and $n = n_1$.

In order that D should lie on the plane $A'B'C'$, there must be a derivative of A', B', C', say $aA' + bB' + cC'$, which coincides with D. As A, B, C, D are not in a plane, there must then be a syzygy

$$a(mC - nB) + b(nA - lC) + c(lB - mA) = 0,$$

which, since A, B, C are independent, requires the equations

$$bn = cm, \quad cl = an, \quad am = bl;$$

these however require

$$a = cln^{-1}, \quad a = blm^{-1}, \quad cm \,.\, m^{-1}ln^{-1} = bn \,.\, n^{-1}lm^{-1},$$

and hence $m^{-1}ln^{-1} = n^{-1}lm^{-1}$, or $lm^{-1}n = nm^{-1}l$. By a slight change of symbols we can, without loss of generality, suppose $m = 1$. The condition for the Moebius tetrads is thus $ln = nl$, as was anticipated.

Ex. 12. Obtain the symbolical representation of the result given in Section I (p. 37) that, in four dimensions, an infinite number of planes can be drawn through an arbitrary point to meet three given lines of general position, and that these planes all meet three other lines.

Also of the result that, in five dimensions, an infinite number of planes can be drawn to meet four given lines of general position, and that these planes all meet six other lines.

Ex. 13. It has been seen that a plane meeting four lines, of general position, in four dimensions, can be drawn to meet two of these lines in assigned points (Section I, p. 37). Denote the four lines by a, b, c, d. Let the transversal of b, c, d meet b, c and d, respectively, in C, B' and P'; the transversal of c, a, d meet c, a, d respectively, in A, C' and Q'; and the transversal of a, b, d meet

a, b, d, respectively, in B, A' and R'. The points P', Q', R' are, thence, respectively, derivatives of B' and C, of C' and A, and of A' and B; they are however in syzygy among themselves, as being on the line d. This syzygy leads then to a syzygy connecting the symbols of A, A', B, B', C, C'; by a proper choice of the symbols this last syzygy may be taken to be $A+A'+B+B'+C+C'=0$, any five of these points remaining independent, and sufficient to determine the fourfold space. Hence the symbol of P', a derivative of B' and C, may be taken to be $P'=B'+C$, with, similarly, $Q'=C'+A$, and $R'=A'+B$. The line a is determined by the points B and C', the line b by the points C and A', and the line c by the points A and B'.

If then we take the plane containing the three points

$$B+\rho C', \quad C+\sigma A', \quad A+\rho^{-1}\sigma^{-1}B',$$

we see, because

$$B+\rho C'+\sigma^{-1}(C+\sigma A')+\rho(A+\rho^{-1}\sigma^{-1}B')$$

is the same as

$$\sigma^{-1}(B'+C)+\rho(C'+A)+A'+B,$$

that this plane meets the line d. As ρ, σ may be taken arbitrarily we thus have the general plane meeting the four lines a, b, c and d, spoken of at starting.

With the four given lines is associated another line; it is that, namely, which contains the three points whose symbols are $A+A'$, $B+B'$, $C+C'$, these being in syzygy in virtue of the syzygy connecting the six points A, A', B, B', C, C'. This line may be defined geometrically; if a' be the common transversal of b, c, d; b' of c, a, d; c' of a, b, d and d' of a, b, c, it is the intersection of the four threefolds $\{a, a'\}$, $\{b, b'\}$, $\{c, c'\}$, $\{d, d'\}$, which meet in a line. For brevity we omit the geometrical proof of this, which will arise later; it is independent of Pappus' theorem.

But now we remark that

$$\rho^{-1}(B+\rho C')+C+\sigma A'+\sigma(A+\rho^{-1}\sigma^{-1}B')$$

is the same as

$$\sigma(A+A')+\rho^{-1}B+\sigma\rho^{-1}\sigma^{-1}B'+C+C'.$$

The point of which this is the symbol will lie on the line containing the three points $A+A'$, $B+B'$, $C+C'$, only if $\rho^{-1}=\sigma\rho^{-1}\sigma^{-1}$, or $\rho\sigma=\sigma\rho$. Hence we forecast a geometrical theorem: *If, and only if, Pappus' theorem be assumed, all planes meeting four lines of general position in four dimensions are met by another line.*

A proof of this theorem, apart from the symbolism, will be given later (in Volume IV).

Ex. 14. Finally we make a brief remark in regard to von Staudt's introduction of numbers in Geometry. This depends (*Beiträge zur*

Geometrie der Lage, Zweites Heft, No. 256, p. 166) upon considering two sets of four points, on two different lines, each set taken in a definite order, as being equivalent, when they are in perspective with one another. In effect such a set of four points, (or *Wurf*), is regarded as determining what we have called an algebraical symbol, and rules for the sum and product of two such symbols, or, in general, for computation with these symbols, are developed from geometrical theorems previously established on geometrical grounds.

It is impossible in a few words to make a comparison, between two methods of arranging the fundamental logical ideas, which shall not be open to objection. But it would seem that von Staudt's scheme, when approached from the point of view we have taken up, assumes Pappus' theorem in its initial definition. For, as will appear more fully below, for four points of a line which have, with the suppositions here made, the respective symbols A, B, $A+\lambda B$, $A+\mu B$, the symbol of von Staudt corresponding to one arrangement of these points, is effectively $\lambda\mu^{-1}$. We have shewn (p. 25 above) that these points can be placed in perspective with the points B, A, $A+\mu B$, $A+\lambda B$; in accordance with our conventions these last may equally be written $B, A, B+\mu^{-1}A, B+\lambda^{-1}A$. The symbol associated with these four, by the rule suggested, would be $\mu^{-1}\lambda$. The equivalence of the symbols $\lambda\mu^{-1}$ and $\mu^{-1}\lambda$ involves however $\mu\lambda=\lambda\mu$. We have shewn that, unless λ, μ be iterative symbols, that is (p. 86 above) unless the points $A+\lambda B$, $A+\mu B$ are limited to such as are obtainable, from the points A, B and another point of the line taken to be $A+B$, by a finite number of harmonic constructions, the equation $\mu\lambda=\lambda\mu$ in general requires Pappus' theorem.

It is very interesting however to notice that von Staudt recognises the possibility that the symbols which he introduces may not be commutative in multiplication. He gives a proof that the set of four points by which he defines the product of two of his symbols, each defined by a set of four points, is independent of the order in which these two sets are taken (*loc. cit.*, § 20, No. 268, p. 171).

The relation of Pappus' theorem with commutativity of multiplication, under certain hypotheses, is considered by F. Schur, *Analy. Geom.*, *Introd.*, 1898, and by Hilbert, *Grundlagen der Geometrie*, 1899, § 31, p. 71.

CHAPTER II

REAL GEOMETRY

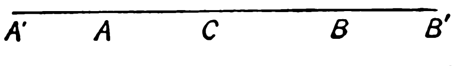
SECTION I. THE PROPOSITIONS OF INCIDENCE. INTRODUCTION OF A PLANE, AND OF A SPACE

Preliminary remarks. The point of view to which we have sought to guide the reader by the preceding discussion is that which we finally adopt as basis of the theory; it appears to possess a simplicity which justifies its being taken first. But it is general, and therefore abstract; as, for instance, in its use of the word *line* in such a sense that every two lines of a plane intersect one another. And it may appear to be artificial; as, for instance, in its adoption of Pappus' theorem. Moreover, it gives no recognition to at least two notions which are, probably, inseparable from any conception of space founded directly on experience. One of these notions is, that space consists of a limited part which is *accessible*, surrounded by an unlimited part which is inaccessible. The other notion, intimately connected with the former, is, that, when a point is given upon a line, there is thereby effected a distinction, between the points of the line on one side of the given point, and those on the other; or, when a line is given in a given plane, there is thereby effected a distinction between the points of the plane, according as they lie on one side, or the other, of the given line; or, when a plane is given in space, a similar separation is thereby made. This notion, applied to the points of a line, leads to the further notion, of the *order* of a set of points on the line. It will be found that the development of this notion of order suggests a view of what points are possible upon a line which, if it were adopted, would make Pappus' theorem inevitable. Though we regard this view as, finally, inadequate, we follow the usual procedure, of allowing the suggestion of a simpler case to become a starting point of the theory of the more general case.

We proceed, then, to examine the fundamental conceptions in a more concrete way than has hitherto been done. Logically, this examination should precede the foregoing formulation; but it will readily be seen that the examination, in proportion as it is complete, is prolix. Moreover, it will appear that the real geometry, which is built up on the basis of this examination, may be regarded as included in the geometry so far dealt with.

Frankly recognising, now, the possibility of inaccessible points, we can assume no general proposition that every two lines in a plane intersect one another, or that any two planes intersect one another; and, requiring, now, that all constructions made shall utilise only accessible points, we need assumptions as to what points are accessible when others are known to be so. These we obtain, for points of a line, by recognising the separation effected by the assignment of a point of the line; this leads to the notion of the points of the line which are *between* two given points, all of which are regarded as being equally accessible. A similar notion dominates our recognition of the points of a plane which are to be regarded as accessible when three points are given as being so; and similarly for the points of (three dimensioned) space when four points are given.

Betweenness for points of a line. Segments. We assume that when two points, A and B, are given, there exists a point, C, which is *between* A and B; and then, also, a point, B', such that B is between A and B'; and also a point, A', such that A is between A' and B.



Thus, between C and B there exists a point, C'; and between A and C there exists a point, C_1.

We assume that the point, C', between C and B, is between A and B, and the point, C_1, between A and C, is equally between A and B. And we assume, conversely, that every point between A and B, not coinciding with C, is either between A and C or between C and B. Also that B is not between A and C, nor A between C and B. Thence it follows that the point C, not being between C' and B, is between A and C'; and C is, similarly, between C_1 and B.

There is then, for example, a point between C and C', and this point is between C and B, and, therefore, is between A and B. This argument can be continued. There is thus an infinite aggregate of points between A and B; and every point between A and B, not coinciding with C_1, or C, or C', is between A and C_1, or between C_1 and C, or between C and C', or between C' and B.

Again, as B is between A and B', and not between A and C, it is between C and B'. In this statement, C may be any point between A and B. Similarly the point A is between A' and any point which is between A and B.

It appears then, similarly, that there is an infinite aggregate of points B', and an infinite aggregate of points A'.

And, as B is between A and B', the point A is not between B and B'; thus a point A' cannot be the same as a point B'.

Any point, P, between A' and B', and not between A and B, if not coincident with A or with B, is then between A' and A or between B and B'. But there exist points which are not between A' and B', in infinite number, namely points, Q', such that B' is between A' and Q', and also points, P', such that A' is between P' and B'.

We regard the aggregate, of all the points spoken of, as being determined when the points A and B are given. We assume that the same aggregate is determined when any two points of this aggregate are the given points.

When the points A, B are given, and the point C is between them, and B' is a point such that B is between C and B', we say that the points $ACBB'$ are *in order*. If C' is a point between C and B, it is also between A and B, and B is between C' and B', as we have remarked. Thus $AC'BB'$ are in order. These orders are regarded as identical. Again C is between A and C', as we have said, and C' between C and B. Thus $ACC'B$ are in order. This order we again regard as identical with the former. Similarly, A' being, as before, a point such that A is between A' and C, the points $A'ACB$ are in order; and we regard this as identical with the preceding. In this order we then say that B is subsequent to, or follows A, or is superior to A; and that A is anterior to, or precedes B, or is inferior to B. And for greater clearness, we sometimes write this in the form $A < B$. Thus B' follows B, and A' precedes A. Similarly C' follows C, but precedes B.

The order described is determined by the points A, C, B. A similar account may be given of an order determined by the three points B, C, A; this we regard as inverse to the former, speaking of A as, in this order, *following* B, and of A' as following A, of B' as preceding B, and so on.

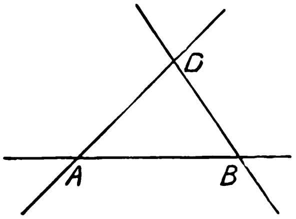
The aggregate of points C between A and B, together with A and B, we speak of as lying upon the *segment* AB, of which A, B are the end points. The complete aggregate of points determined by A and B, that is, of points C, and of points B' which follow B, and of points A' which precede A, we speak of as lying upon a *line*.

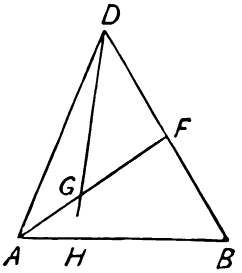
A more minute disentanglement of the ideas involved, than in the foregoing, may be found in the authorities quoted in the Bibliography at the end of this volume.

Points determined by three points. Intersections of lines determined therewith. We now suppose that, beside the points of the line determined by the points A, B, there is given a point D. Each of the three pairs of points, A and B, A and D, B and D, will then be the end points of a segment, and each of these three segments will be part of a line. The point A will not be on the line DB, nor B on DA.

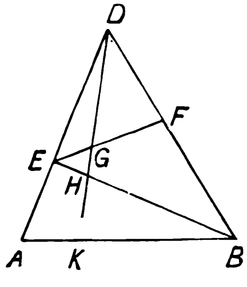
An important step in the argument is then the following: let F

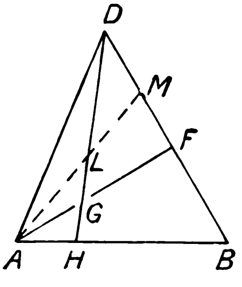
be a point of the segment DB, and G a point of the segment AF: we *assume that there is a point, H, of the segment AB, such that G is a point of the segment DH.* In particular when F is *between* D and B, and G is between A and F, then H is between A and B. For clearness of reference we may often refer to this assumption as Peano's axiom.





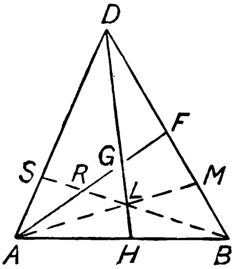
From this it follows that, if F be between D and B, and E be between D and A, and G be taken between E and F, then there is a point K between A and B such that G is between D and K. For, applying the axiom to D, E, B, we infer a point H, between E and B, such that G is between D and H; and then, considering D, A, B, from H, between E and B, we infer K, such that H is between D and K. Then as G is between D and H, it is also between D and K.



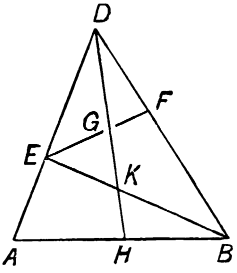


And it also follows that, if F be between D and B, and H be between A and B, there is a point G which is between A and F and is also between D and H. For, if L be a point between D and H, it follows, from the axiom, that there is a point, M, between D and B, such that L is between A and M. If M be at F we may take for G the point L. If M be not at F, it is between D and F, or between F and B. Suppose, first, that M is between D and F; then the existence of L between A and M, involves, by the axiom, the existence of a point G_1, between A and F, such that L is between D and G_1; and the existence of G_1 between A and F again involves a point H_1 between A and B, such that G_1 is between D and H_1. Then L, between D and G_1, is between D and H_1. But L

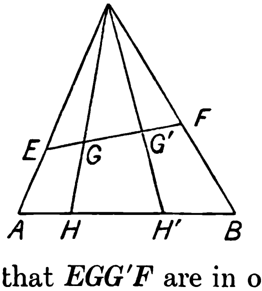
is also between D and H. Thus either H and H_1 coincide, or there is a line determined by H and H_1 which contains both L and D; in the latter case D would be on the line AB. Therefore H_1 coincides with H, and thence G_1, between D and H, and between A and F, is the point G required. Next, suppose that M is between F and B; then, considering A, B, F, the point L, between A and M, involves, as before, a point R, between A and F, such that L is between B and R; and, considering D, A, B, the point R, between A and F, involves S, between A and D, such that R is between B and S; while, as L is between B and R, the point R cannot be between L and B, nor coincide with L, and is between S and L. Then, from A, L, D, the point R, between S and L, involves a point G_1, between D and L, with R between A and G_1. However, R was between A and F. Thus, considering the line determined by A and R, if we assume that G_1 is between A and F, as it is between D and L and therefore between D and H, it is such a point G as was required. And, indeed, considering D, A, M, the point G_1, between D and L, involves a point, F_1, between D and M, such that G_1 is between A and F_1; then F and F_1 are both on the line AR, and, as A is not on the line DB, the point F_1 coincides with F, and so G_1 is between A and F.



Whence, further, if E be between D and A, and F be between D and B, and H be between A and B, there is a point G between E and F which is also between D and H. For, from D, A, B, there follows K, between E and B and between D and H. And then, from D, E, B, from K, between E and B, and F, between D and B, there follows G, between D and K and between E and F. And this G, between D and K, is between D and H.

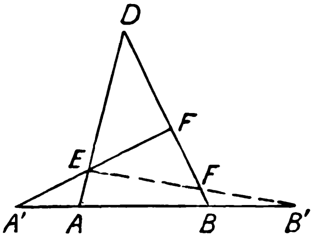


Also, still with E given between D and A, and F given between D and B, if G, G' be between E and F, with G between E and G' and G' between G and F, so that $EGG'F$ are in order, and if H, H' be between A and B such that G is between D and H and G' is between D and H', then also the points $AHH'B$ are in order. For, from D, A, H', as G is between E and G', so also is H between A and H'; while, similarly, from DHB, the point H' is between H and B. And conversely, given $AHH'B$ in order, we can infer that $EGG'F$ are in order.

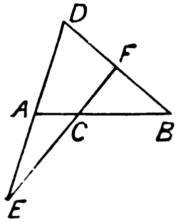


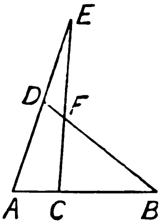
The statement that when H is between A and B then G is between D and H is the same as that, unless E be at A or F be at B, there is no point of the segment EF which is also a point of the segment AB. Consider now, taking E on the line DA, and F on the line DB, the question whether there are points of the *line* EF which are also points of the *line* AB.

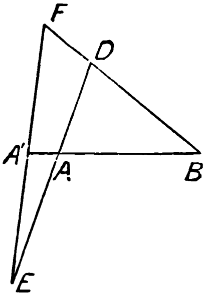
If a point A' be such that A is between A' and B, it follows, by Peano's axiom, considering D, A', B, that, when E is between D and A, there is F, between D and B, such that E is between A' and F; and, also, from what we have seen, if B' be such that B is between A and B', there is an F', between E and B', which is between D and B. Thus, when E, F are, respectively, between D and A and between D and B, while there is no point of the segment EF which is a point of the segment AB, there *may* be a point, A', or B', of the *line* AB which is a point of the *line* EF.

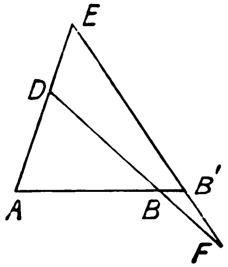


We may examine the various combinations of the possible positions of E on the line DA, with those of F on DB, putting together those in which such a common point of the two lines AB, EF necessarily follows from Peano's axiom, and then those for which this does not follow. There are evidently nine possible combinations.



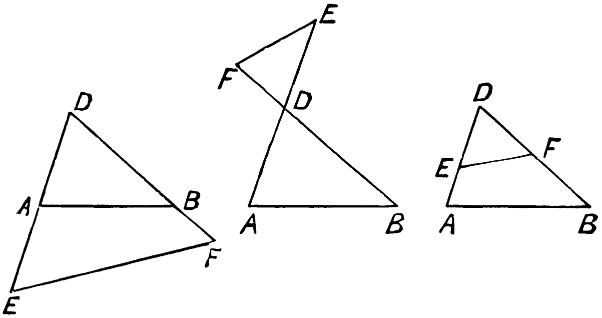






When F is between D and B and E not between D and A, whether A be between D and E, or D be between A and E, there is necessarily a point, C, of the line EF which is a point between A and B. And similarly when E is between D and A. This accounts for four combinations. When F is not between D and B, it may be such that D is between F and B; then if E be such that A is between E and D, there is a point A' between E and F such that A is between A' and B; while, if F be such that B is between D and F, and E be such that D is between A and E, there is a point B'

between E and F such that B is between A and B'. This accounts for two other combinations. For the three remaining combinations no common point of the two lines is certain, the last of these being the case considered above. In these three cases, E, F are either both interior points of the segments DA, DB, or neither is an interior point. In none of these three cases can there be a common point of the segments AB and EF, as we easily prove from the axiom.



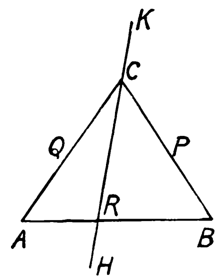
In any case, the *total number of points of the line EF which lie within one of the three segments AB, DA, DB, is zero or two.*

Example. If E, F be points such that D is between A and E, and D is between B and F, and G be any point between E and F, prove that there is a point C between A and B such that D is between C and G.

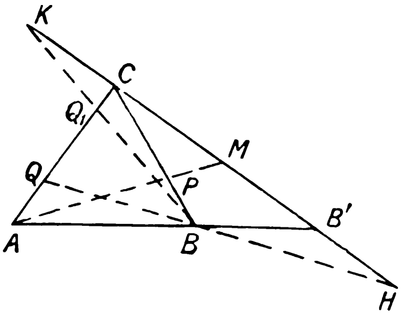
Considering E, F, B, there follows a point, L, of DE, between B and G, and, then, considering A, B, G, there follows C.

Points of a plane system. Let A, B, C be three given points, not belonging to one line. A line is determined by the point A and any point, P, of the *segment* BC; so, a line is determined by the point B and any point, Q, of the segment CA, and a line is determined by the point C and any point, R, of the segment AB. The system of points lying upon the aggregate of all such lines, of the three kinds, is called a plane system, and the points are said to lie in a plane. All points of the lines BC, CA, AB belong to this system. The system contains points lying upon a line of all the three kinds, AP, BQ and CR; but, also, it contains points lying upon a line of one kind only.

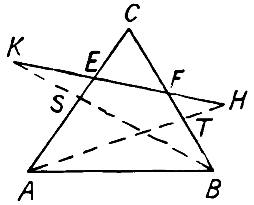
Consider a line of the kind CR, R being between A and B, and, thereon, points, H and K, such that R is between H and C, and C is between R and K. A point between C and R is equally upon a line AP, and upon a line BQ, by what we have shewn; and, therefore, neither H nor K is upon



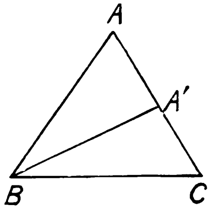
a line of the kind AP or the kind BQ. If B' be a point of the line AB such that B is between A and B', a point, M, between C and B' is on a line AP; a point, H, such that B' is between C and H, is upon a line BQ, as also is a point, K, such that C is between K and B'. A similar remark can be made, starting from a point A' such that A is between A' and B. The plane system thus contains the points of all lines determined by C and a point of the *line* AB; but to say that the system consisted only of such points would be to assume that every line, in the plane, drawn through C, had a point of intersection with the line AB.



Let E be a point between C and A, and F a point between C and B; and let H, K be points of the line EF, the point F being between E and H and the point E between K and F. It is clear from what has been said that a point of this line between E and F lies on a line CR, where R is between A and B. Consider C, A, H; as E is between C and A, and F is between E and H, there is a point, T, between A and H, such that F is between C and T; thus H lies on a line through A containing a point of the line CB. We remarked that the plane system contains all points of a line determined by C and a point of the line AB. By similar reasoning it contains all points of a line determined by A and a point of the line CB. Thus H is a point of the system. Again consider C, K, B; as F is between C and B, and E is between K and F, there is a point, S, between K and B, such that E is between C and S; thus K lies on a line through B containing a point of the line CA. It is thus shewn that every point of the line EF belongs to the plane system. Therefore a line, containing points of any two of the segments BC, CA, AB, belongs to the plane.



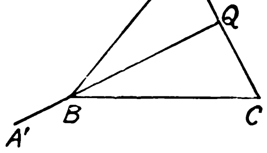
Now let A', B', C' be any three points of the plane system not lying on one line. We shew that these may be used, instead of A, B, C, to determine the plane system. For this it is sufficient to prove that if H be a point such that at least one of the three possibilities, that the line HA' contains a point of the segment $B'C'$, or the line HB' contains a point of the segment $C'A'$, or the line HC' contains a point of the segment $A'B'$, is a fact, then at least one of the corresponding possibilities, for H in regard to A, B, C, is also a fact, and to prove that the converse is also true. This proof will follow if we shew that, when A' is any point of the plane system (A, B, C), the plane systems, (A', B, C) and (A, B, C), are the same.

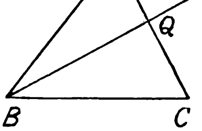


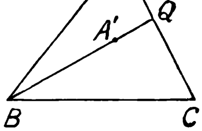
First, if A' be between A and C, then a point, H, for which the line HA' contains a point between B and C, is on a line containing points of two of the segments AC, CB, BA; so that such point H belongs to the plane system (A, B, C), by what was proved above. The same follows if the line HA' contains B, or C. If the line HB contains a point of the segment $A'C$, it contains a point of the segment AC; and if the line HC contains a point of the segment BA', it contains a point of the segment AB; in either case it belongs to the plane system (A, B, C). Conversely, if the line HA contains a point of the segment BC, other than B, it contains a point of the segment BA', and so belongs to the plane system (A', B, C), by what was proved above; and the same follows when H is on the line AB. Again, if the line HB contains a point of the segment CA, it contains a point of the line CA', and belongs to the system (A', B, C); while, if the line HC contains a point of the segment AB, it contains a point of the segment $A'B$, and then, also, belongs to (A', B, C). A point between any two of the points A, B, C may then be used instead of either of these to determine the plane system. The plane systems so obtained are the same. But from this it follows that any one of the points, A, may be replaced by any point except B and C on either of the *lines*, AB, AC, containing this point.

Next, let A' be any point of the plane system (A, B, C), not lying on the line BC: then, either

(*a*) the line BA' contains a point of the segment CA, say the

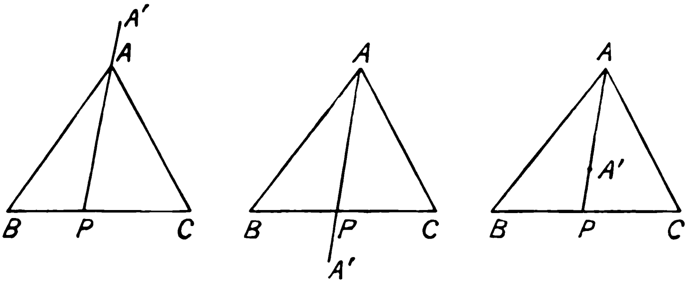






point Q; then the plane system (A', B, C) is the same as (Q, B, C) —each being the same as (Q, A', C)—and (Q, B, C) is the same as (A, B, C), or

(*b*) the line CA' contains a point of the segment BA, in which case a similar argument shews that the systems, (A', B, C), (A, B, C), are the same, or, lastly, (*c*) the line AA' contains a point of the segment BC, say the



point P; then the system (A', B, C) is the same as (A', B, P), and this as (A, B, P), and this as (A, B, C).

It is thus established, whatever be the point A' of the plane system (A, B, C), not lying on the line BC, that the system (A', B, C) is the same as (A, B, C). Hence it is easy to deduce that the system (A, B, C) may be defined from any three points (A', B', C') of itself which are not in line.

An incidental consequence is that all the points of the line determined by any two points of a plane system lie also in the system.

Separation of the points of a plane effected by a line therein. Let us say that two points of a plane system belong to the same class when the segment of which they are the end points contains no point of a certain line lying in the plane, but that two points belong to different classes in the contrary case. Then the results we have developed shew that every point of the plane belongs to one of two classes, save that the points of the chosen line are exceptional. For let A, B be any two chosen points of different class, the segment AB containing a point of the line; let C be any other point of the system not lying on the chosen line: we have shewn that, of points of the three segments AB, BC, AC, there are two or none lying on a line of the plane: the chosen line therefore contains a point of the segment AC, or a point of the segment BC. The point C thus belongs either to the same class as A or to the same class as B. Moreover, in this description, A may be replaced by any point of its own class, and B by any point of its class. For if A' and C be of the same class as A, the line not containing a point of either segment AA' or AC, then the line does not contain a point of the segment $A'C$, and C belongs to the same class as A'. Similarly if B' be of the same class as B, but C of a different class from B, then C, B' are of different class.

As soon as we are in a position to shew that we can do so in a self-consistent manner, we shall discard the distinction between the accessible and the inaccessible points of a plane, upon which our theory at present rests; and then the separation of the points of a plane, effected by a line, will disappear, unless reintroduced by a convention as to which points are to be regarded as accessible. But for the present this separation is most important. If it were introduced at the start, as an axiom, and three lines were taken in the plane, not having a common point; and the two classes of points of the plane with reference to one line were denoted, say, by α and α', the two classes with reference to another of these lines by β and β', and the two classes with reference to the remaining line by γ and γ', then the points of the plane, not lying on any of the lines, would be each of one of seven categories (α, β, γ), (α', β, γ), (α, β', γ), (α, β, γ'), $(\alpha, \beta', \gamma')$, $(\alpha', \beta, \gamma')$, $(\alpha', \beta', \gamma)$. Peano's axiom would then arise in a very natural way.

Example. Given two lines, AB, AC, with a common point, A, it may be proposed to define a plane system as the aggregate of points through which a line can be drawn having a point, other than A, common with each of the two given lines. Examine whether this system is coextensive with that, adopted above, defined by the points A, B, C.

Space systems, defined by four points not lying in a plane. As a preliminary remark, before proceeding to a formal definition, suppose that we have a system of points, not lying in a plane, of such character and multiplicity that it contains an infinite number of plane systems, while those of the system not lying on a specified plane are, by means of this plane, divided into two classes. Then, if A, B, C, D be four points of the system not lying in a plane, the plane determined by A, B, C distinguishes two classes, say δ and δ'; similarly the plane BCD distinguishes two classes, α and α'; the plane CAD two classes, β and β'; and the plane ABD two classes, γ and γ'. The points of the system are then, by these four planes, distinguished into $2^4 - 1$, or fifteen, categories, such as $(\alpha, \beta, \gamma, \delta)$, or $(\alpha', \beta, \gamma, \delta)$, etc., exception made of points on one of the four planes. Suppose further that two points of the system are of the same class, with respect to one of the planes, or of different class, according as the segment of which these are the end points does not, or does, contain a point of this plane, it being understood that, with reference to the plane ABC, the point D is of class δ, while A is of class α with reference to the plane BCD, and B of class β with reference to the plane CAD, and similarly for C. Then, if a point of the system, P, be of the category $(\alpha, \beta, \gamma, \delta')$, the segment PD, whose end points are respectively of classes δ' and δ, contains a point of the plane ABC; this will, however, be of category (α, β, γ) with reference to the other three planes, this being so both for P and D. A point P of the category $(\alpha, \beta, \gamma, \delta')$ may therefore be said to be such that the line PD contains a point of the *face* ABC; this statement is then equally true for a point of the category (α', β', γ', δ). But if a point, P, be of either of the categories (α, β', γ', δ) or (α', β, γ, δ'), then a line can be drawn through P to contain both a point of the segment BC and a point of the segment AD. And similarly in other cases. We therefore say:

Let A, B, C, D be four points not lying in a plane; let the points, Q, of the plane ABC which are such that, simultaneously, the line AQ contains a point of the segment BC, the line BQ contains a point of the segment CA and the line CQ contains a point of the segment AB, be said to belong to the *face* ABC; with a similar definition of the faces BCD, CAD, ABD. Then a (threefold) space system, or, briefly, a space, is the aggregate of all possible points, P, which are such that, either the line PD contains a point of the *face* ABC, or the line PA of the face BCD, or PB of CAD, or PC of ABD, or all of these, together with points, P, such that a line is possible containing P which contains a point of each of the segments BC and AD, or a line, containing P, which contains a point of each of the segments CA and BD, or a line, containing P, which contains a point of each of the segments AB and CD. To this space belong all the points of the four planes ABC, BCD, CAD, ABD.

In a manner analogous to that employed for plane systems it can then be deduced

(*a*) That, if A', B', C', D' be any four points of the space system which do not lie in a plane, the system can equally be determined by these. In particular the points of the line determined by any two points of the system, or the points of the plane determined by any three points of the system not lying in line, all belong to the space system.

(*b*) That, when a plane of the space is given, the points of the space system are divided into two classes, two points, E, F, being of the same or of different classes, according as there is no point of the segment EF, or there is a point, which belongs to the plane.

(*c*) That any two planes of the space which have a point in common have all the points of a line in common.

(*d*) That, if P, Q, R be three points of the space system which are not in line, there are none, or two, points of any plane, belonging to the space, which are points of the segments QR, RP, PQ.

Of these, (*a*) is proved by first proving that D can be replaced by any point on any of the lines DA, DB, DC, and continuing this process; then (*b*), from the definition of the space system, is seen to be true for any one of the planes ABC, BCD, CAD, ABD; after (*a*) it is then true for any plane. For (*c*), if α, β denote the two planes, and O their common point, take two points P, P' in the plane α such that O is between them. As O belongs to the plane β, the points P, P' are of different class with respect to β. Now let

Q be another point of the plane α, not lying on β; of the two points P, P', let P be that one which is of the same class as Q with respect to the plane β, so that P', Q are of different class. The segment $P'Q$ thus contains a point of the plane β, say O'; this point, lying on the segment $P'Q$, is also on the plane α. Thus both the planes contain the two points O and O', and the line determined by these is, therefore, common to the two planes. The statement (d) then follows by remarking that, in virtue of (c), if a plane contain a point of one of the segments QR, RP, PQ, it meets the plane PQR in a line. For we have shewn that in a plane (PQR) a line contains none, or two, points of the segments QR, RP, PQ.

Extension to fourfold and higher space. If now it be allowed that five points A, B, C, D, E can exist, of which A, B, C, D are not in a plane, such that E does not belong to the threefold space system determined by A, B, C, D, we can regard these five points as determining a fourfold space, specifying, in a manner analogous to that followed above for twofold and for threefold space, what points are to be regarded as belonging thereto. Such a space will contain lines, and planes, and also threefold space systems. It will not be true, in such a fourfold system, to take one illustrative example, that two planes which have one point in common, necessarily have in common the points of a line; for it will now be by a threefold space, and not by a plane, that the points of the fourfold system are separated into two classes. But a similar proof to that followed above will shew that two threefold spaces of the fourfold system which have a point in common, have also a plane in common; let α, β denote the threefold spaces, O the assumed common point, and P, P' two points of α having O between them; as before a point Q is possible in α such that the segment QP' contains a point, O', of β which also lies in α, so that the line OO' is common to α and β. But now, beside Q, a point R is possible, in α, which does not lie in the plane QPO; and this gives a further point, O'', common to α and β, which does not belong to the line OO'. The points O, O', O'' determine a plane common to α and β.

We regard such a fourfold space, or spaces of higher multiplicity, as entirely possible; and experience has shewn the great usefulness and interest of taking them into consideration. It seems, however, unnecessary, at this stage, to enter into further detail.

SECTION II. THE GENERALISATION OF THE REAL GEOMETRY BY THE INTRODUCTION OF POSTULATED POINTS

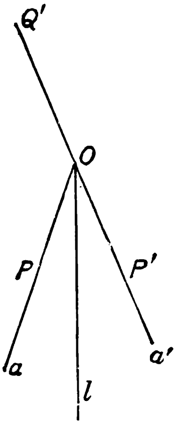
Purpose of the Section. In comparison with the geometry of Chapter I, the Real Geometry we have dealt with in the preceding Section is inconvenient to apply, owing to such circumstances as that two lines in a plane may not have a common point, and two planes in a threefold space may not have a common line. The common point of two lines, in Chapter I, is, however, only of use because, as a point, it can serve as one of two points determining a line; in other words, the proposition of Chapter I is that, if two lines be given in a plane, there is thereby determined through an arbitrary point which does not lie on either of them, a definite line having no common point with either of them, save perhaps where they have a common point. Now, in this form, the proposition is equally true for the Real Geometry. When this is made clear it will be convenient to speak of the two given lines as having in common a so-called *postulated point*, leaving open the question whether this point is accessible or not. Similar remarks apply to the other cases in which the Real Geometry appears incomplete in comparison with that dealt with in Chapter I. The result of the whole examination now to be made is that, we may regard the space of the Real Geometry as part of a space in which the Propositions of Incidence formulated in Chapter I are completely valid, provided that postulated points, lines and planes are allowed an existence, whether they be accessible or not.

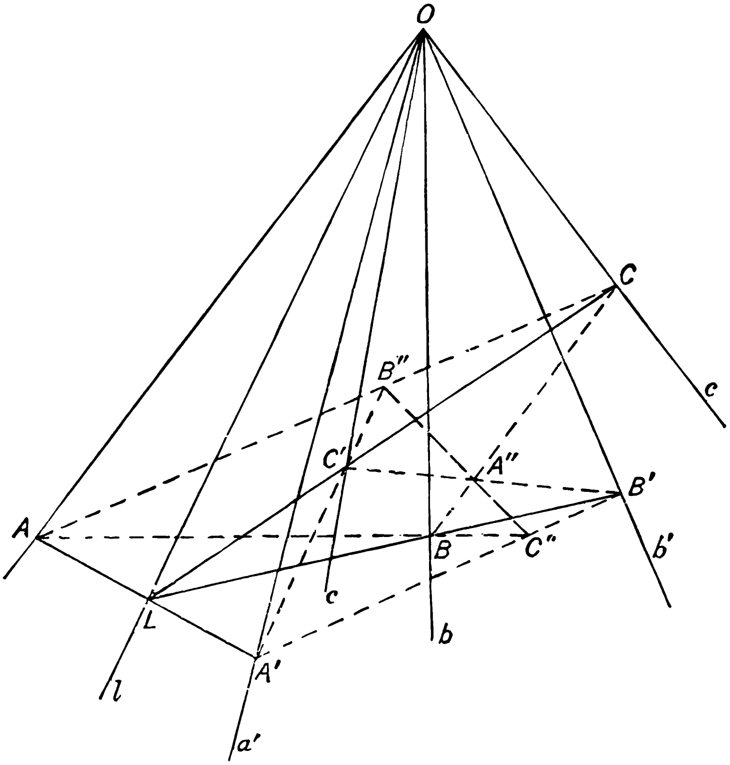
Extended form of Desargues' Theorem, for lines and planes having a common point. Let O be a point, and a, b, c, a', b', c' be six lines passing through this point, no three of which lie in a plane. The pairs, a, a', and b, b', and c, c', of these lines, will determine three planes containing the point O; any two of these planes will, therefore, have a line in common, passing through O. Suppose the three lines so arising coincide with one another, so that the three planes all contain one line, l, passing through O. Consider six other planes determined by the given lines, of which two are the planes containing respectively the pairs b and c, and b' and c'; these two planes, which we may respectively call $[b, c]$ and $[b', c']$, meet in a line through O. There are then two other lines through O, given, respectively, by the planes $[c, a]$, $[c', a']$ and $[a, b]$, $[a', b']$. With the hypothesis made, that the three planes $[a, a']$, $[b, b']$, $[c, c']$ have a line, l, in common, we prove that the three lines which are the intersections of the respective pairs of planes

$$[b, c], [b', c']; \quad [c, a], [c', a']; \quad [a, b], [a', b'],$$

lie in one plane. This plane will pass through O.

To prove this, remark, first, that if three lines a, a', l in a plane have a point O in common, and points P', Q' be taken on a' so that O is between P' and Q', the line l must have a point in common either with PP' or PQ'. For, as we saw in Section I, the line l has none or two points, in all, lying on the segments PP', $P'Q'$, $Q'P$; and it has the point O on the segment $P'Q'$. It is thus possible to take P' and P (or Q' and P), respectively on a' and a, so as to lie on opposite sides of the line l.





It follows that, in our figure, points A, A' can be taken, respectively on the lines a and a', such that there is a point, L, of the line l, lying between them. By a similar argument, a point, C, can be taken, on the line c, so that there is a point, C', of the line c', lying between L and C. Then it follows, from Peano's axiom, that, in the plane $AA'C$, there is a point, B'', lying between A and C, such that C' is between A' and B''. Again, a point, B', can be taken, on the line b', so that there is a point, B, of the line b, lying between L and B'; then it follows, from Peano's axiom, that, in the plane $AB'A'$, there is a point, C'', between A' and B', such that B is between A and C''. It follows further, by the axiom, that, in the plane CLB', there is a point, A'', which is between C' and B' and also between C and B.

It is at once seen that the points A'', B'', C'' are upon the plane ABC and upon the plane $A'B'C'$. Thus A'', B'', C'' are in line. But the line OA'' is the line of intersection of the planes $[b, c]$ and $[b', c']$; similarly OB'' is the line of intersection of the planes $[c, a]$ and $[c', a']$, and OC'' is the line of intersection of the planes $[a, b]$ and $[a', b']$. These three lines of intersection are therefore in one plane; as we desired to prove.

Consider now the converse proposition. As before consider six lines a, b, c, a', b', c', passing through the point O, of which no three are in one plane; suppose that the lines of intersection of the respective pairs of planes, $[b, c]$ and $[b', c']$, $[c, a]$ and $[c', a']$, $[a, b]$ and $[a', b']$, are in one plane. It can be shewn that the planes $[a, a']$, $[b, b']$, $[c, c']$ have a line in common.

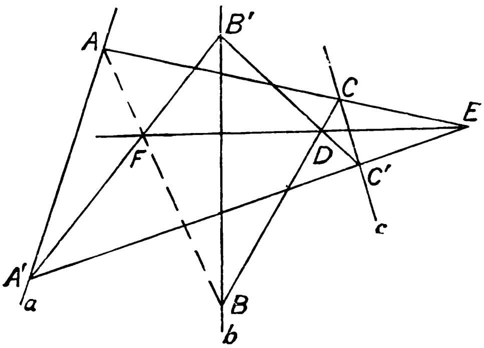
For, let the planes $[a, a']$, $[b, b']$, which meet in O, meet in the line l. Let the line of intersection of the plane $[l, c]$ with the plane $[a', c']$ be the line c_1, passing through O; so that the planes $[a, a']$, $[b, b']$, $[c, c_1]$ have the line l in common. Then, by the preceding, it follows that the lines of intersection of the three pairs of planes $[b, c]$ and $[b', c_1]$, $[c, a]$ and $[c_1, a']$, $[a, b]$ and $[a', b']$, lie in one plane. By construction, however, the plane $[c_1, a']$ is the same as the plane $[c', a']$; thus, of the three lines which are in one plane, two are the intersections, respectively, of $[c, a]$ and $[c', a']$ and of $[a, b]$ and $[a', b']$; and it was to be supposed that the plane of these contains the line of intersection of the planes $[b, c]$ and $[b', c']$. The line of intersection of the plane of these, with the plane $[b, c]$, thus lies in both the planes $[b', c_1]$ and $[b', c']$; and, therefore, these last planes, both containing the line b', coincide with one another. Wherefore the lines c_1, c' are the same, or the plane containing them contains the line b'. By construction, however, the plane of c_1 and c' contains the line a'; and, it was assumed that the lines a', b', c' are not in one plane. Thus it follows that the lines c_1 and c' coincide; and, therefore, the planes $[a, a']$, $[b, b']$, $[c, c']$ meet in a line, as was to be proved.

For the proposition here given, and its application, we may refer to Reyes-y-Prosper, "Sur les propriétés graphiques des figures centriques," *Math. Annal.* XXXII, 1888, 157; Pasch, *Math. Annal.* XXXII, 1888, 159; F. Schur, *Grundlagen der Geometrie*, 1909, § 2.

Fundamental theorem in regard to the correspondence of the lines and planes of two central figures, or stars. A figure consisting of lines and planes passing through a point, such as that considered above, may be called a *central figure*, or a *star*; the point itself being called the centre. Suppose now we have two centres, O_1 and O_2. Let α be a plane, not passing through O_1 or O_2.

To every line through the point O_1 which has a point in common with the plane α, we can evidently make correspond a line through the point O_2, namely that which meets the plane α in the same point as does the former; and either of these lines determines the other. To establish such a correspondence it is not necessary, however, to assume an actual, or accessible, intersection of the former line with the plane α. We can shew that, *to every line through the centre* O_1, *there corresponds a definite line through the centre* O_2, *and conversely, without utilising an actual, or accessible, point common to the plane* α *and the lines. And this in such a way that to three lines through* O_1 *which lie in a plane, there shall correspond three lines through* O_2 *which also lie in a plane—these planes coinciding when the former plane, through* O_1, *passes through* O_2.

First consider the statement in regard to single lines through O_1 and O_2. Let l_1 be any line through O_1; we make no use of any intersection it may have with the plane α. Upon the plane α take three arbitrary points; through the line l_1 pass three planes, each containing one of these points; any one of these planes, having a point common with the plane α, will have a line of intersection with it. Denote these lines by a, b, c, respectively. If the line l_1 has an actual point of intersection with the plane α, each of the lines a, b, c will pass through this point; conversely a point, common to two of the lines a, b, c, lies upon two planes passing through the line l_1, and therefore lies upon l_1, as well as upon the plane α. Thus, to refrain from using any possible intersection of the line l_1 with the plane α, we must avoid the assumption of an accessible intersection of any two of the lines a, b, c. On the line a, take two arbitrary points, A and A'. By what has been seen above in regard to the separation of the points of a plane effected by a line of that plane, it is possible to take a point, E, of the plane α, such that each of the segments EA and EA' contains a point of the line c. Say these points are, respectively, C and C'. On the line b take an arbitrary point, B; it is then possible to take a further point, B', upon the line b, such that there is a point, D, of the segment BC lying between B' and C'. Then, considering the points A', C', B', we see that there is a point F between A' and B', such that D is between F and E.



We can now prove, by the theorem of the foregoing article, that the points A, F, B are in line. For, let the lines joining the point O_1, respectively to the points A, B, C, A', B', C', be called $a_1, b_1, c_1, a_1', b_1', c_1'$; so that the planes $[a_1, a_1']$, $[b_1, b_1']$, $[c_1, c_1']$ are, respectively, the planes through O_1 containing the lines a, b, c. By construction these planes have a line in common, the line l_1. Therefore, by the theorem referred to, the lines of intersection of the three pairs of planes

$$[b_1, c_1] \text{ and } [b_1', c_1'],\quad [c_1, a_1] \text{ and } [c_1', a_1'],\quad [a_1, b_1] \text{ and } [a_1', b_1']$$

lie all in one plane; of these lines, however, the two former are respectively the lines O_1D and O_1E; and the last line meets the plane α in a point lying upon both the lines AB and $A'B'$. Thus the point F must lie on the line AB.

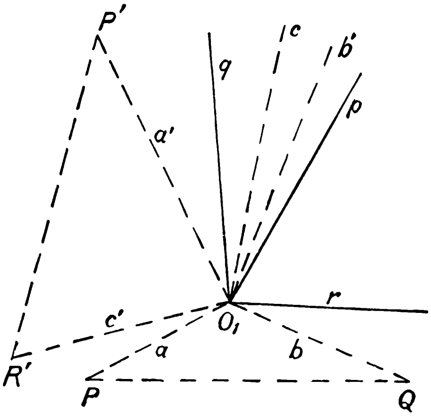
By the converse part of the theorem of the foregoing article, we can thence infer that the planes through O_2 which contain, respectively, the lines a, b, c, also meet in a line, which we shall call l_2. For, if the lines joining the point O_2 to the points A, B, C, A', B', C' be, respectively, called $a_2, b_2, c_2, a_2', b_2', c_2'$, it follows from the fact that the lines which are the intersections of the three pairs of planes

$$[b_2, c_2] \text{ and } [b_2', c_2'],\quad [c_2, a_2] \text{ and } [c_2', a_2'],\quad [a_2, b_2] \text{ and } [a_2', b_2'],$$

lie in a plane, namely the plane through O_2 which contains the line DEF, that the three planes $[a_2, a_2']$, $[b_2, b_2']$, $[c_2, c_2']$ meet in a line. These are the planes joining O_2 respectively to the lines a, b, c.

It is thus proved that, given the points O_1 and O_2, and a plane α not containing O_1 or O_2, if any line l_1 be drawn through O_1, and, through this, be taken three planes intersecting the plane α respectively in the actual lines a, b, c, then the planes through O_2 containing these lines a, b, c have in common another line, l_2, which will pass through O_2. There is thus determined a line through O_2 corresponding to any given line passing through O_1; and, if the line through O_2 be given, that through O_1 is determined by the same construction. The lines a, b, c were determined by planes containing l_1, drawn, respectively, through three arbitrarily taken points of the plane α; it is easy to see that the line l_2 is the same whatever these points may be. For, if two of these points remain the same, say those which lead to the lines b and c, the third may vary; the line l_2 will still be determined by the intersection of the planes joining O_2 to the lines b and c. By varying, thus, one point at a time, all can be varied. The construction given has not used any intersection of the plane α with the line l_1; when such a point is given the line l_2 is that joining O_2 to this point.

Next consider three lines, passing through O_1, which lie on a plane; we desire to prove that the lines through O_2, corresponding to these respectively, by the above rule, also lie in a plane. Let the given lines through O_1 be p, q, r. Take a point P of the plane α; the plane, Pr, containing the line r and the point P of the plane α, will meet α in a line; let Q be a point of this line other than P. Let the lines O_1P and O_1Q be called, respectively, a and b. The planes Pq and Qp, that is the planes joining the points P and Q respectively to the lines q and p, have the point O_1 in common; they therefore have a line in common, which we call c. Similarly, take another point P' of the plane α, and then, in the line in which the plane $P'q$ meets the plane α, take another point R'; denote the lines O_1P' and O_1R', respectively, by a' and c', and denote the line of intersection of the planes $P'r$ and $R'p$ by b'. Then



(a) the plane Qp contains the lines p, b and c; the plane $R'p$ contains the lines p, b' and c'; thus the planes $[b, c]$ and $[b', c']$ meet in the line p;

(b) the plane Pq contains the lines q, c and a; the plane containing q and $P'R'$ contains the lines q, c' and a'; thus the planes $[c, a]$ and $[c', a']$ meet in the line q;

(c) the plane $P'r$ contains the lines r, a' and b'; the plane containing r and PQ contains the lines r, a and b; thus the planes $[a, b]$ and $[a', b']$ meet in the line r.

It was said, however, that the lines p, q, r are in one plane. Thus, by the theorem of the last section, we are able to infer that the planes $[a, a']$, $[b, b']$, $[c, c']$ have a line in common. Call this line l_1. Further these planes have each a line common with the plane α, having, respectively, thereon, the point P (upon a), the point Q (on b) and the point R' (on c'). Whence, by what has immediately preceded, the planes joining the point O_2, respectively to these lines of the plane α, have also a line in common, say l_2. And, also, to the six lines a, b, c, a', b', c' through O_1, will correspond, respectively, lines through O_2, say a_2, b_2, c_2, a_2', b_2', c_2', there being through O_2, corresponding to the planes $[a, a']$, $[b, b']$, $[c, c']$, the planes $[a_2, a_2']$, $[b_2, b_2']$, $[c_2, c_2']$. As these meet in a line, l_2, the lines of intersection of the three pairs of planes

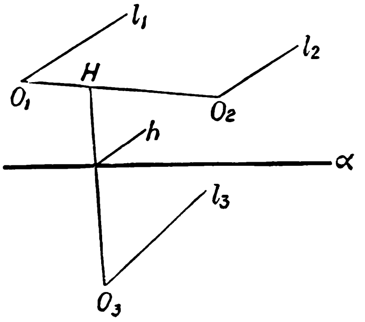
$$[b_2, c_2] \text{ and } [b_2', c_2'],\quad [c_2, a_2] \text{ and } [c_2', a_2'],\quad [a_2, b_2] \text{ and } [a_2', b_2'],$$

are three lines, through O_2, lying in a plane. These are the lines, say p_2, q_2, r_2, through O_2, which correspond, respectively, to p, q, r. We have thus proved what we desired to prove. We have not utilised any intersections of p, q, r with the plane α; if such points exist, they will lie, respectively, on p_2, q_2, r_2.

Lastly, we prove that, in this manner, to a plane, ϖ, through O_1 which contains O_2, corresponds, as plane through O_2, this plane itself. The result of course is obvious if the plane ϖ meets the plane α, any line through O_1 in the plane ϖ corresponding then to a line through O_2 in this plane meeting the plane α in the same point as the former; but, as before, we can avoid using the possible intersection of the plane ϖ with the plane α.

When there is a point of the plane α between O_1 and O_2, any plane through O_1O_2 will intersect the plane α in a line, and any line through O_1 drawn in such plane to contain a point of the plane α on this line, will correspond to a line through O_2, lying in such plane, meeting the plane α in the same point as does the line to which it corresponds. In this case the argument can be simplified; it will then be sufficient to suppose that there is no point of the plane α lying between O_1 and O_2. We can then take a point O_3 so situated that the plane α contains a point of both the segments O_1O_3 and O_2O_3; the simplifying considerations are then effective, for example, for O_2 and O_3.

To any line, l_1, drawn through O_1, we can make correspond, as above, with respect to the plane α, a line, l_2, through O_2, and, also, a line, l_3, through O_3. Take a point, H, between O_1 and O_2, so that the plane Hl_3, through H and l_3, containing a point of the plane α, meets α in a line, say h. We can then prove that the line l_2 lies in both the planes O_2l_3 and O_2h; it lies in the plane O_2l_3, because this plane meets α in a line, of which any point, joined to O_2 and O_3, gives corresponding lines, while, as we have proved, lines through O_2 lying in a plane correspond to lines through O_3 also lying in a plane; it lies in the plane O_2h, because it must lie in the plane through O_2 corresponding to the plane Hl_3 through O_3, which contains l_3, and this latter plane meets the plane α in the line h.



Now consider correspondence, not with respect to the plane α, but with respect to the plane Hl_3; it will be seen that the line through O_2 corresponding to l_1 in this way, is also l_2. For just as l_2 was shewn to lie in the plane O_2h, so it follows that l_1 lies in the plane O_1h. The line through O_2 corresponding to l_1, with respect to the plane Hl_3, must therefore lie in the plane O_2h, the line h being in the plane Hl_3; for the same reason it must be in the plane O_2l_3. These two facts shew that this line is l_2.

But then, as l_1, l_2 correspond to one another with respect to the plane Hl_3, which contains a point H between O_1 and O_2, they lie in a plane through O_1 and O_2. And, then, as l_1 is an arbitrary line through O_1, there follows what was desired, that, to any plane through O_1 containing O_1O_2, there corresponds, with respect to the plane α, as plane through O_2, the same plane.

Postulated points. Consider any two lines in a plane, of which the intersection, if it exists, is not given. With the help of the foregoing considerations, we can shew that it is possible to make constructions which are of the same effect as if the point of intersection were known to exist and were accessible and given; and this in a unique manner. This will enable us to speak of the lines as having what we may call a *postulated point* of intersection.

Let the lines be a, b, lying in the plane α. Let O be any point, not lying in this plane. The two planes Oa, Ob, with the common point O, have a line in common, passing through O, which we call l. Let c be a third line of the plane α, such that the plane Oc also contains l. We desire to find justification for saying that the lines a, b have a postulated point of intersection, and that the line c passes through this. For this to be legitimate it is sufficient, first, that the statement shall not be dependent upon the position of the point O; the preceding article shews that it is not; and, second, that if the lines a, b have an actual point of intersection, the line c shall contain this, which is obvious.

Then, if C be an arbitrary point of the plane α, the line from C to the postulated point of intersection of the lines a and b, would, by the definition, be the line of intersection, with the plane α, of the plane Cl. As the preceding article shews, the construction for this line may be made in the plane α alone; we have only to take two arbitrary points, A, A', on the line a, an arbitrary point, B, on b, then a point, B', on b such that a point, F, between A and B, is between A' and B'; then, further a point, E, so that the given point C is between A and E, so that, from the points A, B, E, there is a point, D, between B and C which is also between F and E, and there is also, from the points A', B', E, a point, C', between A' and E, such that D is between B' and C'. The line CC' is then the line required. The line which we regard as determined by the postulated point, and a point O not lying in the plane of a, b, is the line, l, found as above, from the planes Oa and Ob.

The postulated point has then, like an actual point, the capability of determining a line, when taken with another point. It is likewise sufficient, when taken with two other points, O and O', to determine a plane; for we have seen, regarding the postulated point as arising from two given lines a, b, lying in a plane α, that these, with the point O, outside this plane, give rise to a line, l, passing through O; with the point O', they also give rise to a line, l', passing through O'; and we have seen that these corresponding lines, through O and O', lie in a plane. This plane, in virtue of its construction, may be said to contain the postulated point.

If we have two pairs of lines in the plane α, namely a, b and a', b', but no actual intersection of a, b, or of a', b', we have, thereby, two postulated points. With a point O, not lying in the plane α, these two points determine a plane; for they determine, by the preceding, two lines through the point O, say the lines l and l'. The plane of these is the plane in question.

When we have three postulated points of the plane α, it may happen that the lines l, l', l'' similarly arising, one from each of these points, through a point O, not in the plane α, lie in one plane. By the preceding article it follows, that, if this is so for one position of the point O, it is so for another position. We shall then be justified in speaking of the three postulated points as being in line. This leads to a new conception, that of the *postulated line*, which is defined in the first instance by two postulated points; if the postulated points be actual, the postulated line which joins them is also actual, and subject to the construction given.

The postulated point may equally be defined by means of a plane, α, and a line, l, not lying in this plane; the line joining any given point, P, of the plane α, to the postulated point, being the intersection of the plane Pl with the plane α, this definition accords with the former. And, similarly, the postulated line joining two postulated points of the plane α, is, by the preceding, in fact determined by two planes, the plane α and another. Conversely, if two planes, say α and ϖ, be given, but no intersection of these, we can find postulated points by the join of which a postulated line is determined which we may regard as determined by the planes α and ϖ; for take on the plane α the point A, and on the plane ϖ the point O; then, an arbitrary plane through the line AO meets the plane ϖ in a line, say l, and meets the plane α in a line, say a; if B be another point of the plane α, the plane through l and B meets the plane α in another line b; these lines a, b, in the plane α, define a postulated point of this plane which is equally, in accordance with what precedes, to be regarded as being on the plane ϖ. It is also clear incidentally that, a postulated line determines, with an actual point, an actual plane.

Summing up the results so far obtained, we may then say:

1. Two actual lines in a plane have a point of intersection, actual or postulated.

2. A line containing an actual point is an actual line; for two planes having an actual point common have an actual line common. But a point lying on an actual line may quite well be a postulated point.

3. An actual line and a postulated line, in the same plane, have a point in common, which is a postulated point. If the postulated line be that joining two postulated points defined respectively by the pairs of actual lines a, b and a', b', lying all in a plane, the actual line being the line, c, of the same plane, and we take a point, O, external to this plane, the planes Oa, Ob intersect in a line l, and the planes Oa', Ob' intersect in a line l'; and the point common to the line, c, and the postulated line is that defined by c and the plane (l, l').

4. Similarly it may be seen that two postulated lines in a plane have a point common, a postulated point. More generally, from an actual point an actual line can be drawn to meet in a point, actual or postulated, each of two skew lines; for an actual plane can be drawn through the point to contain a line, actual or postulated, and two such planes through the point have an actual line in common.

5. We have seen that an actual line and an actual plane not containing this line, define a point, actual or postulated. More generally a postulated line and an actual plane define a point, unless the line lie in the plane; for, from an arbitrary point of the plane, there passes a line to each of two points taken on the line, and these two lines determine a plane meeting the given plane in a line; this line with the postulated line determine the point in question.

6. Thus, also, any three actual planes meet in a point, actual or postulated.

7. The duality between actual lines and points, in a plane, continues to hold for postulated points and lines, being a consequence of the reciprocity existing for a star; not only is it true that two lines through the centre of the star determine a plane, but, also, two planes through the centre of the star meet in a line. In three dimensions, a line and a plane determine a point, which may be a postulated point; the reciprocal theorem would be that a line and a point determine a plane. If the point, or the line, be only postulated, we may still regard them as determining a plane; but in case both the point and line are postulated elements this is a *postulated plane*. It must then be proved that the line determined by two points of a postulated plane lies entirely in that plane; and, when the notion of a postulated plane is acquired, it is to be shewn that two postulated planes determine a line, which will be a postulated line because every plane through an actual line is an actual plane; and, further, that three postulated planes determine a (postulated) point, and that a line and a plane in all cases determine a point. It seems unnecessary to develop these results in detail; the above account of the course of the argument will make its character clear.

Remark on the theory of postulated elements. A particular case of the foregoing theory is that view of Euclid's Geometry wherein two parallel lines are said to have a point in common, lying at infinity. This view is at least as old as Kepler (*Ad Vitellionem paralipomena, de Coni sectionibus*, Francofurti, 1604), who deduced it independently of notions of perspective, and Desargues (*Brouillon project.*, Paris, 1639; *Oeuvres de Desargues, par M. Poudra*, Paris, 1864; t. I, pp. 104, 243. See Ch. Taylor, *Ancient and Modern Geometry of Conics*, Cambridge, 1881, pp. lvi–lxxii). In this view every line has a single postulated point, and two lines are parallel when they intersect therein; if two other lines both pass through the postulated point of a line, this is the postulated point of all. In the more general theory outlined above, two lines, b, c, may determine different postulated points of a line a but intersect one another in an actual point. We arrive at such a theory, in a plane, by confining our attention to a limited portion of the plane, regarding as actual, points in this limited portion, and, as postulated, points without this. The theory involves the definite discovery that we can make constructions affecting the points exterior to the limited portion though only using *as data* the points interior to it. The limited portion of the plane which is considered must be such that the segment, whose end points are any two points of this, contains only points belonging to the limited portion; we have assumed that every point between two actual points is accessible. A point which arises by postulation may very well be actual and accessible.

Application of the theory of postulated elements. Separation. If we now allow to the postulated points, lines and planes, assuming that the theory of these has been shewn to be self-consistent, as real an existence as that which we attribute to the accessible elements, the system of real geometry which results is in accord with that considered in Chapter I, so far as the Propositions of Incidence are concerned. But care must be taken in regard to the modifications thereby introduced in the notions of a segment, and of the order of points on a line, which were fundamental in the development of the Real Geometry of the present Chapter. When postulated points are allowed an equal standing with given points, not only is it true, given a line l and a point O, that every point of this line determines a line through O, but, conversely, every line through O, in the plane Ol, determines a point of the line l; thus notions of separation, and order, for the points of the line l, can only retain their validity so far as similar notions can be established for the lines drawn through O, in this plane. Thus it appears that, without some convention as to which are inaccessible points of a line, two points of the line must be regarded as determining not one segment, but two segments, which can be distinguished from one another only by naming a point contained in the segment referred to, in addition to the two given points. Thus, if A, B be the given points, we may have either the segment ACB, or the segment ADB, where C and D are two points which we speak of as being *separated* by A and B; in this case A and B are equally separated by C and D. An *order*, among points of the line, is now determined by three points; and the orders ACB, CBA, BAC are the same, being the same as BDA, or DAB, or ABD. Thus we can speak of four points of the line as being in order. And to any order there is a reverse, or opposite. When points of a line, $A, C, B, D, E, \ldots$, are in order, the points C and D being separated by A and B, if $a, c, b, d, e, \ldots$ be, respectively, the lines joining these points to a point, O, not on the line, then these lines are also in order, and the lines c and d are separated by a and b. Thus, if these lines are met by another line, respectively in the points $A', C', B', D', E', \ldots$, then these points are also in order, and the points C' and D' are separated by A' and B'. It is important to notice, however, that *we may not speak of $A'C'B'D'$ as being the same order as $ACBD$.* For if this were justified, the distinction between the order $ACBD$ and its reverse, given by $CADB$, would persist after any number of perspectivities. We have shewn however in Chapter I (p. 25 above) that, by a succession of perspectivities, we can relate the points A, C, B, D respectively to C, A, D, B.

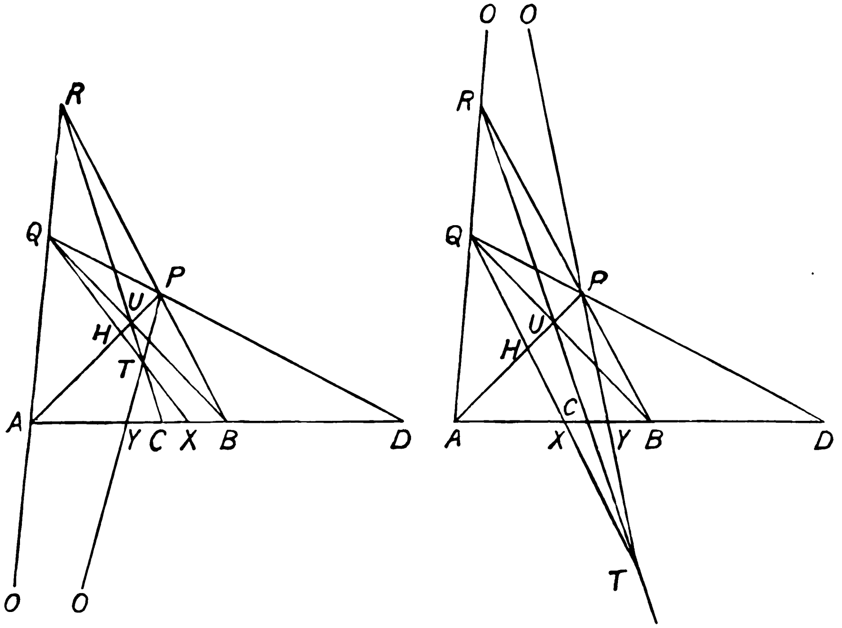
This remark shews that the ideas involved might well be submitted to a more minute analysis than we have entered upon.

The question at issue is intimately related with the fact that, if all points of a line be regarded as accessible, not only does a point of a line cease to separate the other points into two classes, but a line in a plane ceases to separate the points of the plane, and a plane in threefold space ceases to separate the points of the space, and so on. For if l be a line in a plane, and A, B be two points, not on this line, such that one of the segments AB contains a point of the line l, the other of the segments determined by A and B will not contain a point of this line; and a similar statement holds when l is replaced by a plane in space, and so on. The statement is sometimes made that, under the hypotheses adopted in Chapter I, the plane is a *onesided* surface; but an examination of this requires other explanations. (See Note III, at the end of the Volume.)

Separation for four points in harmonic relation. An important result which serves well to illustrate the ideas just discussed is that, if C, D be two points of a line which are harmonic conjugates of one another in regard to two points A, B of the line, then these points C, D are separated by A and B. (Cf. pp. 4 and 14.)

Join the points A, B to a point R; on RC take U; let AU, BU

meet *RB* and *RA*, respectively, in *P* and *Q*, and let *QP* meet *AB* in *D*.



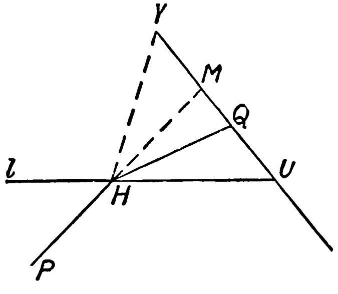
Now, on *AR* take *O*, separated from *Q* by *A* and *R*; let *OP* meet *RC* in *T* and *TQ* meet *AP* in *H*; let *TP*, *TQ* meet *AB* in *Y* and *X*, respectively.

Then, as *OAQR* are in order, so are *PAHU*, by perspective from *T*, and, thence, so are *DAXB*, by perspective of these from *Q*. Again, as *QAOR* are in order, so are *DAYB*, by perspective from *P*. Finally, as *AQRO* are in order, so are *AXCY*, by perspective from *T*.

From the orders *DAXB* and *DAYB*, wherein *D*, *A*, *B* are common and determine the order, it follows that either *DAXYB*, or *DAYXB*, are in order. Either of these contains *A*, *X*, *Y*, the former as *AXY*, the latter as *AYX*; while both *AXCY* and its reverse, *AYCX*, are in order, as we have seen. Thus either *DAXCYB*, or *DAYCXB*, are in order. In either case *C* and *D* are separated by *A* and *B* (as well as by *X* and *Y*).

This argument, which is found in F. Enriques, *Proj. Geom.* (Deutsch by Fleischer, Leipzig, 1903, p. 53), assumes that an order remains an order after perspective, and, also, as stated here, a rule for obtaining an aggregate order from two orders, specified by two sets of points containing, both, the same set of three points occurring in the same order. If we retain the point of view from which the present Chapter began, taking *C* between *A* and *B*, the point D may be only a postulated point; but the application of Peano's axiom to the theorem in question is immediate.

The impossibility of Desargues' theorem from plane Propositions of Incidence. In Chapter I we gave a proof of Desargues' theorem for two triangles in the same plane, based on a construction in three dimensions, assuming only the Propositions of Incidence. In the present Section we have given a construction for postulated points, based on Desargues' theorem for a star, which equally involves (beside Peano's axiom) the consideration of three dimensions. We now give an account of a formal proof that it is impossible to prove Desargues' theorem for the plane from the Propositions of Incidence which apply to figures in a plane, utilising for this the notions of betweenness which formed the basis of this Chapter. The reader may compare Moulton, "A simple non-Desarguesian plane geometry," *Trans. Amer. Math. Soc.*, III, 1902; Peano, "Sui fondamenti...," *Rivista di Mat.*, IV (1894), 73; and Hilbert, *Grundlagen der Geom.*, Göttingen, 1899, § 23.



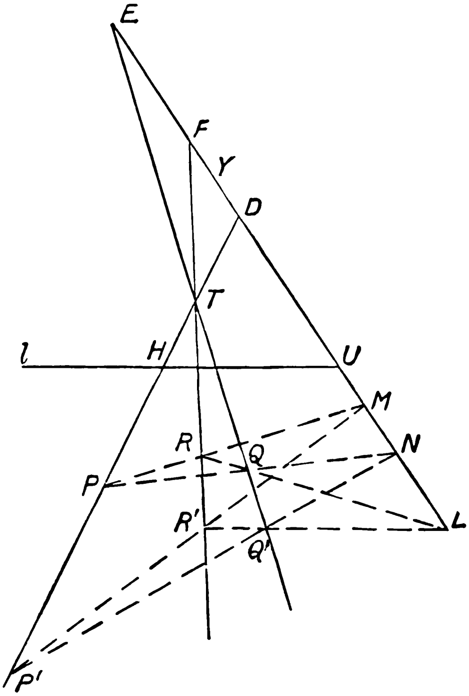
Assume two lines l, m, to be given, dividing the plane into two regions α, β (each representable diagrammatically by two opposite sectors connected through inaccessible points); let U be the intersection of these lines, and YU a given segment of the line m. Any natural line of the plane, meeting the line l in H and the line m in M, contains a segment, a, lying in the region α, and a segment, b, lying in the region β, the points H, M being considered as belonging to the segment α. If now M be in the segment YU, determine Q, in the segment MU, so that $YMQU$ is a harmonic range (or $Q=(U, M)/Y$; see p. 11); then the natural line gives rise to a *conventional* line, obtained by replacing the interior points of the segment b by the interior points of the segment HQ. This conventional line then meets the line m in M; one of its segments, a or HQ, is indefinitely continued. If the line joining Y to any point, M', of the segment a, meet l in U', the line of the segment HQ passes through the point, Q', of $M'U'$, for which $YM'Q'U'$ is a harmonic range; this remark is useful in constructing the conventional line through a point, M', of the region α, and a point of the region β. A natural line not containing a point of the segment YU, as also l or m, gives rise to a conventional line coinciding with itself.

It can now be shewn, with the convention that all points of the lines l, m belong to the region α, and with proper regard to the regions in which the points lie, that any two points of the plane lie on one conventional line, and that any two conventional lines have one point in common.

But it can at once be seen that, with these conventional lines, Desargues' theorem is not always true.

For consider two triads of points, P, Q, R, and P', Q', R', lying suitably in the region we have called α, whose corresponding joins QR and $Q'R'$, RP and $R'P'$, PQ and $P'Q'$, meet, respectively, in points L, M, N, lying on the line YU, but not in the segment YU; while the joins of corresponding points, PP', QQ' and RR', which meet in a point T, meet the line YU, respectively in points D, E and F, of which only D is between Y and U. Such a figure is clearly possible.

Then of the nine lines in this figure, consisting of QR, RP, PQ, $Q'R'$, $R'P'$, $P'Q'$, with the joins PP', QQ', RR', there is only one which is not a conventional line by the previous definition, namely the line PP'; if this meet the line l in H, it would need to be modified by the replacement of HD by a line HK, to a point K of YU given by $K=(U, D)/Y$; the conventional line so obtained does not pass through the intersection, T, of QQ' and RR'.



Thus the Propositions of Incidence in a plane do not logically involve Desargues' theorem.

SECTION III. A DEDUCTION OF PAPPUS' THEOREM FROM THE NOTION OF ORDER AMONG THE POINTS OF A LINE, IN THE CASE OF THE REAL GEOMETRY AS AMPLIFIED BY THE ADJUNCTION OF THE POSTULATED POINTS

The abstract notion of order. We consider order in the abstract, independently of the objects to which this may be applied. These may, for example, be instants of time. To indicate this we speak of *positions*, of this order.

We conceive that the following must be granted, as necessarily inherent in the notion of such an abstract order:

(1) If two positions, say A and B, of this order, be considered, one of these, say B, is *in advance of* the other, A; and then A is *behind* B. We may denote this by $B > A$, or $A < B$; or even, as ordinary language is somewhat ambiguous, we may be allowed to say that B is to the right of A, and A to the left of B. If, then, Q is a third position which is in advance of B, it is assumed that Q is also in advance of A; and, if P is a position which is behind A, it is assumed that P is also behind B; while there may also be positions, R, which are both in advance of A and also behind B, these being said to be between A and B. In symbols, $A < B$, $B < Q$, together, involve $A < Q$; $A < B$, $P < A$, together, involve $P < B$; and there may be positions R for which $A < R < B$. It is assumed that every position, other than A and B, is such as Q, or P, or R. We thus build up the notion of an order of succession of any finite number of positions, determined by three of these.

(2) Between any two positions of the abstract order, there is another, and, therefore, by reapplication of the assumption, an unlimited number of other positions.

(3) Let A and B be any two positions of the order, for which, suppose, $A < B$. Consider the positions which are between A and B. Suppose that a rule has been devised, or exists, whereby everyone of these positions between A and B falls under one of two categories, (α), or (β); further, that every position falling under category (α) is seen, or known, to be behind every position falling under category (β), so that we may say that every (α) is less than every (β). Then it is in the nature of an abstract order, as we understand it, that, there is a position of the order, say C, lying between A and B, such that every position of the order which is between A and C falls under category (α), and every position of the order which is between C and B falls under category (β). The position C itself falls under category (α) or category (β). Thus, conversely, every position (α), between A and B, if not C itself, must be between A and C; for, if it were between C and B, it would be a position (β); similarly, every position (β), if not C itself, must be between C and B.

In cases, we may, conventionally, extend the result, regarding C as coincident with B when no positions (β) exist.

Remarks in regard to the preceding formulation. When it is said that any set of objects are in order, it is often meant, merely, that they satisfy no. (1) of the preceding descriptions. For instance the integer numbers 1, 2, 3, ... satisfy (1); they do not satisfy (2) or (3). If we take all positive rational fractions, such as $\frac{1}{2}, \frac{2}{3}, \frac{3}{4}, \ldots$, arranged in ascending order of magnitude, they satisfy (1) and (2); they do not satisfy (3). We may for instance, among these fractions, consider, as falling under category (α), those whose square is less than $\frac{1}{2}$, and, as falling under category (β), those whose square is greater than $\frac{1}{2}$; there is, then, no rational fraction occupying the position required for C in the abstract order, that is, no rational fraction whose square is $\frac{1}{2}$; and, any fraction whose square is less than $\frac{1}{2}$, has, in advance of it, others whose squares are yet less than $\frac{1}{2}$. We may arrange these fractions, say those only which are less than 1, in another way, so that they satisfy (1), but do not satisfy (2), by supposing them to follow one another in batches, of which all those in a batch have the sum of their numerator and denominator the same; the position of each fraction may then be given by one of the numbers 2, 3, 4, ... From these, and other examples, it is clear that a set of concrete objects, infinite in number, may be such as to correspond uniquely, each to one position of such an abstract order as we have explained, though yet not containing objects corresponding to every position of such order. We may give a concrete example of this, which is capable of general statement; it assumes some acquaintance with the elements of Euclidean Geometry. Take a circle, of centre O, and radius OA; let the points of the plane interior to this circle be placed in order by the following rule: through any such point, P, draw a circle, also with centre O, which intersects OA in the point A_1; let the points on the circumference of this circle be placed in order, beginning with A_1, by regarding a point Q of this circumference as being in advance of the point P of this circumference ($Q > P$), when the positive angle A_1OQ, which is to be taken greater than or equal to zero, but *less* than four right angles, is greater than the positive angle A_1OP. Then, let all the points of the circumference of another circle of centre O, of radius OA_2 greater than OA_1 but less than OA, the first of these points being A_2, be regarded as being $>$ all the points of the circumference of the circle of radius OA_1, the points on the circumference of this second circle being, among themselves, in order by the rule above stated for the circle of radius OA_1. With such provision for any two circles of centre O within the original circle, all the points interior to this circle are arranged in order, and the above conditions, (1), and (2), are satisfied. Consider condition (3); regarding A_1 as a definite point between O and A, let the category (α) be that of all points on the circumference through A_1 and of all points on circumferences of radius less than OA_1, and let the category (β) be that of all points on circumferences of radius greater than OA_1 (but less than OA). Then every point interior to the circle of radius OA falls under one of these categories, and every point of category (α) is $<$ every point of category (β). But there is no point, C, such that every point $< C$ belongs to the category (α), and every point $> C$ belongs to the category (β). If we take any point, Q, of the circumference through A_1, there are always points,

Q', of this circumference, which are $> Q$; and then there are points, Q'', of this circumference, which are $>$ any such points Q', and so on continually; the process will not have an end unless either the point A_1 is allowed as $>$ all the various points $Q, Q', Q'', \ldots$, which, however, is not the case, since $A_1 < Q < Q' < Q'' \ldots$, or some point is allowed $>$ all the various points $Q, Q', Q'' \ldots$ which is a point of a circumference of radius greater than OA_1; and this, again, does not provide the point C in question, since all such points are of category (β). Thus, while the construction furnishes points arranged in such an abstract order as we have described, it does not give points corresponding to every position of such an order.

A further remark may be made: The notion of an abstract order furnishes no means for saying that the positions of the order between two positions A and B form an aggregate of the same *length*, or *magnitude*, or *power*, as the aggregate of positions between two other positions C and D. Such a notion of *congruence* must be supplied, if at all, by additional conditions. And only when this is supplied can there be question of the fulfilment of what is known as the axiom of Archimedes: the axiom namely, for an aggregate of elements arranged in order wherein the notion of equality of intervals between pairs of elements has been established, which states that, if A, B be two elements, and $P_1, P_2, \ldots$ be elements, such that $A < B$ and $A < P_1 < P_2 < \ldots$, and also such that the intervals $AP_1, P_1P_2, P_2P_3, \ldots$ are all *equal*, then there is a number n for which $B < P_n$. We may, as before, be allowed, in this case a very simple and concrete illustration, for the purpose of helping to fix the ideas; though, like a diagram used to assist the conception of a geometrical figure, the illustration may suggest implications which are not intended: In the case of time we measure intervals by observing the succession of natural phenomena, as for instance by heart-beats, or by a clock. But if all the clocks went twice as fast between what we now call 12 o'clock and 12.30 o'clock, as they now do, so that they indicated 1 o'clock at the time we now call 12.30, and went two-thirds as fast as they now do between the times we now call 12.30 and 2 o'clock, so that they marked 2 o'clock as they now do, we should, if we had agreed to regard as standard time that given by the clocks, reckon the interval between our present times 12 and 12.30 as being equal to the interval between 12.30 and 2. Though this would lead to modifications in our description of the behaviour of natural bodies, as, for instance, the contractions of the heart, it would not affect our notion of the succession of time, or of the order of events. The questions suggested in this connexion, recently also in vogue as arising in discussions of the Principle of Relativity in Physical Science, are inherent in the consideration of the Foundations of Geometry. The Theory of Proportion in Euclid's Fifth Book is evidence of their antiquity. In modern literature, the analysis leading to condition (3) above, relating to the existence of a dividing position there called C, was suggested by R. Dedekind, *Stetigkeit und irrationale Zahlen*, Braunschweig, 1872. Also for the relation of number and the measurement of quantity an article by O. Hölder, *Die Axiome der Quantität*, *Leipzig. Berichte*, LIII, 1901, may be consulted; and for this, and other fundamental questions, see F. Enriques, *Enzyklopädie der Math. Wiss.*, III, 1. 1, *Prinzipien der Geometrie*, where many references are given.

A theorem in regard to corresponding positions of an abstract order. Let us now suppose that we have some means of establishing a correspondence between two positions, P and Q, of such an abstract order, so that (i) to any position P there corresponds a position Q, and conversely; and (ii) so that the positions Q', Q'' corresponding to two positions P', P'', for which $P'' > P'$, are also such that $Q'' > Q'$. Let us suppose, further, that there are two positions of P, say A and B, for each of which the corresponding position of Q coincides with that of P; and suppose that the position of Q does not coincide with that of P for every position of P between A and B. When P has a position between A and B, the position of Q, if not coincident with P, relatively to P, may agree with or differ from that of B relatively to A; it will be sufficient to, and we shall, suppose $A < B$, and the two possibilities are, then, $Q > P$ and $Q < P$, the former being that when Q is in advance of P, and the latter that in which Q is behind P. It may be that Q, which coincides with P when P is at A, and coincides with P when P is at B, is, otherwise, for every position of P between A and B, in advance of P; or is, for every position of P between A and B, behind P. In either case we may say that Q *preserves the same relation to* P when P is anywhere within AB. More generally, if Q coincides with P when P is at each of two positions, P_1 and P_2, between A and B, and Q preserves the same relation to P when P is anywhere within P_1P_2, being either in advance of P for every position of P between P_1 and P_2, or behind P for every position of P between P_1 and P_2, it will be convenient to speak of P_1P_2 as a *complete interval.* We desire, then, to prove, assuming, as we have said, that Q does not coincide with P for every position of P between A and B, that, if AB is not a complete interval, it contains complete intervals, the end positions of these, whereat Q coincides with P, being definite. For this, consider a position, P_0, of P, between A and B, for which the corresponding position, Q_0, of Q, is not coincident with P_0. For definiteness suppose that Q_0 is in advance of P_0; a similar argument is applicable when Q_0 is behind P_0; it may be that, as P takes positions between P_0 and B, Q preserves that relation to P (of being in advance of P) which it has when P is at P_0, coinciding with P only when P is at B. In any case we prove that there is a definite position, V, between P_0 and B or identical with B, such that Q is in advance of P for every position of P between P_0 and V, but coincides with P when P is at V. And a similar argument will establish the existence of a definite position, U, between A and P_0 or identical with A, such that Q is in advance of P for every position of P between U and P_0, but coincides with P when P is at U. The segment UV will then be complete, in the sense adopted. For greater definiteness, let any position P between P_0 and B be said to be *like* P_0, when the corresponding position of Q is in advance of that position of P, and be said to be unlike P_0, when the corresponding position of Q either coincides with that position of P or is behind it. In particular B is unlike P_0. We may then place every position, F, between P_0 and B, under one of two categories, (α) or (β), agreeing that F is of category (α) when every position between P_0 and F, and F itself, is like P_0, but that F is of category (β) when there is one or more position between P_0 and F, or at F, which is unlike P_0. By condition (ii), the positions P between P_0 and Q_0 have their corresponding Q in advance of Q_0 and are of category (α); and B may be taken of category (β), since Q there coincides with P. A position of category (β) cannot coincide with a position of category (α); nor can any position of category (β) lie between P_0 and a position of category (α). In other words every position of category (α) is behind every position of category (β). Thus, recalling the condition (3) attached to the notion of an abstract order, there exists a position, V, between P_0 and B or at B, such that all positions of P in P_0B which are behind V are of category (α), and all positions in advance of V of category (β). This is equivalent to saying that every position, X, of P_0B, which is behind V, is like P_0, and every position of P_0B which is in advance of V, is either unlike P_0 or has positions unlike P_0 lying behind it; thus every position, Y, of P_0B, in advance of V, has positions unlike P_0 lying behind it; for every position between V and Y, being in advance of V, is either itself unlike P_0 or has such positions lying behind it.

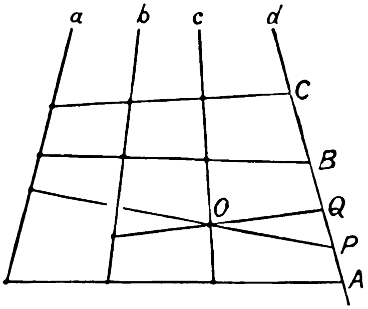
Hence, any position, X, of P_0B, which is behind V, is such that, when P is at X, the position Q is in advance of X; and every position Y, of P_0B, which is in advance of V, is such that, between V and Y, there is a position of P for which the corresponding Q is behind P, or a position P for which the corresponding Q coincides with it.

Now use again the condition (ii) above, that, if Q_1, Q_2 be the positions of Q corresponding to two positions P_1, P_2 of P for which P_2 is in advance of P_1, then Q_2 is in advance of Q_1. Then we can shew that, when P is at V, so also is Q. For if, when P is at V, the corresponding Q were at Q', behind V, and we take a position of P between Q' and V, and, therefore, behind V, the corresponding Q would, by the property of V, be in advance of P, and, therefore, in advance of Q', though the P to which this corresponds is not in advance of the P to which Q' corresponds, which is at V. Or, again, if, when P is at V, the corresponding Q were in advance of V, say at Q'', and we take a position of P between V and Q'', and, therefore, in advance of V, the corresponding Q would, by the property of V, either be at this P or behind it, and in either case behind Q'', though the P to which this corresponds is not behind the P to which Q'' corresponds, this being at V.

Thus, it is proved that, when P is at V, the corresponding Q coincides with it, there being between P_0 and V no position of P for which Q is not in the same relation to P as when P is at P_0. And, in particular, V may be B.

The proof of the existence of U is similar. Suppose that $Q_0 > P_0$, and let positions of P, between A and P_0, for which Q is in advance of P, be said to be like P_0, positions for which Q coincides with, or is behind P, being said to be unlike P_0; so that A is unlike P_0. Every position, F, between A and P_0 or at A, is either, (α), such that every position between F and P_0, and F itself, is like P_0, or, (β), such that there is one or more position between F and P_0, or at F, which is unlike P_0. By condition (ii), the P_1 whose Q is at P_0 is behind P_0, and all positions between P_1 and P_0 are of category (α). Every (α) is in advance of every (β); and, by the condition (3) for an abstract order, there exists a position, U, between A and P_0, or at A, separating positions (α) from positions (β). Thus, every position, X, between U and P_0, is like P_0, and every position between A and U is either unlike P_0 or has such positions lying in advance of it; from which, every position, Y, between A and U, has positions unlike P_0 lying in advance of it. Or, when P is at X, the corresponding position Q is in advance of it, while between Y and U there are positions of P for which Q, if not coincident with P, is behind P. And, as before, we can shew that when P is at U, so is Q. For, if the position U for Q arose from a position, P', of P, lying between U and P_0, a position Q, between U and P', would, by the property of U, correspond to a position P behind Q, and, therefore, behind P', and we should have the results $P' > P$, $U < Q$, which, by hypothesis, are inconsistent; while, if the position U for Q corresponded to a position P'' between A and U, then a position Q between P'' and U would correspond to a position which, if not coincident with Q, is in advance of Q, and is, therefore, in advance of P''; then we should have the inconsistent results $P'' < P$ and $U > Q$.

segments AB, consider that one which does not contain the point C. Let P be any point of the line d; from P draw the transversal to meet the lines a and c, its point of meeting with c being O; from O draw the transversal to meet the lines b and d, its intersection with d being Q. Then, to any position of P on the line d corresponds a definite position of Q, and, conversely, to every Q a definite P. The various positions of P correspond, each to one of an axial pencil of planes, having the line a for axis, the points P being the intersections of the planes of this pencil with the line d; three of these planes, in particular, are those containing, respectively, the points A, B and C. The planes of this pencil, respectively, are also intersected in points by the line c, the point O of this being that which corresponds to P. But, again, the various positions of O, give rise, with the line b for axis, to an axial pencil of planes, of which every plane has also a point on the line d, the point Q being that so arising from O. Therefore, four positions of P which are in order, give rise to four positions of O which are in order, and these, in their turn, to four positions of Q which are in order. In particular, Q coincides with P when P is at A, or at B, or at C. Thus, if P_1, P_2 be two positions of P such that A, P_1, P_2, B, C are in order, and if Q_1, Q_2 be the positions of Q respectively corresponding to P_1 and P_2, then, also, A, Q_1, Q_2, B, C are in order. We may regard the points ABC as defining, for the points of the line d, such an order as was contemplated in the discussion of an abstract order above, which is also such as was considered at the beginning of the present chapter (p. 96, above), where the inaccessible points of a line in fact play the part here played by the point C. We may then say, limiting the position of P, now, to the segment AB which does not contain C, that: *To any position of P between A and B there corresponds a definite position of Q, also between A and B, and conversely; and, if Q_1, Q_2 be the positions of Q corresponding to the positions P_1, P_2, of P, of which P_2 is in advance of P_1, then, also, Q_2 is in advance of Q_1.*



It therefore follows, from the preceding theory, that, unless, for all positions of P between A and B, the position of Q is coincident therewith, there can be found two positions, U and V, between A and B, or coinciding, respectively, with A and with B, such that, when P is at either U or V, then Q coincides with P, while, for a position of P between U and V, the position of Q preserves the same relation to that of P, and never coincides with it. This last alternative is, however, untenable: For, if we take the harmonic conjugate of the point C in regard to U and V, we obtain a point, C', lying between A and B, as has been proved (p. 119, above). By the construction given, four positions of P which are in harmonic relation, give rise to four positions of Q also in harmonic relation, as follows from the properties of this relation (Chapter I, p. 13, above). Therefore, as the positions of Q coincide with those of P when P is at U, or V, or C, the position of Q coincides with that of P when P is at C'. The remaining alternative must then be taken: *The positions of P and Q are coincident for all positions of P between A and B; and hence for all positions of P on the line d; and the transversal drawn from any point of d to meet two of the lines a, b, c, also meets the third.*

As has been said, it follows from the theory given in Section II of Chapter I (p. 49, above), that this amounts to a deduction o Pappus' theorem, under the assumptions made above as to the points that are possible upon a line. It proves also, with the same assumptions, that if, of two related ranges on two lines, possibly coincident, there be given three points, A', B', C', of one range, to correspond, respectively, to three points, A, B, C, of the other, then the point, D', of the former range, which corresponds to an arbitrary point D, of the latter, has a unique position (see pp. 45 ff., above). In particular, if, of two related ranges on the same line, there be three common points, each self-corresponding, then the ranges are identical.

Similar statements then follow in regard to flat pencils, of lines in a plane all passing through the same point, related to one another; and in regard to axial pencils, of planes in space all passing through the same line, related to one another.

Alternative deduction of related ranges, based on a harmonic net. In what has preceded in this volume, two ranges have been related to one another by a sequence of perspectivities. In a perspectivity four points of a line which are in harmonic relation lead to four points of another line which are also in harmonic relation. Conversely, suppose that we can set up a correspondence between the points of two lines, of such character that to any point of either line there belongs a definite point of the other, in such a way that any four points of either line which are in harmonic relation, say A, B, C, D, of which B, D are harmonic conjugates of one another in regard to A and C, correspond to four points of the other also in harmonic relation, say, respectively, A', B', C', D', of which B', D' are harmonic conjugates of one another in regard to A' and C'; suppose further that the order $A'B'C'$ is the same as, or different from, a definite order previously established on the second line, according as the order ABC is the same as, or different from, a definite order previously established on the first line; then it may well appear probable that the two ranges are related, in the sense previously employed.

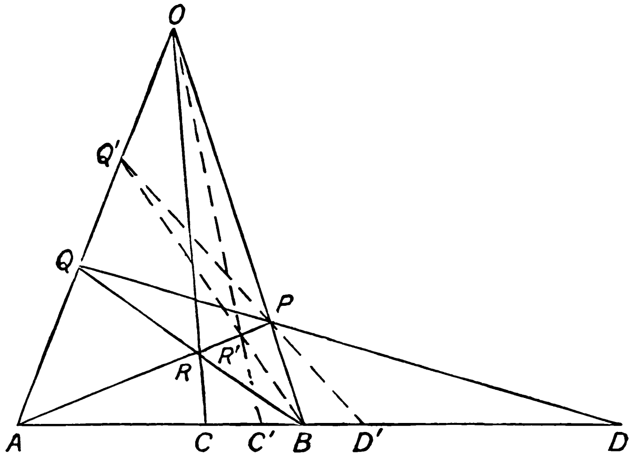
We do not enter fully into the analysis of this suggestion. But there is one result which would be necessary for this purpose, to which we should refer; it has an interest and importance by itself, and its deduction is by reasoning cognate to that immediately preceding. Suppose that, upon any line, are taken three points, A, B, and C; and, then, the harmonic conjugate of each of these in regard to the other two, and, then, further, the harmonic conjugates of each of the new points in regard to every other two, and so on continually. The points so obtained will have the property that, in each of the two segments determined by any two of the points, there are other points of the set; for beside these two points there are certainly others, and one such, lying in one of these segments, necessitates one, the harmonic conjugate of the other, lying in the other segment. This property, however, by itself, does not secure that, if two *arbitrary* points be taken on the line, not assumed to be points of the constructed set, there is a point of the set lying in a specified one of the two segments determined by these arbitrary points, though, if not, such points are in the other segment. In virtue of the special character of the harmonic relation it is however the case that this is so, and it is this fact which we now prove.

The definition of related ranges here referred to, founded on the condition that four harmonic points always correspond to four harmonic points, is that which was adopted by von Staudt (*Geometrie der Lage*, 1847, § 9, p. 49), who assumed without proof the result we have stated—that a point of a harmonic net of points constructed as above is found in every arbitrary segment. This omission was remarked by F. Klein, who gives (*Math. Annal.* VII, 1874; *Ges. Abh.* I, p. 344) the following demonstration, as due to Zeuthen, stating it to be equivalent to another simultaneously communicated by Lüroth. See also Darboux, *Math. Annal.* XVII (1880), p. 52.

Two assumptions are made, into a detailed analysis of which we need not enter:

(1) If, in regard to two points A, B, the harmonic conjugates of two points C, C' be respectively D and D', then the orders $CC'B$ and $DD'B$ are different, as also are the orders ACC' and ADD'. In other words, if $ACC'B$ be in order, then $ABDD'$ are not in order; but if $ABDD'$ are in order, then $ACC'B$ are not in order.

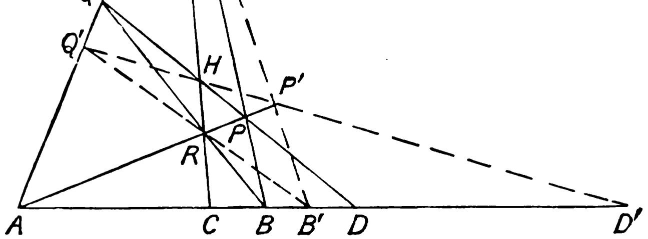
For let A, C, B be in perspective, from a point O, with A, R, P, respectively, and A, R, P be in perspective, from B, with A, Q, O, respectively, and, lastly, A, Q, O be in perspective, from P, with A, D, B, respectively. If then C' be in the segment CB which does not contain A, it gives rise, by perspective from O, to a point, R', in the segment RP which does not contain A; and R', by perspective from B, gives rise to a point, Q', in the segment QO which does not contain A; and, then, Q', by perspective from P, gives rise to



the point, D', in the segment DB which does not contain A; and D' is the harmonic conjugate of C' in regard to A and B.

The assumption may be expressed by saying that points which are harmonic conjugates of one another, in regard to two fixed points, move in opposite directions.

(2) If of the four points $ACBD$, in harmonic relation, we modify,



not C and, consequently, D, but, keeping C the same, we modify B, and, consequently, D, then, when $ACBB'$ are in order, so are $ABDD'$, and conversely; the orders CBB' and CDD' are the same, as are ABB' and ADD'.

For, with the same construction for D, from C, as in (1), let a point, B', of AB, be joined to R and O by lines meeting AQ and

AP respectively in Q' and P', and $Q'P'$ meet *AB* in D', so that D' is the harmonic conjugate of *C* in regard to *A* and B'; then, if B' be in the segment *AB* which does not contain *C*, it follows, by perspective from *O*, that P' is in the segment *AP* which does not contain *R*, and, by perspective from *R*, that Q' is in the segment *AQ* which does not contain *O*. Hence, remarking that *OR*, *PQ*, $P'Q'$ meet in a point, *H*, as follows from the triads *P*, P', *O* and *Q*, Q', *R*, it is seen that D' is in the segment *DA* which does not contain *B*.

In (1) two separated points, of four in harmonic relation, were kept unaltered; in (2) two contiguous points are to be kept unaltered. Then, we may say, the other two, contiguous, points move in the same direction.

These conditions being understood, consider such a set of points on a line as was described, containing the harmonic conjugate of every one of them in regard to every other two. We may speak of such a set as a harmonic net; and may associate with it the name of Moebius. Suppose, if possible, there are two points, *F*, *G*, of the line, such that there are no points of the harmonic net on one of the two segments determined by *F* and *G*. Points of this segment may be spoken of as lying between *F* and *G*; and, by taking a further point of the line to define, with *F* and *G*, an order, we may, without loss of generality, speak of *G* as being in advance of *F*. We first extend this segment *FG* as much as possible, seeking to replace *F* by a point *X* behind *F*, and replace *G* by a point *Y* in advance of *G*. Precisely, we shew that there are two definite points, *X*, *Y*, upon the line, of which *X* either coincides with *F* or is behind it, and *Y* either coincides with *G* or is in advance of it, so that *XFGY* are in order, having the properties, (*a*), that there is no point of the harmonic net within the segment *XY*, which contains *F* and *G*, (*b*), that either *X* is a point of the harmonic net, or there are points of the harmonic net lying between *X* and any *arbitrary* point taken behind *X*, (*c*), that either *Y* is a point of the harmonic net, or there are points of the harmonic net lying between *Y* and any arbitrary point taken in advance of *Y*.

To prove the existence of the point *Y*, we remark, first, that if *G* be a point of the harmonic net we may take *Y* at *G*. Suppose, that *G* is not a point of the harmonic net; there must, then, be points of the harmonic net in advance of *G*, or behind *F*, since otherwise, there being none between *F* and *G*, there would be none anywhere. In our conventions of order, however, there is, finally, no distinction between points said to be in advance of *G*, and points said to be behind *F*. We shall therefore say that there is a point, *N*, of the harmonic net which is in advance of *G*. Consider now the segment *GN*, containing points in advance of *G*, but not containing F. We apply the formal argument introduced in our discussion of an abstract order, to shew that there is such a point as Y within this segment. The points of the segment GN, other than G, are of one of two categories: (α), Points, R, such that there is no point of the harmonic net between G and R, or at R; it is assumed that points (α) exist; but, if not, we may take Y at G; (β), Points, S, such that there is a point of the harmonic net between G and S, or at S. It is clear that every point (α) is behind every point (β). Therefore, by the condition named (3) in the discussion of an abstract order, there is a point, Y, between G and N, or at N, such that all points of the segment GN which are behind Y are points (α), and all points of the segment YN are points (β), the point Y, itself, being of one of these categories. Every such point (β) of the segment YN, say S, is then either, itself, a point of the harmonic net, or has such points, lying in GN, behind it. If behind S there be no such harmonic points, so that, in particular, Y is not a harmonic point, and if, further, there are no harmonic points between Y and S, in which case S itself is a harmonic point, then there are points (α) in the segment YS, which is contrary to the definition of Y. Wherefore, every point, S, of category (β), in advance of Y, has points of the harmonic net behind it, and these, by the construction, are not behind Y. Thus, either Y is a harmonic point, or such harmonic points lie between Y and T, whatever point of the segment YN the point T may be. Thus Y is such a point as was to be shewn to exist. The existence of X can be shewn in a similar manner.

Having thus deduced, from the hypothesis of the existence of the segment FG containing no points of the harmonic net, the existence of X and Y, with no harmonic points between them, we proceed, with use of the precise definitions of X and Y, to give a construction for finding a point of the harmonic net which does actually lie between X and Y. We shall then be able, finally, to conclude that such a segment as FG is not possible.

For this purpose, suppose, first, that neither X nor Y is a point of the harmonic net. And, for the sake of clearness, denote points of the harmonic net which arise in the construction by A_1, B_1, C_1, D_1, points not assumed to belong to the harmonic net being denoted by letters without suffix. Then make the following construction:

(1) Take any point, A_1, of the harmonic net, not in the segment XY containing the segment FG first considered, the point A_1 being, say, behind X. From A_1 find the harmonic conjugate in regard to X and Y, say H, represented by

$$H = (X, Y)/A_1,$$

so that H is within the segment XY.

(2) Take also the point J given by

$$J = (A_1, Y)/X,$$

so that J is in advance of Y.

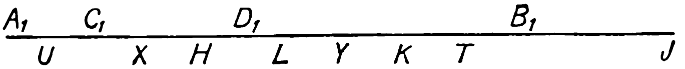
(3) Remembering the property of the point Y, take a point, B_1, of the harmonic net, in advance of Y but behind J, and then a point, T, in advance of Y but behind B_1, and thence find the point, U, such that

$$U = (A_1, H)/T.$$

This shews that U is in advance of A_1 but behind H; while, as we also have

$$X = (A_1, H)/Y,$$

we can infer, from the assumption (1) above, that the order A_1XU is the opposite of the order A_1YT, namely that U is behind X, and it is in advance of A_1.



(4) By the property of the point X, there is a point of the harmonic net in advance of U and behind X; take such a point, C_1. From this find K so that

$$K = (A_1, H)/C_1;$$

then, as UC_1XY are in order, and A_1, U, H, T and A_1, X, H, Y, as well as A_1, C_1, H, K, are all sets in harmonic relation, it follows, also from assumption (1) above, that $TKYX$ are in order, or that K is in advance of Y and behind T.

(5) Next take L so that

$$L = (C_1, J)/A_1.$$

Then, comparing the facts that A_1, J, L, C_1 and A_1, J, Y, X are both sets in harmonic relation, we infer, from assumption (2) above, that A_1, L, Y are in the same order as A_1, C_1, X, or that L is behind Y. While, comparing the facts that A_1, C_1, H, K and A_1, C_1, L, J are also both sets in harmonic relation, we similarly infer that A_1, H, L are in the same order as A_1, K, J, or that L is in advance of H.

(6) Lastly take D_1, belonging to the harmonic net, such that

$$D_1 = (C_1, B_1)/A_1.$$

Then, from the harmonic sets, A_1, C_1, D_1, B_1 and A_1, C_1, L, J, we similarly infer that C_1, D_1, L are in the same order as C_1, B_1, J, or, that D_1 is behind L. And, from the harmonic sets, A_1, C_1, H, K and A_1, C_1, D_1, B_1, we infer that the order A_1KB_1 is the same as A_1HD_1, so that D_1 is in advance of H.

We may then say that D_1 is between H and L. But, similarly, H is between X and Y, and L is between H and Y. Thus D_1 is between X and Y; and is a point of the harmonic net. Wherefore, in the case when neither X nor Y is a point of the harmonic net, we are able to infer that the hypothesis of the segment FG is untenable.

Next suppose that X is a point of the harmonic net, but, as before, that Y is not such a point. Then the point C_1, which was any point of the harmonic net between U and X, can be taken, instead, to be at X. Hence, by comparison of (3) and (4), the point K will be at Y; and, by comparison of (2) and (5), the point L will be at Y. But D_1 will still be between X and Y; and the same conclusion will follow.

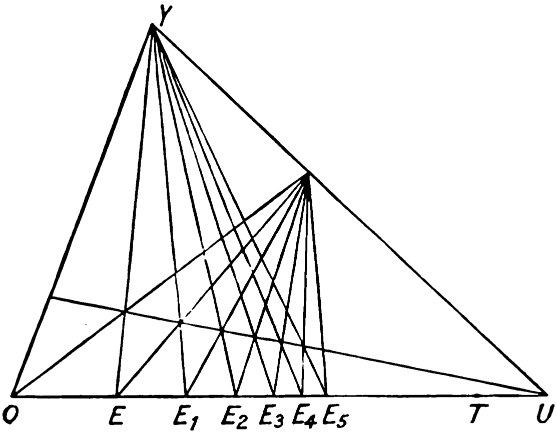
If Y, but not X, be a point of the harmonic net, we can interchange the parts played by X and Y in the preceding case, with the same inference.

While, finally, if both X and Y belong to the harmonic net, the harmonic conjugate of A_1 in regard to X and Y is between X and Y, and, in this case, is a point of the harmonic net.

The conclusion, then, is, that every segment of the line contains one, and, therefore, an infinite number of points of the harmonic net.

Consequences of the equable distribution of points of the harmonic net. It follows from the preceding theorem that any point, P, of a line upon which a harmonic net has been constructed, may be regarded as lying in advance of an indefinitely continued sequence of points of the harmonic net, say $A_1, A_2, A_3, \ldots$, where $A_1A_2A_3\ldots P$ are in order, and also as being behind another such sequence, $B_1, B_2, B_3, \ldots$, where $P\ldots B_3B_2B_1$ are in order. We have only to take two arbitrary points, A, B, upon the line, such that APB are in order; there is, then, a harmonic point, A_1, between A and P, and a harmonic point, B_1, between P and B. There is, also, a harmonic point, A_2, between A_1 and P, and another, B_2, between P and B_1; and so on, indefinitely. Conversely, if we have an indefinitely continued sequence of points of the harmonic net, in order, say $A_1, A_2, A_3, \ldots$, and, also, another indefinitely continued sequence of harmonic points $\ldots, B_3, B_2, B_1$, in the same order, and if every point of the former set lies behind every point of the latter, there is, by the condition (3) introduced in the discussion of an abstract order, a point P which has the specified relation to the two given sets of harmonic points. This point P may be, or may not be, a point of the harmonic net.

Another result, involving similar ideas, should be referred to here. If O, E, U be any three points of a line, and we carry out in succession the operations of finding the harmonic conjugate, E_1, of O in regard to E and U; then the harmonic conjugate of E in regard to E_1 and U, say E_2; then the harmonic conjugate of E_1 in regard to E_2 and U, say E_3, and so on, indefinitely, the points $OEE_1E_2E_3\ldots U$ will be in order. And, if T be any point of that

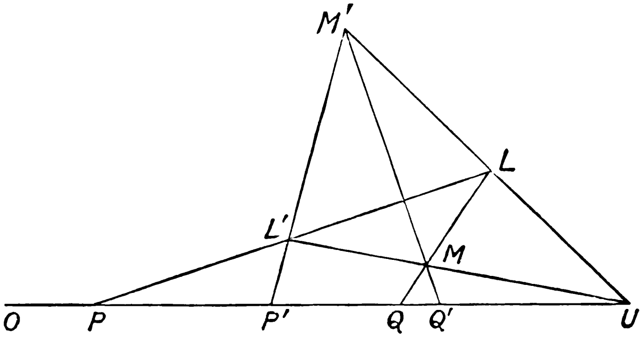


segment EU which does not contain O, there will be found points of the set E_1, E_2, E_3, ..., in infinite number, in that segment TU which does not contain E, *and this wherever T be taken.* This result is like one referred to previously (p. 124, above), applicable to measurable quantities, known as Archimedes' axiom, which would state that, if EE_1, E_1E_2, E_2E_3, ... were *equal lengths*, and T arbitrary, there is an n such that OE_n is greater than OT. But the fundamental ideas are somewhat different: the result here stated is a theorem of 'betweenness,' when all the points of the line are supposed accessible; Archimedes' axiom is a theorem of that which is beyond what is given.

Introduction of symbols, in particular of the iterative symbols. We have, in this chapter, avoided reference, so far, to the algebraic symbolism described in Chapter I, and to the numbers of ordinary arithmetic. But the effect of the hypothesis introduced, for the points of a line, to obtain a deduction of Pappus' theorem, that the real points existing on a line are such, and only such, that condition (3) for an abstract order (p. 122, above) is satisfied, is to set up a correspondence between the points of a line and the numbers of arithmetic. In this correspondence, the numbers are used only to specify order of succession, not magnitude, and there is one postulated number, denoted by ∞, which is to be regarded as coming not only after all positive numbers but also before all negative numbers; this being understood, the numbers associated with three arbitrary points of the line may be taken arbitrarily, and the correspondence is then definite.

Taking three arbitrary points of the line O, E, U, and supposing the symbols belonging to these to be such that $E=O+U$, as was explained in Chapter I, we have obtained an interpretation, by a point of the line, of the symbols $nO+U$, $O+mU$, $nO+mU$, $nO-mU$, wherein m, n are iterative symbols; and it is easy to establish, by induction, from the assumptions of the present chapter, that, if the positive numbers of arithmetic, $\bar{n}$, $\bar{m}$, $\bar{n}'$, $\bar{m}'$, with which the symbols n, m, n', m' are formed, be such that $\bar{m}'/\bar{n}'$ is greater than $\bar{m}/\bar{n}$, then the points of which the symbols are, respectively, O, $nO+mU$, $n'O+m'U$, U, are in order; with a similar conclusion for points of symbol $nO-mU$. By this, a correspondence is established between the points of a harmonic net upon the line, built up from the points, O, E, U and the rational numbers of arithmetic, taken in order in both cases, the points O, E, U being associated respectively with the numbers 0, 1, ∞. Then, by the proposition of the equable distribution of the points of the harmonic net, proved above, the points of the line not belonging to the harmonic net are made to correspond, uniquely, each to an irrational number. It will be seen, immediately, below, that any other numbers than 0, 1, ∞, might have been attached to the points O, E, U.

It is not, however, thereby asserted, as has several times been



remarked, that, if two points, P, Q, of the line be thus associated with two symbols p, q, respectively, and two other points, P', Q', with two symbols p', q', and if $q'-p'=q-p$, then the *length* $P'Q'$ is equal to the length PQ. Such an assertion would be meaningless in the absence of a definition of length. As we have seen, the points P, Q, ... being $O+pU$, $O+qU$, ..., and therefore, the points P', Q, Q' being, respectively, $P+(p'-p)U$, $P+(q-p)U$, $P+(q'-p)U$, the equation $q'-p'=q-p$, or $q'-q=p'-p$, expresses that, if arbitrary lines be drawn through P, P', Q, respectively, in one plane containing the line, that through P meeting those through P' and Q respectively in L' and L, and UL, UL' meet the lines through P' and Q respectively in M' and M, then the line $M'M$ meets the original line in the point Q'. Evidently, when P, P' and Q are assigned, the position of Q' depends on the position of U.

Thus the following question arises: If we take three arbitrary points of the line, O, $O+U$, U, and thereby associate every point of the line, of symbol $O+xU$, with a number, which we shall denote by x; and also take three other arbitrary points, denoting these by O', $O'+U'$, U', and thereby associate every point, $O'+x'U'$, with a number x'; what is the relation of the numbers x', x, when the symbols $O+xU$, $O'+x'U'$ refer to the same point? By denoting an arbitrary point by $O'+U'$, we have fixed the multiplier of the symbol U'; we have, therefore, syzygies

$$O' = mO + aU, \quad U' = bO + cU,$$

where m is arbitrary, and may be replaced by 1 unless O' coincides with U, but $m^{-1}a$, b, and c, are definite. Thence

$$O' + x'U' = mO + aU + x'(bO + cU), \ = (m + x'b)\,O + (a + x'c)\,U;$$

identifying this with $O+xU$, we have a relation connecting x and x'. We saw, in Chapter I, that, without assumption of Pappus' theorem, the iterative symbols, corresponding to the rational numbers of Arithmetic, are commutative in multiplication; the hypotheses of the present chapter involve Pappus' theorem, and therefore that the symbols of all the real points of the line recognised by these hypotheses, are also commutative in multiplication. We may, therefore, write

$$x = \frac{a + cx'}{m + bx'}, \quad x' = \frac{mx - a}{c - bx}.$$

In other words, the use of the fundamental points O', $O'+U'$, U', instead of O, $O+U$, U, leads to the substitution of x by a general linear (fractional) function of x, involving three coefficients.

Consider, now, two related ranges upon the line. By what we have seen, two such ranges are obtained in the most general way by taking three points O, E, U, of one range, to correspond, respectively, to three points, O', E', U', of the other. In particular, any set of four points, of the first range, which are in harmonic relation, gives rise to four points of the second range in similar relation. Thus, every point of the harmonic net constructed from O, E, U, corresponds to a point, constructed, with precisely similar steps, from O', E', U', belonging to the harmonic net built up from these. By using the symbols U, U' with proper multipliers, we can suppose the symbols E, E' to be such that $E = O + U$, and $E' = O' + U'$. Then the point $P = mO + nU$ corresponds to the point $P' = mO' + nU'$, where m, n are iterative symbols; and, hence, $P = O + xU$ corresponds to $P' = O' + xU'$, where x is the symbol for any real point of the line. When $O' = mO + aU$, $U' = bO + cU$, as above, this last is $P' = (m + xb)\,O + (a + xc)\,U$. Thus: *In order that a range of points* $P, = O + xU$, *for varying* x, *should be related to a range of points* P', $= O + yU$, *the symbols* x, y *must be connected by an equation of the form* $y = (cx + a)/(bx + m)$. By proper choice of c, a, b, m, it is possible, in this formula, to make three arbitrary points of the first range correspond, respectively, to three arbitrary points of the second; the formula appears thus to cover the case of every two possible related ranges.

Ex. 1. In the construction above given to prove the equable distribution of the points of a harmonic net, prove that the symbols of the various points may be supposed to be of the following forms, respectively,

$$X = A_1 + Y,\quad H = A_1 + 2Y,\quad J = A_1 - Y,\quad B_1 = A_1 - bY,\quad T = A_1 - tY,$$
$$U = (t+1)\,A_1 + tY,\quad C_1 = (c+1)\,A_1 + cY,\quad K = A_1 - cY,\quad L = A_1 + 2cY$$

leading to

$$\begin{aligned} D_1 &= (bc - c + b)\,A_1 + 2bcY \\ &= (b-1)\,c^2H + (c-b)\,L, \end{aligned}$$

the numbers of arithmetic belonging to the symbols c, t, b, 1, being such that

$$c > t > b > 1,$$

shewing that, then, the points are in the order required in the demonstration.

Ex. 2. In the Ex. 4, p. 84, of Section III of Chapter I, shew that it is impossible, consistently with the assumptions, in regard to order, adopted in this chapter, for the point $Q = O + a^2U$ to coincide with the point $O - U$, obtained as $(O, U)/E$. Give constructions for which $O + a^3U$ coincides with $O + U$, or $O - U$.

Ex. 3. If the points $O + x'U$, $O + xU$, be harmonic conjugates in regard to the points $O + aU$, $O + bU$, prove that

$$x' = [x\,(a+b) - 2ab] \div [2x - a - b].$$

Using the same letters for the associated numbers, deduce that

$$\frac{\partial x'}{\partial x} = -\frac{(a-b)^2}{(2x-a-b)^2},\quad \frac{\partial x'}{\partial b} = 2\,\frac{(x-a)^2}{(2x-a-b)^2};$$

these are in accordance with the two assumptions made for the proof of the equable distribution of the points of a harmonic net (above, p. 132).

Ex. 4. In the correspondence of p. 125, prove that the conditions (i), (ii) involve that if Q_0, corresponding to P_0, is in advance of P_0, and P_1 is the P-position whose corresponding Q is at P_0, then P_0 is in advance of P_1; and that, for every P between P_1 and Q_0, the corresponding Q is in advance of P.

CHAPTER III

ABSTRACT GEOMETRY, RESUMED

RELATED SPACES; JUSTIFICATION OF THE SYMBOLS. GEOMETRICAL ASSUMPTION FOR IMAGINARY ELEMENTS; REPLACEMENT OF IMAGINARY ELEMENTS BY SERIES OF REAL ELEMENTS

General discussion of the problems of this chapter. The preceding chapter has shewn how, by the recognition of the order of the real points of a line, and by adjunction of postulated points defined by constructions in a limited accessible space, we can build up a geometry in which, with a definite assumption as to the points existing upon a line, Pappus' theorem can be proved. The Real Geometry so arising may then be regarded as a particular case of the Abstract Geometry considered in Chapter I; it was seen that the algebraic symbols which arise in this Real Geometry are precisely similar, in their mutual relations, to the numbers of real arithmetic.

The present chapter is a continuation of Chapter I. It was there shewn that upon the Propositions of Incidence, and the assumption of Pappus' theorem, a theory of related ranges can be built, the correspondence of two such ranges being without ambiguity when three points of one are assigned to correspond to three points of the other. This establishes a corresponding theory for related flat pencils of lines in a plane, all passing through the same point, and for related axial pencils of planes in space, all passing through the same line. And it is, here, further, shewn that there follows from this a theory of two related planes, in which every point of either plane corresponds to a point of the other plane, and every line of either plane, with any range thereon, corresponds to a line of the other plane, with a range thereon which is related to the former; this correspondence, of the points of one plane to those of the other, is determined when *four* points of one plane, of which no three are in line, are assigned to correspond to four arbitrary points, of similar generality, in the other plane. Then, further still, it is shewn that there follows the possibility of a similar unique correspondence of the points of two threefold spaces, in which not only every point of either space corresponds to a definite point of the other, and every range of either space corresponds to a related range of the other space, but also every plane of either space, with the points and ranges thereon, corresponds to a definite plane of the other space which is related to the former plane, as regards its points and ranges, in the manner just described for two related planes; this correspondence is determined when *five* points of one of the two spaces, of which no four are in a plane, and, therefore, no three are in line, are assigned to correspond to five arbitrary points of similar generality in the other space. A similar theory of the correspondence of two n-fold spaces can be deduced, which is determined when $(n+2)$ points of one space, of general position, are assigned to correspond to $(n+2)$ points, of general position, of the other space.

There is, as we shall point out, an exact similarity between the condition necessary to fix the correspondence of the points of two spaces, and the condition necessary to fix the correspondence between the points of either of these spaces and the algebraic symbols by which these points are represented. To fix the correspondence between the points of a line and the symbols by which these points are represented, it is necessary to assign the symbols of three points of the line. This is a consequence of our initial assumption whereby a point by itself is represented as well by a symbol P as by a symbol mP, in which m is an arbitrary algebraic symbol; in what precedes we have frequently employed the remark, having denoted three arbitrary points of a line, respectively, by symbols A, B and $A+B$, thus fixing the multiplier of the symbol B with respect to that of A, and also the multiplier of the symbol of the third point. To fix the correspondence between the points of a plane and the symbols by which these points are represented, it is similarly necessary to assign the symbols of four points of the plane, the points being such that no three of them are in line, and the symbols, therefore, such that no three of them are in syzygy. It is the same for higher cases.

The symbolism is, then, in exact correspondence with the geometry, provided that, (1), to every geometric operation there corresponds a definite operation with the symbols; (2), to every operation with the symbols there corresponds a definite geometrical operation. That the former condition is satisfied follows from the initial descriptions of the use of the symbols; and the latter condition is satisfied for the fundamental laws of operation of the symbols (above, p. 74), each of which has been interpreted geometrically. The Abstract Geometry is not opposed to, but includes, as part of itself, the Real Geometry discussed in the last chapter, the symbols then appropriate being those iterative symbols, and those deduced from them, which correspond to the numbers of ordinary arithmetic. But now the way seems open to us, still further to generalise the Abstract Geometry, with the help of suggestions arising from the symbols themselves, using the words point, line, etc., in a proper sense consistent therewith.

We have in fact remarked (p. 66, above) the existence of a system of algebraic symbols, each formed with two numbers of ordinary arithmetic, which obey the laws of operation set out above, and are subject to the commutative law of multiplication; and these contain among themselves symbols corresponding to the numbers of ordinary arithmetic. These symbols, then, are a system appropriate to the Abstract Geometry, as so far developed, assuming Pappus' theorem. This system of symbols has, however, a possibility which we have not alluded to as yet: *to every symbol c, of the system, there corresponds a symbol z, such that $z^2=c$.* In fact, denoting any of the symbols of this system by (x, y), where x, y are numbers of ordinary arithmetic, we have $[(0, 1)]^2=[-1, 0]$, and, more generally, if $r=(x^2+y^2)^{\frac{1}{2}}$, $p=\frac{1}{2}(r+x)$, $q=\frac{1}{2}(r-x)$, then

$$(p^{\frac{1}{2}}, q^{\frac{1}{2}})^2=(x, y);$$

while, since $(-z)(-z)=z^2=(z)(z)$, beside any z satisfying $z^2=c$, there is also $-z$. Thus, in the geometry to which the symbols of this system are appropriate, the geometrical operation, previously given (p. 76), by which we pass from a point $O+zU$ to a point $O+z^2U$, must be capable of reversion in all cases; we must assign to the Abstract Geometry such points that, when $O+cU$ is a point, there is also a point $O+zU$, in which $z^2=c$. It will be shewn that a geometrical fact corresponding to this is that, if A, B, C be given points, and a, b, c be given lines, in a plane containing A, B, C, then it is possible to draw, in this plane, a line p through the point A, a line q through the point B, and a line r through the point C, so that the point (q, r), where the lines q and r intersect, lies on the line a, and, similarly, the point (r, p) lies on the line b, and the point (p, q) lies on the line c. Another geometrical fact corresponding to the algebraic condition, which, therefore, is geometrically reducible to the former, requires the notion of related ranges, which we have developed on the basis of Pappus' theorem. This theorem has been used to shew that, if two related ranges on the same line have *three* corresponding points in common, then they coincide entirely. In the Real Geometry two such related ranges may, however, have *two* corresponding points in common; for instance, it may be shewn, by the assumptions employed in the last chapter, that a *sufficient* condition for this, when the points A, B, C of one range correspond respectively to the points A', B', C' of the other, is that the order ABC should be opposite to the order $A'B'C'$. The geometrical fact now referred to, for the case of the Abstract Geometry represented by the system of symbols now being considered, is that two related ranges on the same line, which do not coincide entirely, *always have two corresponding points in common*, which, however, may coincide with one another in particular cases. We shall give the geometrical deduction of this geometrical fact from the former, relating to three given points and three given lines. It is clear from what has been proved (cf. pp. 18, 129), that a still further way of stating a geometrical fact equivalent to the above, would be to assume that four lines in threefold space, of which no two intersect, have always two common transversals. Though this is clear by the intervention of the theory of related ranges, it will be proper to reduce it directly to the previously stated theorem for three given points and three given lines. This last theorem, though not considered by Steiner in this general way, we shall refer to, for the sake of brevity, as Steiner's theorem. (See Steiner's *Gesamm. Werke*, Vol. I, pp. 303—305, where reference is made to papers by Servois, Gergonne and L'huilier, in Vol. II, 1811, 1812, of the *Annales de Mathématiques.*)

When we extend the Abstract Geometry in accordance with the suggestions of the system of algebraic symbols above referred to, or in some other way that may prove possible, two questions naturally arise: (1), Is there any geometrical utility in this extension? (2), Is it legitimate to use the postulated properties of the abstract points, lines, etc., in order to prove relations existing among the real points, lines, etc., that is, relations which can be stated without any reference to the abstract elements? The former question is analogous to the question: Is there any utility, for the purposes of the calculus of real numbers, in the introduction of complex numbers? And, as in that case, it may be said, briefly, that experience has amply shewn that the gain in the generality of the statements of geometrical fact, and the increased power of recognising the properties of a geometrical figure, enormously outweigh the initial feeling of artificiality and abstractness[1]. The second question may perhaps be made clearer by reference to two simple examples: (1) By the use of complex numbers it is easy to prove that a polynomial of the form $x^{2n} - 2x^n \cos n\theta + 1$ is the product of quadratic factors of the form $x^2 - 2x \cos (\theta + 2k\pi/n) + 1$, where n is a positive integer and k has one of the values $0, 1, \ldots, (n-1)$. In this theorem, x may be a real number, and θ a real angle whose cosine is determined by constructions made with only real points. Is then this result, for real numbers only, legitimately proved by the use of complex numbers? And, if so, does this proof involve that it must be possible to prove the theorem with the use of real numbers only? (as in fact it is). This example, though referring to matters outside our plan, is given as having been of interest to eminent mathematicians. (2) Another example is of directly geometrical importance; but involves some anticipation of succeeding work. As we shall see, for the curve which is called a conic section, if A, B, C, A', B', C' be any six points of the curve, the three point intersections, of pairs of joins of these points, represented, respectively, by $(BC', B'C)$, $(CA', C'A)$ and $(AB', A'B)$, lie on a line. Of this theorem, in fact, Pappus' theorem is a particular case, namely when the conic section degenerates into two lines containing, respectively, the points A, B, C and A', B', C'. It is possible to establish, for the points of a conic section, a theory of related ranges precisely like the theory of related ranges on a line; and, as in that case, three points of a range assigned as corresponding to three given points of another range, suffice to determine the correspondence of other pairs of two points, belonging to these ranges, respectively. Suppose then we establish two related ranges upon the conic, in which the points A, B, C, of one range, correspond, respectively, to the points A', B', C' of the other. Then it may, or may not, happen, that upon the conic, regarded as a locus of real points, there are two points, U, V, each of which, regarded as belonging to one range, corresponds to itself, regarded as belonging to the other range. When these points U, V are existent, as real points, the theorem above stated can be proved at once; the line of the theorem is then, in fact, the join of the points U and V. The question, of which the theorem is to serve as an example, becomes then: Is the theorem then necessarily true, without further proof, when the points U, V do not exist as real points? and can a proof be devised for this case which shall only employ real points? In the Abstract Geometry, the points U, V always exist, and a proof of the theorem may be given identical in form with that which is valid in the real geometry: does this suffice to prove the theorem for the Real Geometry when the points U, V do not exist?

---

[1] Cayley's remarks may be quoted (Presidential Address, Brit. Assoc., 1883, Collected Papers, xi, 434): "The notion which is really the fundamental one (and I cannot too strongly emphasize the assertion), underlying and pervading the whole of modern analysis and geometry, that of imaginary magnitude in analysis, and of imaginary space (or of space as a *locus in quo* of imaginary points and figures) in geometry."

The opening words of the brief *Vorwort* of von Staudt's *Beiträge zur Geometrie der Lage* (Erlangen, 1856) may also be quoted: "Indem die Mathematik darnach strebt, Ausnahmen von Regeln zu beseitigen und verschiedene Sätze aus einem Gesichtspunkte aufzufassen, wird sie häufig genöthigt, Begriffe zu erweitern oder neue Begriffe aufzustellen, was beinahe immer einen Fortschritt in der Wissenschaft bezeichnet. Dahin gehört namentlich die Einführung von imaginären Grössen in der Analysis und die Einführung von imaginären Elementen in der Geometrie."

Some of the objections raised to the original introduction of complex numbers in Geometry and Analysis are very interesting to read. Many references to the early literature are given by Cayley, *On multiple algebra*, Coll. Papers, xii, 466. A single reference additional to these is Caspar Wessel, *Essai sur la représentation analytique de la direction*, Kopenhagen, 1799.

The question is an old one. The reader may compare the discussion of Kepler's ideas, and of the Principle of Continuity, in Ch. Taylor, *Ancient and Modern Geometry of Conics*, Cambridge, 1881, p. lviii, etc.

In a less concrete form, the matter may be stated thus: We have a set of entities, $a, b, c, \ldots$, subject to certain laws of combination; we have also another set of entities, $A, B, C, \ldots, A', B', C', \ldots$, subject to certain laws of combination; these laws will include laws for the combination of $A, B, C, \ldots$ among themselves alone, as well as laws for the combination of the whole aggregate $A, B, C, \ldots, A', B', C', \ldots$, when some of $A', B', C', \ldots$ enter. Suppose now that to every law for the combination of $A, B, C, \ldots$ among themselves alone, there corresponds a precisely similar law for the combination of $a, b, c, \ldots$ among themselves, *and conversely*. Then any theorem concerning $A, B, C, \ldots$ alone, which is obtainable logically by the application of the laws of combination which relate to $A, B, C, \ldots$ alone, is equally true for $a, b, c, \ldots$, being obtainable from the laws of combination of $a, b, c, \ldots$ by exactly similar logical processes. Now it may very well happen that a theorem relating to $A, B, C, \ldots$ alone, is easier to prove when regarded as a theorem for particular entities of the whole aggregate $A, B, C, \ldots, A', B', C', \ldots$, the natural method of proof being one which employs not only the laws of combination of $A, B, C, \ldots$ among themselves alone, but also the laws relating to the whole aggregate, using, in its course, one at least of the entities $A', B', C', \ldots$. The question then is, does such a method of proof establish the corresponding theorem for $a, b, c, \ldots$? And can a method of proof be, therefore, devised, employing only the laws of combination of these alone?

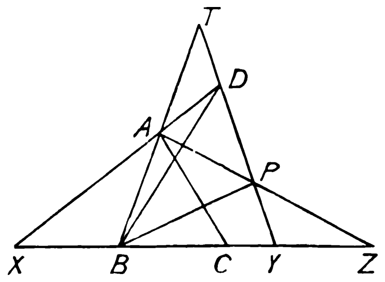
In the former of the two examples quoted above, the entities $a, b, c, \ldots$ are the real numbers; the entities $A, B, C, \ldots, A', B', C', \ldots$ are the complex numbers; each of these, we know, is representable as a couple, (x, y), of two real numbers, and among these are the couples $(x, 0)$ whose laws of combination among themselves are precisely similar to those of the real numbers. These couples $(x, 0)$, whose second element is zero, are the entities $A, B, C, \ldots$ of our abstract formulation of the question; the entities $A', B', C', \ldots$ are those complex numbers, (x, y), for which y is not zero, among which is the number $(0, 1)$ whose square is equal to $(-1, 0)$. In the latter of the two examples discussed above, the entities $a, b, c, \ldots$ are the real points, lines, etc., of a Real Geometry, widened by the introduction of the postulated points, lines, etc. The entities $A, B, C, \ldots, A', B', C', \ldots$ are the elements called points, lines, etc. in the Abstract Geometry, among which are elements $A, B, C, \ldots$ (associable with the iterative symbols and those derived from them, which behave like the real numbers of ordinary arithmetic) whose laws of combination and mutual relations (as to order, etc.) are precisely similar to those of the elements of the Real Geometry.

When stated in this abstract form, the question at issue would seem to evaporate. To say that a theorem, which may have been proved with mention of elements $A', B', C', \ldots$, relates to $A, B, C, \ldots$ alone, must mean that the theorem is a logical consequence of the laws of combination of these among themselves alone; it must therefore be capable of proof with only the use of these laws, provided sufficient ingenuity be forthcoming. That such a constructive faculty of ingenuity is indispensable to any fruitful combination of the preliminary formal laws of combination of the entities of mathematics, is a familiar experience of the study of mathematics; and an explicit recognition of this fact should not seem out of place in discussing such a question as that before us. When however the proof is found which can be stated in terms of $A, B, C, \ldots$, and their laws of combination, alone, an identical proof is possible for the corresponding theorem relating to $a, b, c, \ldots$. That the theorem may have been originally found by considerations in which the elements $A', B', C', \ldots$, were involved, as well as $A, B, C, \ldots$, thus does not affect the truth of the theorem for $a, b, c, \ldots$. But the introduction of the elements $A', B', C', \ldots$ may well have assisted the constructive faculty to which reference has been made; that this may happen is, indeed, one of the discoveries of the history of reasoning. The argument is not invalidated by the fact that the elements $A', B', C', \ldots$, in their first conception, may be creations of a judicious imagination; so regarded, they may be called abstract elements, and then the elements $A, B, C, \ldots$, as forming part of an aggregate containing $A', B', C', \ldots$, may equally be regarded as abstract, though framed to have the same relations with one another as have the elements $a, b, c, \ldots$.

The importance, and wide bearing, of the matter, seem to call for the indications, which have been given, of the argument by which the attitude we adopt is to be justified. There is however another way in which the use of so-called imaginary elements in geometry may be justified. As complex numbers may be introduced in arithmetic, each as a pair of real numbers, so aggregates of real elements may be introduced in the Real Geometry—if such aggregates can be discovered—whose laws of combination among themselves, and with the existing real elements, shall be those which we ascribe to the imaginary elements. Then such aggregates may be used in place of the imaginary elements; any proposition which we should otherwise state for the imaginary elements, becomes then a proposition for aggregates of real elements, capable of proof by real geometry only. And no doubt arises that a result thereby found, relating to the original real elements only, may not be true. It must always remain a striking monument to Karl Georg Christian von Staudt, that he should have elaborated, on a descriptive basis, a theory of aggregates, of real geometrical elements, with the necessary properties (with which should be compared the, frankly metrical and less complete, work of Chasles, *Géométrie supérieure*, esp. Ch. v and Ch. xxxiii). Such a theory does not raise the same logical difficulties as that spoken of above; but, setting aside the necessary prolixity of shewing that the system itself is logical, it should not be out of place to recognise explicitly that the proof of any property of these real aggregates, by the methods of real geometry, is often hard to find; it is often easier to use the language, if not the associated symbolism, of the abstract geometry. When such a theory as von Staudt's has been established this is logically allowable, if it is preferred to such a frank recognition of abstract elements as is suggested above. However this may be, the properties of such aggregates of real elements are interesting in themselves; and we give some account of them, choosing for this purpose a scheme elaborated since von Staudt's time.

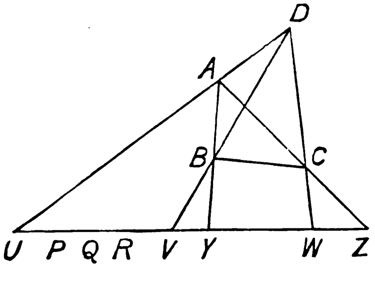
Theory of two related plane systems. Suppose two planes, ϖ, ϖ', to be given; and, in one of these, four points, A, B, C, D, which do not lie in line, there being also, in the other plane, four points, A', B', C', D', given, not lying in line. As has been indicated, we agree to say that two flat pencils, each consisting of lines through a point lying in a plane, are related to one another, when the range of points, determined by the former pencil of lines upon an arbitrary transversal, is related to the range similarly determined by the latter pencil upon any transversal. Here, as in what follows, unless the contrary be said, we are assuming Pappus' theorem. If, then, in the former plane, ϖ, any line, l, be drawn through D, a definite line, l', in the plane ϖ', passing through D', is determined, corresponding to l, by the condition that the flat pencil of four lines, $D'A'$, $D'B'$, $D'C'$, l', shall be related to the pencil of four lines, DA, DB, DC, l. In the same way, to any line drawn, in the plane ϖ, through the point A, we can make correspond a definite line, drawn, in the plane ϖ', through the point A'; and similarly for lines drawn through B and B', and for lines drawn through C and C'.

Hence, if P be any point of the plane ϖ, and we draw the lines DP, AP, and then, in the plane ϖ', we draw the lines, through D' and A', corresponding, respectively, to the lines DP, AP, in the sense just explained, we obtain, by the intersection of these, a point, P', of the plane ϖ'. It can be shewn that, then, the lines $B'P'$ and $C'P'$ also correspond, respectively, to BP and CP, in the sense just explained. For, in the plane ϖ, let the lines DA, DP, AP meet the line BC, in the points X, Y, Z, respectively, and let DP meet AB in the point T. The pencil of lines, with D as centre, passing, respectively, to B, C, A, P, is in perspective with the range B, C, X, Y. As this pencil of lines is related to the corresponding pencil of the plane ϖ', it follows that the range B, C, X, Y is related to the range obtained by similar construction in the plane ϖ'. The same may be said of the range B, C, X, Z, which lies on lines from A passing, respectively, to the points B, C, D, P. We have shewn that, if we assume Pappus' theorem, as we do, here, and in the following work, two ranges are uniquely related by the assignment of three points of one to correspond to three points of the other. Thus, as B, C, X, Y and B, C, X, Z have the three points B, C, X in common, it follows that the range B, C, X, Y, Z is related to the similarly constructed range of the plane ϖ'. However, the points of this range, B, Y, X, Z, by perspective from A, give rise to the points T, Y, D, P, respectively, and these lie on the lines from B, respectively, to the points A,C,D,P; the pencil $B\,(A, C, D, P)$ is, thus, related to the similar pencil $B'\,(A', C', D', P')$ of the plane ϖ'. A similar proof shews that the pencil $C'\,(A', B', D', P')$ is related to the pencil $C\,(A, B, D, P)$.



It can, next, be shewn that to any range of points, lying on a line of the plane ϖ, there corresponds, by the construction used to determine P' from P, a range of points lying on a line of the plane ϖ', and that this range is related to the former. For this, we shew that, if P, Q, R be three points of the plane ϖ, lying in line, and if P', Q' be the points of the plane ϖ' which correspond, respectively, to P and Q, then there is, upon the line $P'Q'$ a point, R', similarly corresponding to R. Let the points where the line PQ is met by the lines DA, DB, DC, respectively, be called U, V and W; and, similarly, the points where $P'Q'$ is met by $D'A'$, $D'B'$, $D'C'$ be called U', V' and W'. Then, by what has been said, the range (U', V', W', P') is related to the range (U, V, W, P), and the range (U', V', W', Q') is related to (U, V, W, Q); hence the range (U', V', W', P', Q') is related to (U, V, W, P, Q). And to the point R, of the line PQ, regarded as a point of the range (U, V, W, P, Q, R), will correspond a point, R_1', of the line $P'Q'$, such that the range $(U', V', W', P', Q', R_1')$ is related to the former; we are to shew that this point R_1' is the same as the point, R', constructed, with the help of A', B', C', D', to correspond to R. Let AB, AC meet the line PQ, respectively, in Y and Z, and $A'B'$, $A'C'$ meet $P'Q'$ in

Y', Z'. Then, by the original construction, by perspective from A, the range (U', P', Q', Y', Z') is related to (U, P, Q, Y, Z); and, therefore, as three points suffice to identify a range which is related to another, the range $(U', V', W', P', Q', R_1', Y', Z')$ is related to (U, V, W, P, Q, R, Y, Z). Thus the point R_1' satisfies the condition which is to be satisfied by R' with regard to pencils of lines whose centre is A', and also with regard to pencils of lines whose centre is D'. These two are sufficient to identify R_1' with R'. There is thus a range $P'Q'R'$... in the plane ϖ' which is related to the arbitrary range PQR... in the plane ϖ, as we desired to prove. From this it is easy to deduce that there is a pencil of lines, passing through a point, in the plane ϖ', which is related to any such pencil of the plane ϖ.

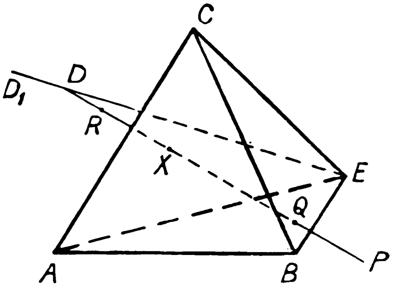


The plane systems, in ϖ and ϖ', so constructed, will be said to be *related*. The assumption made that, given DA, DB, DC, l, in one plane, and $D'A'$, $D'B'$, $D'C'$, in the other, then l' is determinate, is to be noticed.

Two related threefold systems, or spaces. A similar correspondence may be set up between the points, lines and planes of two three-dimensioned spaces, Σ and Σ', by taking any five points A', B', C', D', E' of the space Σ', of which no four lie in a plane, to correspond, respectively, to five arbitrary points A, B, C, D, E, of similar generality, in the space Σ.

There is a preliminary point to which a word may be given. In establishing a correspondence between two planes, we have presupposed a construction possible by which ranges on two lines, in these planes respectively, may be related to one another; this is certainly so when the planes lie in the same threefold space. But in comparing two threefold spaces, the presupposition must be a definite one; in the absence of a briefer general method, we may suppose the two threefold spaces to be both contained in a higher space, and ranges lying therein to be related by a chain of perspectivities, as in the foregoing theory, in Chapter I. When ranges belonging to the two spaces have been related, plane pencils of lines, and axial pencils of planes, can be related, by the ranges they determine on a transversal. In particular, however, the two threefold spaces may be the same.

This being understood, let ϖ be any plane through the line BC of the space Σ; with the planes joining BC to the points A, D, E, we then have an axial pencil of four planes. The planes, in the space Σ', which join $B'C'$ to A', D', E' respectively, taken with a plane, ϖ', through $B'C'$, in this space, form another axial pencil; and the plane ϖ' is determined to correspond to ϖ when we suppose it taken so that these two axial pencils of planes are related. Now let the line DE meet the plane ABC in the point D_1, and, similarly, the line $D'E'$ meet the plane $A'B'C'$ in the point D_1'; then, suppose the planes ABC and $A'B'C'$ related to one another, as in the preceding article, by the condition that the points A, B, C, D_1 shall correspond, respectively, to A', B', C', D_1'; and let P' be the point of the plane $A'B'C'$ so corresponding to a point P of the plane ABC. Next, let the planes BCE and $B'C'E'$, in the spaces Σ and Σ', meet DP and $D'P'$, respectively, in Q and Q'; and, corresponding to any point R taken upon the line DP, let R' be the point of the line $D'P'$ determined by the condition that the ranges $P\,Q'R'D'$, $PQRD$ shall be related. Then R' is such that the two axial pencils, each of four planes, in the spaces Σ' and Σ, represented, respectively, by $B'C'$ (A', E', R', D') and BC (A, E, R, D), with axes $B'C'$ and BC, are related to one another. The axial pencils represented, respectively, by $A'D'$ (B', C', E', R') and AD (B, C, E, R) are also related, since, on the planes $A'B'C'$ and ABC, these give, respectively, the flat pencils A' (B', C', D_1', P') and A (B, C, D_1, P), of centres A' and A; and, by construction, the plane systems, (A, B, C, D_1, P) and (A', B', C', D_1', P'), are related. The five given points A, B, C, D, E lead to ten lines joining pairs of these; by passing through each of these joining lines a plane, to the other three of the five given points, and to the point R, we obtain eight axial pencils, each of four planes, beside the two we have considered having BC and AD for axes. It can be shewn that every one of these is related to the axial pencil similarly constructed in the space Σ'. Consider, for instance, the axial pencil CA (B, D, E, R), of axis CA. The point P is on the plane ABC, and the point Q is on the plane BCE; let the line DP meet the plane ACE in the point X. The axial pencil CA (B, D, E, R) gives, on the line DP, the range (P, D, X, R). The line ED meets the plane CAB in the point D_1. Thus, the range (P, D, X, Q), being a section of the axial pencil CE (P, D, A, B), of which a plane section is the flat pencil C (P, D_1, A, B), is related to this flat pencil; and this, by construction, is related to the corresponding flat pencil C' (P', D_1', A', B') of the space Σ'. Wherefore the range (P, D, X, Q) is related to the corresponding range $(P', D'\ X', Q')$ of the space Σ'. By definition of R', however, the



range (P, D, Q, R) is related to the corresponding range (P', D', Q', R'); as (P, D, X, Q) and (P, D, Q, R) have the three points P, D, Q in common, we infer that the range (P, D, X, Q, R) is related to the corresponding range (P', D', X', Q', R'). We have seen, however, that the range (P, D, X, R) is a section of the axial pencil CA (B, D, E, R). This axial pencil is thus related to the corresponding axial pencil $C'A'$ (B', D', E', R'), of the space Σ', as we desired to shew. The range (D, X, Q, R) is also a section of the axial pencil EC (D, A, B, R), which is, therefore, related to the corresponding axial pencil $E'C'$ (D', A', B', R').

The point R is any point of the line DP, and P is any point of the plane ABC; thus the point R is any point of the threefold space A, B, C, D, E. With the proof of the theorem above stated, that the ten axial pencils of planes whose axes are the joins of pairs of the points A, B, C, D, E, each pencil containing a plane passing through R, are related, respectively, to the corresponding axial pencils in the space Σ', there is thus established a correspondence between the points of the spaces Σ and Σ'. It can then be shewn, in a manner analogous to that adopted for the case of two planes, that a range of four points lying in line in the space Σ corresponds to a related range of four points lying in line in the space Σ'; and then that a set of five points lying in a plane in the space Σ gives rise to a set of five points lying in a plane in the space Σ', in such a way that the pencil of lines joining one of the five points to the other four, in Σ, is related to the corresponding pencil in Σ'.

Case of two spaces both of n dimensions. And the argument can, it appears, be extended, by the method of induction, to two spaces of any number of dimensions, it being necessary and sufficient, in order that two n-fold spaces should be related, that $(n+2)$ points of one space, of general position, be assigned to correspond to $(n+2)$ points of the other, also of general position; and also a range in one space related to a range in the other. See Note I, at the end of the Volume.

Comparison of the correspondence between two spaces with the correspondence between either space and the symbols used to represent it. The correspondence in the three foregoing articles is established by purely geometrical considerations, based on the Propositions of Incidence, and the assumption of Pappus' theorem. When two spaces are so related to one another, either may be regarded as representative of the other, there being a geometrical incidence, or theorem, in either, corresponding to any geometrical incidence, or theorem, in the other. Conversely two spaces, in which are given two related ranges, one in each, which are such that, to every incidence of elements in one space corresponds a precisely similar incidence of elements in the other, are necessarily related, as we see by recalling the construction of two related ranges. Now compare, with this correspondence between two spaces, the correspondence we have sought to set up between one of these spaces, and the realm of the symbolism we have introduced to represent this space (Chap. I, Section III). To every element, or incidence of elements, in the space, corresponds a symbol, or agreement of two symbols, in the algebraic realm; and, conversely, to every fundamental identity (law of operation) between the symbols, and, hence, to every derived identity, corresponds a coincidence of points in the space, as we have shewn in detail. Moreover the *freedom* in the establishment of the correspondence between the related spaces, that $(n+2)$ points of one space may be chosen arbitrarily to correspond to $(n+2)$ points of the other, agrees with the circumstance that, to fix the symbol of every point of the space, the symbols of $(n+2)$ of its points must be assigned, although these $(n+2)$ symbols will be in syzygy. This condition is, in part, to be compared with the fundamental proviso that the dimensions of the two spaces must be the same; but is vital in order that the points referred to, in the statement that every identity of symbols corresponds to a coincidence of points, shall be without ambiguity; this however requires also, in the case of the abstract points not corresponding to iterative symbols, that the correspondence of the symbols and points be supposed assigned for all the points of one line of the space. See Note I, at the end of the Volume.

For the points of a line, in order to be able to assign a definite symbol to every point, it is necessary that the symbols belonging to three points of the line should be assigned. If A, B be two points of the line, the former of these may, by the rules given for the symbols, be represented either by a symbol A, or by a symbol mA, where m is any one of the algebraic symbols. Thus the symbol for a general point of the line, $A+xB$, is incapable of identifying a particular point, since it might equally have arisen in the form $mA+xnB$, where m, n are any two of the algebraic symbols; this is the same as $A+m^{-1}nxB$, since, with Pappus' theorem, the algebraic symbols are commutative in multiplication. If, however, the symbol be given which is to belong to a third definite point of the line, say $A+x_0B$, with a definite symbol for x_0, this suffices to fix the previously unspecified factor $m^{-1}n$. Then every point of the line has a definite symbol; and, conversely, we suppose there exists on the line the point corresponding to every symbol $A+xB$ which can arise by the operations to which these algebraic symbols are liable. That the condition secures the same kind of definiteness as is involved in distinguishing between two related ranges, may be well illustrated by proving the following result, of which frequent use is made subsequently: *The condition that four points of a line represented, respectively, by symbols A, B, $A + xB$, $A + yB$, should be a range related to that of four points, on the same or on another line, which have symbols P, Q, $P + pQ$, $P + qQ$, is that* $yx^{-1} = qp^{-1}$. In accordance with our conventions, this is the same, writing B for xB, and Q for pQ, as saying that the condition that the range of four points represented, respectively, by A, B, $A + B$, $A + \xi B$, should be related to the range of four points represented, respectively, by P, Q, $P + Q$, $P + \sigma Q$, is that $\xi = \sigma$. This is in accordance with the comparison we have made between the condition that two ranges should be related, and the condition that the points of a range should be represented by the symbols. To prove the result, when the two ranges are on non-intersecting lines in three dimensions, let the four joins of the corresponding points, of A to P, of B to Q, of $A + B$ to $P + Q$, and of $A + \xi B$ to $P + \sigma Q$, be met by another line, respectively, in points with symbols $A + \lambda P$, $B + \mu Q$, U and V. As the point U is then a derivative of $A + B$ and $P + Q$, as well as of $A + \lambda P$ and $B + \mu Q$, we infer $\lambda = \mu$, and $U = A + B + \lambda (P + Q)$. As V is a derivative as well of $A + \xi B$ and $P + \sigma Q$ as of $A + \lambda P$ and $B + \lambda Q$, the symbol $A + \xi B + \kappa (P + \sigma Q)$ must, for proper κ, be the same as $A + \lambda P + \xi (B + \lambda Q)$, so that $\kappa = \lambda$, and hence $\lambda\sigma = \xi\lambda$. This gives[1], as stated, $\sigma = \xi$. The symbols are assumed commutative in multiplication, without which, as was shewn in Chapter I, there is not definiteness in the condition that two ranges be related.

For the points of a plane, to render unique the correspondence between the symbols and the points, it is necessary to distinguish between the symbols A, B, C of three fundamental points of the plane, and, respectively, the symbols of the forms lA, mB, nC, which represent the same points. And this can be done by providing that in the symbol $xA + yB + zC$, belonging to a chosen definite point of the plane, the symbols $x^{-1}y$, $x^{-1}z$ shall have stated values. Very often the most convenient way of doing this is, to select the point to which the symbol $A + B + C$ is to be attached. As will be seen later, in dealing with the theory of linear transformations, the plane system of which the points are represented by symbols $xlA + ymB + znC$, wherein l, m, n are the same for all points, is related to the plane system of which the points are represented by symbols $xA + yB + zC$, wherein x, y, z vary from point to point.

---

[1] So that, as was remarked (above, p. 93), when approached from this point of view, von Staudt's introduction of numbers, to represent Würfen, or ranges of four points on a line, involves the assumption of Pappus' Theorem. For, without this Theorem, we have shewn that the range B, A, $B + \mu^{-1} A$, $B + \lambda^{-1} A$ is related to the range A, B, $A + \lambda B$, $A + \mu B$; and $\mu\lambda^{-1} = \lambda^{-1}\mu$ requires $\lambda\mu = \mu\lambda$.

Similar remarks evidently apply whatever be the number of dimensions of the space considered.

A geometrical existence theorem for the solution of an algebraic equation. The preceding article is concerned with the justification of the use of algebraic symbols of any generality which are subject to the laws of combination set out in detail in Section III of Chapter I, together with that of commutative multiplication. As indicated in the discussion at the beginning of this chapter, there is a quite definite system of symbols with these properties which has the further property of containing, corresponding to any one of its members, c, another member, z, which is such that $z^2 = c$. It is desirable then to examine the geometrical meaning of this. If this system of symbols be that which is adopted as guide in formulating the properties of the *points*, *lines*, etc., which we finally adopt as the elements of the Abstract Geometry, it is convenient to summarise these properties, if possible, by enunciating a geometrical construction which can be carried out with the abstract elements, or by stating a theorem which holds when these elements are allowed.

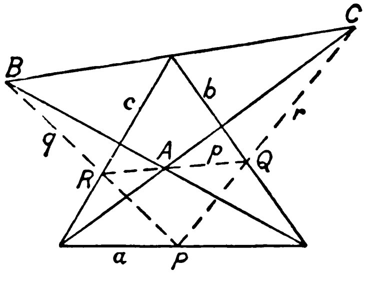
With this object we turn now to a geometrical problem, which we consider, in the first instance, in an elementary way; shewing how it is related to other problems whose fundamental importance may be, at first sight, more obvious:

In a plane, we are given three points, A, B, C, and three lines, a, b, c. It is required to draw three lines, p, q, r, passing, respectively, through the points A, B and C, whose points of intersection in pairs, namely P, of q and r, Q, of r and p, and R of p and q, shall lie, respectively, on the lines a, b, and c. In this case, the lines joining the pairs of points, namely p, of Q to R, q, of R to P, and r, of P to Q, pass, respectively, through the points A, B, and C. Thus the problem is one of a self-dual character.

We arrange our considerations under nine headings:

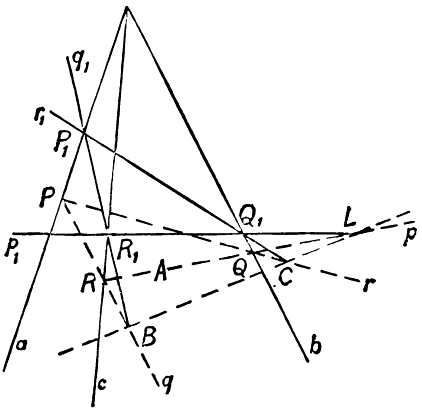
(i) There is an infinite number of solutions of the problem when the lines BC, CA, and AB, pass, respectively, through the points (b, c), (c, a), and (a, b). This is, in fact, another statement of Pappus' theorem.

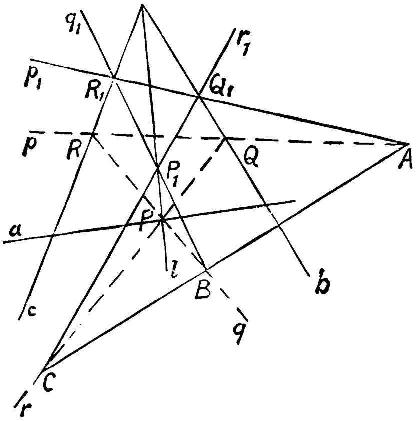
It can be shewn, when no one of the points A, B, C lies on any of the lines a, b, c, and A, B, C are not in line, that this is the only case in which there is an infinite number of solutions of the problem.



(ii) When the points A, B, C are in line, a degenerate solution of the problem is that in which the lines p, q, r all coincide in this line; in this case, another solution can be directly constructed. And dually.

In the first case, when the points A, B, C are in line, draw through A any line, p_1, meeting the lines b and c, respectively, in Q_1 and R_1, and let the lines CQ_1 and BR_1 intersect in the point P_1. Make a similar construction with a line, p_2, drawn through A, so obtaining a point P_2. Then, let the line P_1P_2, or l, which contains (b, c), meet the line a in the point P. It will be seen that, if the lines CP, BP be now drawn to meet the lines b and c, respectively, in Q and R, then the line QR passes through the point A, and we



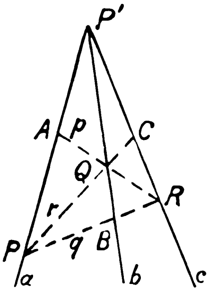


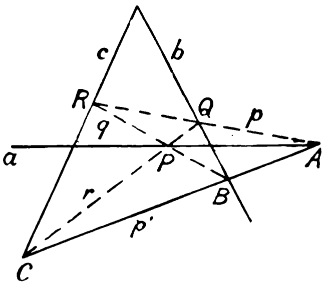
have a solution of the problem. A similar construction is valid for the reciprocal case, starting with points, P_1 and P_2, taken anywhere on the line a; the lines, p_1 and p_2, reciprocal to P_1 and P_2, intersect in a point L, lying on BC; the required line, p, is the line AL.

The proof of the statements made is immediate from Desargues' theorem. In the former case, the corresponding joins of points of the two triads P_1, Q_1, R_1 and P_2, Q_2, R_2, meet in the points A, B, C, respectively, which are in line. Hence the join P_1P_2 passes through the point (b, c), which is the intersection of Q_1Q_2 and R_1R_2. And then, as the lines, PP_1, QQ_1 and RR_1, meet in the point (b, c), it follows, from the triads P, Q, R and P_1, Q_1, R_1, that the lines QR and Q_1R_1 meet on the line BC, in the point A. The proof in the latter case is the reciprocal of this.

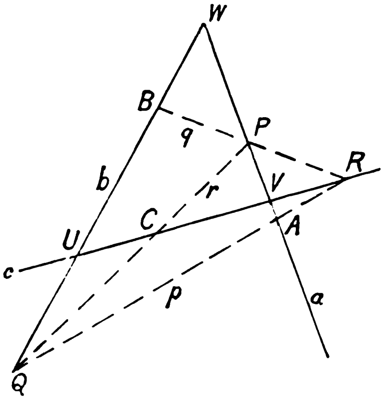
When A, B, C are in line, and, also, a, b, c meet in a point, the degenerate solutions are the only ones, unless, under a certain condition, there is an infinite number of solutions.

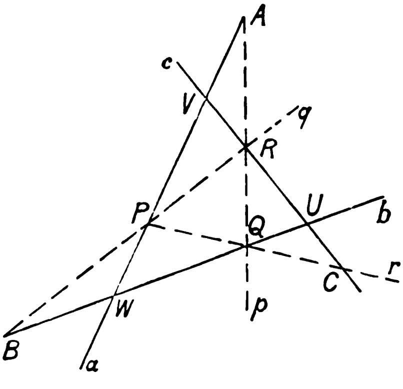
A particular case of the figure arises when the points A, B and C lie, respectively, on the lines a, b and c. Then it is easy to see that the points P, Q, R are harmonic conjugates, respectively, of A, B, C, in regard to the respective couples of lines b and c, c and a, a and b. If the line ABC be denoted by p', then the lines p and p' are harmonic conjugates in regard to the line a and the line joining the points A and (b, c), etc.





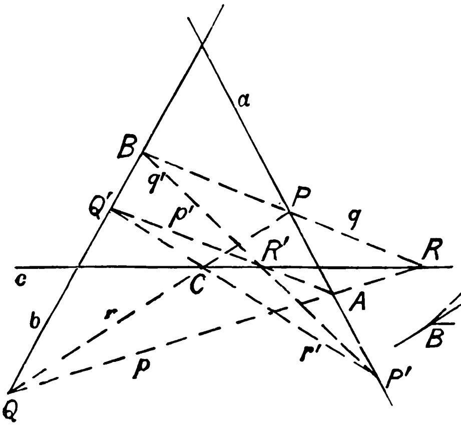
(iii) The simplest, and, as will be seen, the most fundamental of the cases in which the lines p, q, r cannot be directly constructed, is that, in which the points A, B, C lie, respectively, on the lines a, b, c, but are not in line. When this is so, it can be seen, by considerations of betweenness, such as are used in Chapter II, that, in the Real Geometry, there exist lines p, q, r provided the points A, B, C have suitably limited positions. If the points (b, c), (c, a) and (a, b) be denoted, respectively, by U, V and W, this is so when A, B and C are outside the respective segments VW, WU and UV; or when one of them is outside and the other two are inside these segments, respectively.

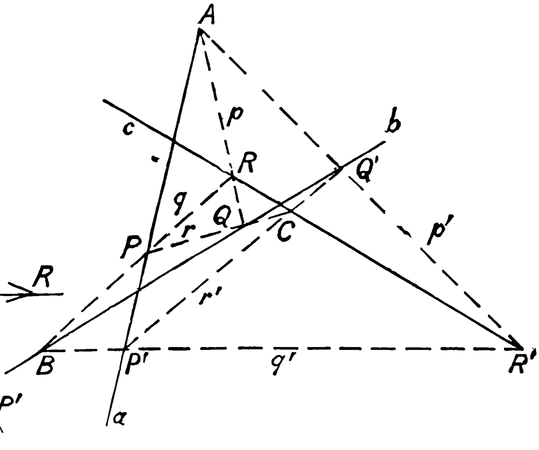




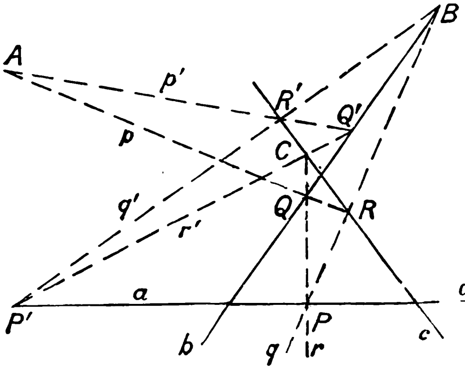
For in the former case, if two lines, p_1 and p_2, be drawn, through the point A, to meet the line b, respectively, in the points Q_1 and Q_2, and these meet the line c, respectively, in R_1 and R_2, in such a way that UR_1R_2V are in order, then also UQ_1Q_2W will be in order. If then BR_1 and CQ_1 meet the line a, respectively, in H_1 and K_1, and BR_2, CQ_2 meet a, respectively, in H_2, K_2, it follows that WH_1H_2V are in order, and that WK_2K_1V are in order. By use of the Dedekind suggestion, as in Chapter II, it can thence be shewn that there is a position of R_2 for which H_2 and K_2 coincide, say in P_2. A similar argument is applicable to the case, for instance, in which B is within the segment WU, and C within the segment UV, but A is without the segment VW, and to the other two such cases. The reciprocal figure, it is easily seen, leads, essentially, to the same results.

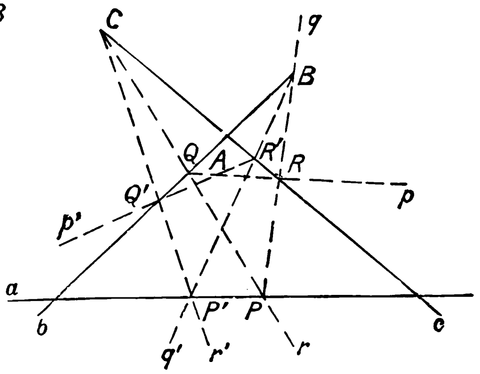
When we have one possible set of positions for P, Q, R, solving the problem, another set can be deduced at once; namely, by taking, in place of P, the point, P', which is the harmonic conjugate of P in regard to V and W, or, say, $P' = (V, W)/P$, and taking, at the same time, $Q' = (W, U)/Q$ and $R' = (U, V)/R$.





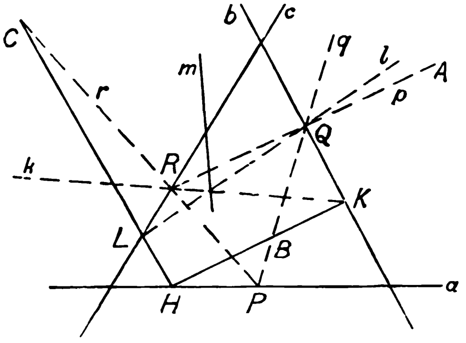
(iv) Another case which is worthy of special mention is that in which the points B and C lie on the lines b and c, respectively, but A does not lie on a.





It will be seen below that the solution in this case can be constructed from that considered under (iii).

(v) The case in which the points A, B, C have arbitrary positions can be reduced to that preceding, in which two of the points, B and C, lie on their respectively associated lines, b and c.



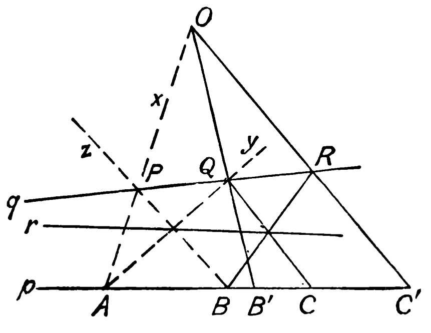
The given lines a, b, c, and the given points, B, C, define a line, m, as follows: taking arbitrary points H, H', H'', ..., on the line a, let the joins of these to the point B, namely the lines HB, $H'B$, $H''B$, ..., meet the line b in the respective points K, K', K'', ..., and the joins of these to the point C, namely the lines HC, $H'C$, $H''C$, ..., meet the line c in the respective points L, L', L'', ...; the two ranges, K, K', K'', ..., and L, L', L'', ..., are then related. Therefore, as was proved in Chapter I, the points of intersection of the various pairs of cross joins of these ranges, namely, the points $(KL', K'L)$, $(KL'', K''L)$, $(K'L'', K''L')$, ..., all lie on a line which we denote by m.

Take two corresponding points, K and L, of these two related ranges, lying, respectively, on the lines b and c, and, with these, the point A. Take the lines b, c and m. By the solution of the previous case, (iv), we can draw through K, L and A, respectively, the lines k, l and p, so that their intersections in pairs shall lie, respectively, on the lines b, c and m, namely the point (l, p) on b, the point (p, k) on c and the point (k, l) on m. Hence, if the points (l, p) and (p, k) be, respectively, Q and R, these will be points of the ranges $(K, K', ...)$ and $(L, L', ...)$ above described, and the lines BQ, CR, which we may call, respectively, q and r, will meet in a point, P, of the line a. The lines p, q, r are then such lines as are required for the solution of the general case of the problem in hand, which is then reduced to the case when B and C lie on b and c respectively, here considered under (iv).

(vi) There is another problem of fundamental importance which is also reducible to the case considered under (iv), that, namely, of the construction of the common corresponding points of two related ranges lying on the same line.

Let $(B, C, ...)$ and $(B', C', ...)$ be two ranges on a line, p, of which the latter is related to the former, according to the definition we have adopted in Chapter I (above, p. 25), by the fact that $(B', C', ...)$ is in perspective, from a point O, with a range, $(Q, R, ...)$, of another line, q, which is related to the range $(B, C, ...)$. The line

q will intersect p. Thus, as was proved for two related ranges on different lines in the same plane, the cross joins BR, CQ meet in a point lying on a definite line, r, whatever pair of corresponding points of these ranges is substituted for C and R.



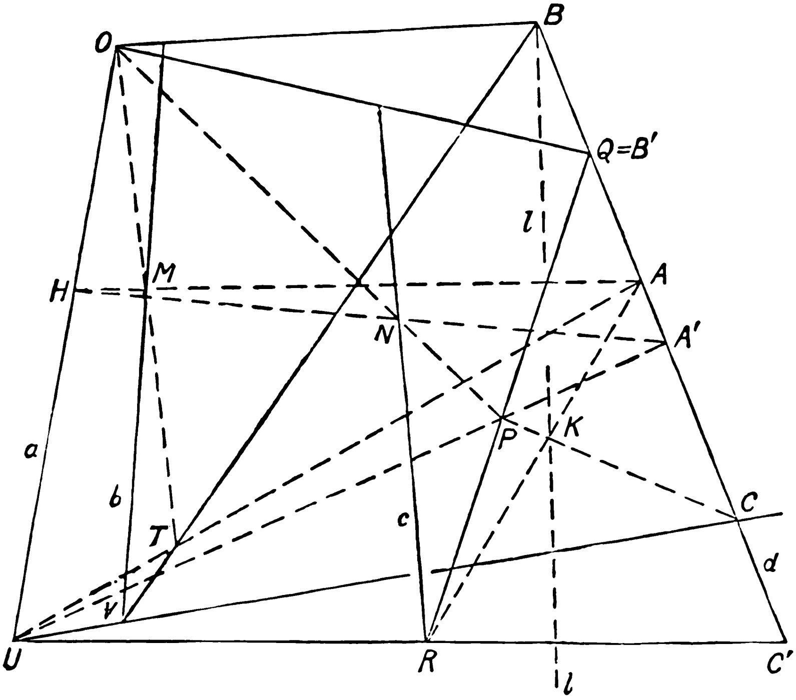
A point, A, of the range (B, C, ...), coincides with the corresponding point, A', of the range (B', C', ...), if, and only if, the corresponding point, P, of the related range on q, lie with A on a straight line through O. Thus, the problem of finding A is that of drawing through the point O, and through two, arbitrarily taken but corresponding, points Q and B, lying, respectively, on the lines q and p, the respective lines x, y and z, so that y and z may meet on r, z and x may meet on q, and x and y may meet on p.

This reduces the problem of finding the common corresponding points to that considered under (iv). For this problem, reference may also be made to a solution of entirely different character, Chasles, *Géom. supér.* (1880), p. 175.

(vii) The problem of finding common transversals of four lines in three dimensions, of which no two intersect, is also reducible to that considered under (iv).

Let a, b, c, d be four lines, in three dimensions, of which no two intersect. Take any two arbitrary fixed points, O and U, upon the line a. Draw from O the transversal to the lines b and d, meeting d in B; also from O the transversal to c and d, meeting d in Q. Draw from U the transversal to the lines b and d, meeting these, respectively, in V and C; also from U the transversal to c and d, meeting these, respectively, in R and C'. The plane VUR contains the line d; the plane from O containing the line b meets the plane VUR in the line VB, and the plane from O containing the line c meets the plane VUR in the line RQ. Now take any point, H, of the line a: from H draw the transversal to the lines b and d, meeting these, respectively, in M and A, and also the transversal to the lines c and d, meeting these, respectively, in N and A'. The plane from M containing the line a will meet the plane VUR in the line UA; this line will, therefore, intersect the line VB, say in the point T, and the line TM will intersect the line a; the line TM lies, however, in the plane MVB, which meets the line a in the point O; thus, the points O, M, T are in line. The plane from N containing the line a will meet the plane VUR in the line UA'; this line will, therefore, intersect the line RQ, say in the point P, and the line

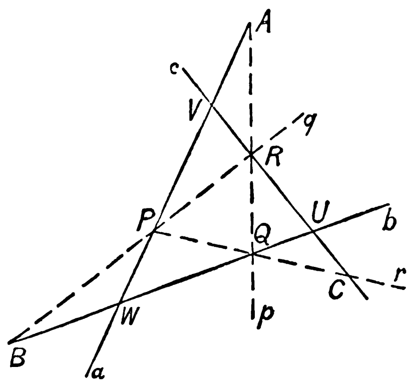
PN will intersect the line *a*; the line *PN* lies, however, in the plane *NRQ*, which meets the line *a* in the point *O*; thus, the points *O*, *N*, *P* are in line.



As the point *H* takes different positions on the line *a*, the points *A′*, *P*, *N*, *M*, *T*, *A* will take different positions, each on a line independent of *H*, constituting ranges which are all related. In particular, when *H* is at *O*, the points *A′*, *P*, *A* will be, respectively, at *B′*, *Q*, *B*, on the line *d*, the points *B′* and *Q* being the same; and, when *H* is at *U*, the same points *A′*, *P*, *A* will be, respectively, at *C′*, *R*, *C*. Considering the two related ranges, in one plane, whose points are the corresponding positions of *P* and *A*, respectively, of which two corresponding points are, respectively, *R* and *C*, arising when *H* is at *U*, the cross joins, *PC* and *AR*, meet in a point, *K*, which describes a definite line, *l*; and this line contains the intersection of the cross joins, *RB* and *CQ*, which is the point *B*; for *Q* and *B* are simultaneous positions of *P* and *A*, arising when *H* is at *O*.

In order, now, to draw a common transversal of *a*, *b*, *c*, *d*, it is necessary to find such a position for *H* that *A* and *A′* may coincide. For this it is necessary, and sufficient, to draw from the given points *U*, *R* and *C*, of the plane *VUR*, three lines *UPA′*, *RA*, *CP*, respectively, lying in this plane, so that the intersections of pairs of these, (*RA*, *CP*), (*CP*, *UPA'*), (*UPA'*, *RA*), shall lie, respectively, on the given lines l, RQ, $C'Q$, of this plane. Of the given points and lines, the points R and C lie, respectively, on RQ and $C'Q$. The problem of drawing the common transversals of the four given lines a, b, c, d, is, thus, reduced to the problem above considered, under (iv). For this problem, the reader may also consult Steiner, *Ges. Werke*, I, p. 403, where reference is made to Gergonne's *Ann. de Math.* XVII (1826, 7), p. 83.

(viii) Consider now the problem above referred to as (iii), in connexion with the symbolism which we have used.



Take the points (b, c), (c, a) and (a, b) as fundamental, the lines a, b, c being supposed not to meet in a point. Denoting these points, respectively, by U, V, and W, we may choose the symbols V and W, in relation to U, so that

$$C = U - V, \quad B = U - W,$$

and then take, for the symbol of the point A,

$$A = a^2V - W,$$

where a^2 is not 1, the points A, B, C not being in line. If then the symbol of the point P be taken as

$$P = \lambda V + W,$$

this involves in turn, for the symbols of the points Q, R and A, respectively

$$Q = \lambda U + W, \quad R = U + \lambda V, \quad A = \lambda^2 V - W.$$

Identifying this form for A with that given, we infer $\lambda^2 - a^2 = 0$, or $(\lambda - a)(\lambda + a) = 0$, and it was definitely assumed that the system of symbols used should have only 0 as singular symbol. Wherefore λ is a or $-a$. Thus, when the given points A, B, C are, respectively, written as $a^2V - W$, $U - W$ and $U - V$, one set of positions, for P, Q, R, is that given by

$$P = aV + W, \quad Q = aU + W, \quad R = U + aV,$$

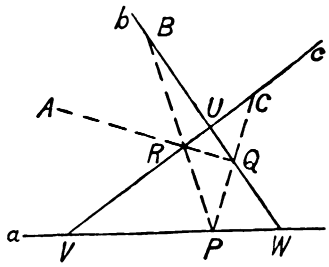
another, and the only other, set being obtained from this by putting $-a$ in place of a.

It is seen without difficulty that the figure employed here agrees with the construction given in Chapter I (above, p. 84) for determining the point $O + a^2U$ when O, U, $O + U$ and $O + aU$ are given.

(ix) Take now the case, considered in (iv), in which the given points B and C lie respectively on the lines b and c.

As before, let the points (b, c), (c, a) and (a, b) be, respectively, denoted by U, V and W, and suppose neither B nor C to be at U. We can, then, suppose the symbols of A, B and C to be, respectively, of the forms

$$B = U - 2W, \quad C = U - 2V,$$
$$A = U + mV + nW.$$



If then the symbol of the point P be taken as

$$P = mV + \lambda W,$$

those of Q and R will, respectively, be

$$Q = mU + 2\lambda W, \quad R = U + 2\lambda^{-1}mV,$$

and, in order that the line QR should pass through the point A, there must exist two symbols, q and r, securing the syzygy

$$q(mU + 2\lambda W) + r(U + 2m\lambda^{-1}V) = U + mV + nW.$$

This requires the equations

$$qm + r = 1, \quad 2rm\lambda^{-1} = m, \quad 2q\lambda = n;$$

we are assuming Pappus' theorem, so that the symbols are commutative in multiplication; hence, eliminating q and r, we deduce

$$mn\lambda^{-1} + \lambda = 2, \quad \lambda^2 - 2\lambda + mn = 0.$$

Thence, if θ be a symbol such that

$$\theta^2 = 1 - mn,$$

we have $(\lambda - 1)^2 = \theta^2$, and hence λ has one of the two forms

$$\lambda = 1 + \theta, \quad \lambda = 1 - \theta.$$

Now, by the constructions given in Chapter I (pp. 74, 76), when the points A, B, C, and therefore the symbols m and n, are given, we can construct the point whose symbol is

$$mV + (1 - mn)W,$$

or $mV + \theta^2 W$. From this, by the construction under (viii), preceding, we can find the two points with symbol

$$mV + \theta W,$$

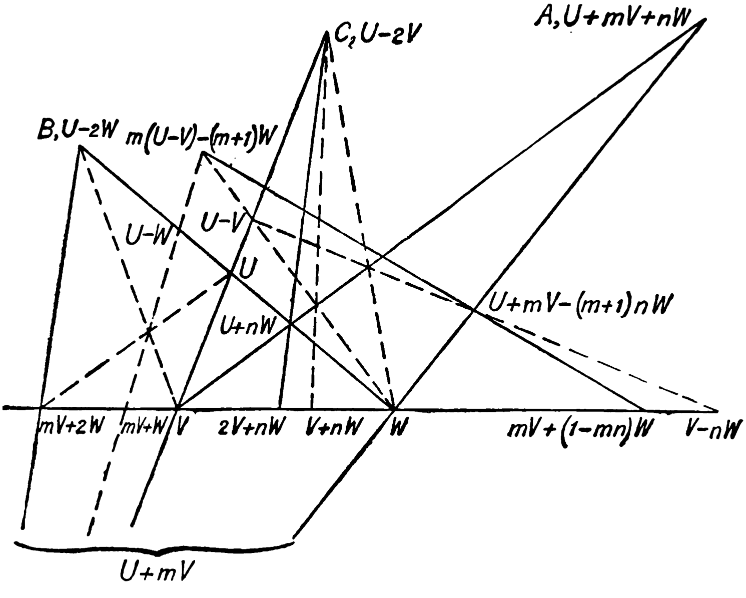
and hence the points of symbol

$$mV + (1 + \theta)W.$$

The general problem now under consideration can, therefore, be solved by direct construction if that under (iii) or (viii) can always be solved.

Remark. The reader may like to see these constructions carried out, in part. The given points are U, V, W, which are the points (b, c), (c, a), (a, b), together with $A = U + mV + nW$, $B = U - 2W$, $C = U - 2V$. A construction for

$mV+(1-mn)W$ is as follows: By joining $U+mV+nW$ to V and W we obtain, respectively, $U+nW$ and $U+mV$, on the lines UW and UV. By joining these, respectively, to $U-2V$ and $U-2W$, we obtain $2V+nW$ and $mV+2W$, on VW. From the former of these we construct $V+nW$, the harmonic conjugate of V in regard to $2V+nW$ and W; from the latter we construct $mV+W$, the harmonic conjugate of W in regard to $mV+2W$ and V. From $V+nW$, by taking its harmonic conjugate in regard to V and W, we obtain $V-nW$. Then, having $V+m^{-1}W$ and $V-nW$, we find $V+(m^{-1}-n)W$, or $mV+(1-mn)W$, by the rule for constructing a point specified by the sum of two algebraic symbols which was given in Chapter I. Namely, two lines through $mV+W$ and $V-nW$, respectively, are met by a line through V in the points $U+mV$ and $U-V$, and lines through W to these points meet the two lines first drawn, alternatively, in $U+mV-(m+1)nW$ and $m(U-V)-(m+1)W$; the join of these gives the point $mV+(1-mn)W$.



This is the point $mV+\theta^2W$, on the line VW; and we have $U-W$ on the line UW, the harmonic conjugate of W in regard to U and $U-2W$, and $mV+U$ on the line UV. Hence, if the result of (viii), preceding, be assumed, we can find $mV+\theta W$, on the line VW. Then, having $mV+W$, we can construct $mV+(1+\theta)W$.

Statement of the further Axiom henceforth assumed in the Abstract Geometry. In accordance with the view here adopted, of the possibility of extending the conception of the geometrical entities discussed, we shall suppose, in future, that, in the Abstract Geometry, the meanings attached to the words *point*, *line*, *plane*, etc., are such that the system of algebraic symbols appropriate to their discussion, beside obeying the formal laws of combination set forth in Chapter I, and the commutative law in multiplication, is also such that, to any symbol, c, there exists another, z, such that $z^2=c$. From the preceding discussion it follows that this is equivalent to supposing that the geometrical entities, beside being subject to the Propositions of Incidence, and such that Pappus' theorem is true, are also such that a certain geometrical problem is always capable, if not of an infinite number, then, of *two*, solutions, which may coincide. We have given three alternative forms for this problem, either of which may be taken, in virtue of the other assumed properties of the entities. Either we may say that, if A, B, C be points given anywhere on three lines a, b, c, lying in a plane, it is possible to draw three lines p, q, r, respectively through A, B, C, such that the points of intersection (q, r), (r, p), (p, q) lie, respectively, on a, b, c. From this it follows that the same is true for quite arbitrary positions of A, B, C, not lying on the lines a, b, c. Or we may say that two related ranges of points on the same line, not entirely identical, have two common corresponding points, which may coincide. Or, finally, we may say that, four lines in space of three dimensions, of which no two intersect, are met, if not by an infinite number, then, by *two* transversals, which may however coincide.

It may be said that, later on, it will be assumed that the geometrical entities are such that, in the symbolism appropriate thereto, equations of general character, not merely $z^2 = c$, are capable of solution. It would be proper to discuss now whether this is an additional condition, or contained in what has been adopted. But we do not enter into this at present.

Clearly, from the preceding discussion, the problem of which we postulate a solution in the Abstract Geometry, has not, in all cases, a solution in the Real Geometry. When the theory is supposed to deal only with a real geometry, it is, therefore, usual to speak of *imaginary* elements. As we have said, we may, however, introduce into the Real Geometry certain aggregates of real elements, whose relations with the primary real elements, and with one another, are formally the same as those of the so-called imaginary elements. We now pass to a brief account of aggregates of this kind which may be taken, if it be desired to maintain the point of view of a Real Geometry.

Aggregates of real elements with the properties of imaginary elements. We desire to avoid the use of the words *imaginary point*, *imaginary line*, etc., when establishing the theory, at least. We shall, therefore, use a phraseology which is, confessedly, somewhat cumbrous. In addition to points, we consider *Point-Sets*, each of three points on a line: Any three points on a line, A, B, C, are regarded as taken in one of two definite orders, the sets B, C, A and C, A, B being regarded as equivalent with the set A, B, C; and the sets C, B, A and A, C, B as equivalent with the set B, A, C. Then, further, the set A, B, C is regarded as equivalent with any other set, A', B', C', of three points of the same line, when the three ranges (A', A, B, C), (B', B, C, A), (C', C, A, B) are related. Thus, Pappus' theorem being assumed, a set, A', B', C', can be found equivalent with the set A, B, C, of which one point, say A', is any arbitrary point of the line, the points B', C', associated therewith, being then determinate. It is easy to prove that the ranges (A, A', B', C'), (B, B', C', A'), (C, C', A', B') are related, so that if the set A', B', C' is equivalent to the set A, B, C, then this latter is equivalent to the former. It can be further shewn that two sets, A', B', C' and A'', B'', C'', which are both equivalent to A, B, C, are equivalent to one another.

The whole aggregate of equivalent point sets of the line is the entity called a *point series*. From three points of the line, taken in different orders, two such point series can be formed; these may be called *conjugate* point series. When two of the points of a set A, B, C, of a point series, are coincident, say A with B, the point sets, equivalent with this, are those formed with A, B and any further arbitrary point of the line, and one particular set, of these, consists of the point A taken three times over. In the Real Geometry we have, upon the line, points; in the scheme we are explaining we have, *general point series*, each determined by a set of three points of which no two coincide, and *the degenerate point series*, each of which is determined by three coincident points; while a general point series lies on a definite line, an infinite number of lines contain the three coincident points of a degenerate point series. The laws of manipulation of the general point series will lead to laws for the degenerate point series which are exactly similar to those of ordinary real points[1]. We may say that the number of point series upon a line is ∞^2; for of a point set determining the series, one point may be at any position chosen beforehand, the same for all series, and any particular series then depends on the positions of the other two points of a set determining the series; each of these two points is capable of positions on the line which we usually say to be ∞^1 in number.

Reciprocal to point sets, each of three points on a line, we consider also plane sets, each of three planes passing through a line. A set of three such planes, α, β, γ, is regarded as equivalent to either of the two sets β, γ, α or γ, α, β, but distinct from the equivalent sets, γ, β, α, or β, α, γ, or α, γ, β. And a set of three other planes, α', β', γ', passing through the same line, is regarded as equivalent to α, β, γ when the axial pencils $(\alpha', \alpha, \beta, \gamma)$, $(\beta', \beta, \gamma, \alpha)$, $(\gamma', \gamma, \alpha, \beta)$ are related. The aggregate of all equivalent plane sets is called a *plane series*; and there are degenerate plane series in which all the equivalent plane sets have two coincident planes in common.

---

[1] The reader may compare the general logical formulation given above, p. 146.

A point series is then said to *lie upon* a plane series, when the points of any one of the equivalent sets of the point series, taken with regard to order, lie, respectively, upon the corresponding planes of any one of the equivalent sets of the plane series. In particular the condition is satisfied if the points A, B, C lie, respectively, upon the planes β, γ, α, as well as if they lie respectively upon α, β, γ. In general the line containing the point series, and the axis of the plane series, are different; but the condition is satisfied of itself when these lines coincide. A point series, (A, B, C), lies on a degenerate plane series, (α, α, γ), when the base line of (A, B, C) lies on the plane α; reciprocally, a degenerate point series (A, A, C) lies on a plane series (α, β, γ), when the axis of the plane series contains the point A. When both the point series and the plane series are degenerate, being (A, A, C) and (α, α, γ), the condition is merely that the point A shall lie on the plane α.

Two point series, whose base lines are not in one plane, determine what we call a *skew linear series*, consisting of sets of three lines of which no two intersect; such a set of three lines is obtained by joining the points, A, B, C, of any set of one of the point series, respectively to the points, A', B', C', of any set of the other point series. From any set of three lines, of which no two intersect, another set may be obtained, by taking any two transversals of these three given lines, meeting them, respectively, in A, B, C and in A', B', C'; then, determining upon the line ABC any point set, (P, Q, R), equivalent with (A, B, C), and upon the line $A'B'C'$ any point set, (P', Q', R'), equivalent with (A', B', C'); and, then, joining P and P', Q and Q', R and R'. The lines PP', QQ', RR' are then equivalent, as a line set, with the set of three given lines. It is clear that if, in this way, a line set (l', m', n') be equivalent with a line set (l, m, n), then the latter is equivalent with the former. It is necessary, however, if the word equivalence is to preserve its usual connotation, to shew, further, geometrically, that no logical inconsistency is involved in regarding two line sets, (l', m', n'), (l'', m'', n''), which are both equivalent, in the above sense, with a line set (l, m, n), as being equivalent with one another. In regard to this it may be remarked that the two common transversals of the six lines l, m, n, l', m', n', which enter into the definition of the equivalence of the line sets (l, m, n) and (l', m', n'), are not necessarily the same as the two common transversals of l, m, n, l'', m'', n'', which enter for the equivalence of (l, m, n) and (l'', m'', n''); it is therefore not part of the definition of the suggested extension of the meaning of the equivalence of two line sets, that the six lines $l', m', n', l'', m'', n''$ should have two common transversals. It is necessary, for our purpose, to retain for the present the point of view of the descriptive Real Geometry; but it can be seen (see Note II, at the end of the Volume), that there is, in fact, no logical difficulty. After what has been said in regard to degenerate point series, it is unnecessary to define degenerate skew linear series.

Reciprocally, a skew linear series may be defined from two plane series, whose axes have no point in common. A set of such a series consists of the intersections of the planes α, β, γ, of any set of one plane series, respectively, with the planes, α', β', γ', of any set of another plane series. If the lines forming a set so defined meet the axes of the two plane series, respectively, in A, B, C and A', B', C', the line set is equally determined by the two point sets A, B, C and A', B', C'. Take any three planes, λ, μ, ν, passing, respectively, through the lines of the line set, having a common axis, and, also, any other three planes, λ', μ', ν', with the same description; let ρ, σ, τ be a plane set equivalent with λ, μ, ν, and ρ', σ', τ' a plane set equivalent with λ', μ', ν'. If we regard the three lines, (ρ, ρ'), (σ, σ'), (τ, τ'), as equivalent with the original set, we shall only be giving, in a different form, the previous definition of equivalent line sets; for two equivalent sets of three planes, with the same axis, meet any base line in equivalent point sets.

A skew linear series is said to contain a point series when one of the equivalent line sets, of the former, contains one of the equivalent point sets of the latter. And, reciprocally, for the condition that a skew linear series should lie on a plane series. Thus, any two point series lying on a skew linear series serve to define the skew linear series (just as any two points of a line serve to define the line); and the skew linear series, which contains two point series lying on the same plane series, lies entirely on the plane series (as the line joining two points of a plane lies entirely on that plane).

It is clear that, if any line set of three lines, belonging to a particular skew linear series, be taken, and then any line, p, be drawn to meet any two transversals of the three lines taken, there is a set, of the skew linear series, of which the line p is one line. If l, m, n be three lines of a set of the series, and p a line, such that two transversals meet these four lines, respectively, in A, B, C, P and in A', B', C', P', then a point set, P, Q, R, can be found, on the former transversal, equivalent to A, B, C, and a point set, P', Q', R', on the latter, equivalent to A', B', C'. Denoting the lines QQ' and RR', respectively, by q and r, the three lines p, q, r are a set of the skew linear series. Hence it follows that, *of a given skew linear series, there is one set of which one line is an arbitrary line.* For, let O, O' be any two points of the arbitrary line; let ABC and $A'B'C'$ be two transversals of one set of the skew linear series; from O draw the line, OPP', meeting these two transversals, respectively, in P and P'. Denoting this line, OPP', by p, there is a set of the skew linear series consisting of p and two other lines, q and r. Now, from O, draw the line, OMN, meeting the lines q and r, respectively, in M and N. Then O, M, N is a set of a point series lying on the skew linear series. Another such set can, similarly, be found from the point O', say O', M', N'. The three lines, OO', MM', NN', are then a set of the skew linear series, of which the given line OO' is one line. For simplicity, the description has supposed all the lines involved to be in general positions relatively to one another.

The skew linear series, as has been indicated, generalises the properties of a line. There is however another aggregate of lines which also generalises the properties of a line. This we shall call a *line series*; it can coexist with, and must be distinguished from, a *skew linear series*. This last has been defined by means of two point series whose base lines do not lie in the same plane. If the base lines of two general point series, (A, B, C) and (A', B', C'), meet in a point, O, we may take, as sets of the two series, respectively, points, O, P, Q, on the former base line, and points, O, P', Q', on the latter base line. If then the lines PP' and QQ' meet in the point H, the three lines, HO, HP, HQ, are a set of three lines which meet in a point and lie in a plane. Taking any three such lines, l, m, n, we may define sets of lines equivalent with this set in a manner analogous to that followed above for point sets and plane sets; namely, we may regard the set l, m, n as equivalent with m, n, l or n, l, m, and as equivalent with any set, l' m', n', of three lines, all passing through the same point H and lying in the same plane, as l, m, n, when the three flat pencils (l', l, m, n), (m', m, n, l), (n', n, l, m) are related. The aggregate of all such equivalent line sets, of three lines in a plane passing through a point, constitutes what we call a *line series*. It is distinguished from a skew linear series by lying in a definite plane and passing through a definite point.

As before, we may then say that such a line series contains a certain point series, when the lines of one set of the line series contain, respectively, with proper regard to order, the points of one set of the point series. For this it is necessary that the base line of the point series lie in the plane of the line series. Reciprocally such a line series is contained in a certain plane series, when the lines of a set of the line series lie, respectively, in the planes of a set of the plane series. For this, the axis of the plane series must contain the point of the line series.

Such a line series may be determined by a general point series and a degenerate point series, of which one set consists of three coincident points. One set of the line series then consists of the lines joining this triple point to the points of a set of the general point series. Such a line series is also determined by a general plane series and a degenerate plane series, of which one set consists of three coincident planes. And, as has been indicated, the fundamental definition of a line series may be by two general plane series of which the axes lie in a plane.

Now consider three kinds of entities. The first kind consists of point series, and of points, the latter being regarded as degenerate point series. The second kind consists of skew linear series, and of line series, and of lines; the lines are here degenerate forms of either of the others. The third kind consists of plane series, and of planes, regarded as degenerate plane series. With appropriate definitions, we can then shew that, as the Propositions of Incidence, with Desargues' theorem, and Pappus' theorem, hold for points, lines and planes, so theorems corresponding thereto hold for the three kinds of entities. It is in the nature of the definitions of these entities that the Principle of Duality continues to hold also.

The detailed verification of the statement will only be sketched: the three kinds of entities will be referred to as point entities, line entities and plane entities:

(*a*) Two point entities define a line entity, which is equally determined by any two point entities lying thereon. Two plane entities similarly determine a line entity. This is clear from what has been said.

(*b*) A point entity and a line entity determine a plane entity; a plane entity and a line entity determine a point entity.

It will be sufficient to consider the former statement. A point and a line determine a plane. A point and a line series determine a plane series, of which one plane set consists of the planes joining the point to the lines of a line set. A point, O, and a skew linear series, determine a plane series; for if u and v be two transversals of a set of three lines in the skew linear series, and p be the line drawn from O to meet u and v, the skew linear series, as we have remarked above, may be determined from a line set consisting of the line p and two other lines, q and r; and, if x be the line drawn from O to meet q and r, the planes xp, xq, xr are a set of a plane series containing both O and the skew linear series. It is interesting to verify that the line x so found is unique. The result involves that, through every point can be drawn a line to contain some point series lying on a given skew linear series (in another phraseology, through every point can be drawn a line to contain an imaginary point lying on a given imaginary line of the second kind; cf. von Staudt, *Geom. der Lage*, *Beiträge*, I, 1856, p. 81, no. 123).

Next, a point series, and a line, determine a plane series, whose axis is the line. A point series and a line series determine a plane when the base line of the point series is in the plane of the line series, namely this plane itself. When this is not so, let *O* be the point in which the plane of the line series is met by the base line of the point series; on this base line take the point set *O*, *P*, *Q* of the point series. If the point of the line series be at *O*, a plane series containing both entities is at once clear. When this is not so, let *H* be the point of the line series, and take a line set of the line series consisting of the line *HO* and two other lines, *p*, *q*, through *H*, lying in the plane of the line series. The planes, *Pp* and *Qq*, will meet in a line, say *l*, passing through *H*; these two planes together with the plane *lO*, are then a plane set containing both the point set *O*, *P*, *Q* and the line set *HO*, *p*, *q*; and they determine a plane series containing both the given point series and the given line series. Now consider a point series and a skew linear series. Let the point series be determined from a point set *P*, *Q*, *R*, and the skew linear series be determined from the two point series (*A*, *B*, *C*) and (*A′*, *B′*, *C′*). A plane series containing the last two series will contain the skew linear series, as we have remarked above; the problem, then, is, to determine a plane series containing three given point series (*P*, *Q*, *R*), (*A*, *B*, *C*), (*A′*, *B′*, *C′*). If (*U*, *V*, *W*) be any point series upon the skew linear series determined by (*P*, *Q*, *R*) and (*A*, *B*, *C*), then a plane series containing (*U*, *V*, *W*) and (*P*, *Q*, *R*) will contain (*A*, *B*, *C*); similarly, if (*U′*, *V′*, *W′*) be any point series upon the skew linear series determined by (*P*, *Q*, *R*) and (*A′*, *B′*, *C′*), then a plane series containing (*U′*, *V′*, *W′*) and (*P*, *Q*, *R*) will contain (*A′*, *B′*, *C′*). It will then be enough to find a plane series containing the point series (*U*, *V*, *W*), (*U′*, *V′*, *W′*) and (*P*, *Q*, *R*). We can, however, so choose (*U*, *V*, *W*) and (*U′*, *V′*, *W′*) that these lie on a line series, as we shall see; any plane series containing this line series will contain (*U*, *V*, *W*) and (*U′*, *V′*, *W′*). It will then be sufficient to find a plane series containing this line series and containing the point series (*P*, *Q*, *R*); which is the problem last considered. There remains then, only, to find the point series (*U*, *V*, *W*) and (*U′*, *V′*, *W′*) in the appropriate way: (*U*, *V*, *W*) is to be a point series lying on the skew linear series determined by (*P*, *Q*, *R*) and (*A*, *B*, *C*), and (*U′*, *V′*, *W′*) is to be a point series on the skew linear series determined by (*P*, *Q*, *R*) and (*A′*, *B′*, *C′*), and the point series (*U*, *V*, *W*), (*U′*, *V′*, *W′*) are to be on a line series. We can suppose that the point *P* is not on the line *AA′*; for if *P*, *Q*, *R* be all, respectively, upon the lines *AA′*, *BB′*, *CC′*, the point series (*P*, *Q*, *R*) lies on the skew linear series determined by (*A*, *B*, *C*) and (*A′*, *B′*, *C′*). The points, *P*, *A*, *A′*, then, determine a plane; let *QB*, *RC* meet this plane in *V* and *W*, respectively, and let the line *PA* meet the line *VW* in *U*;

again, let QB', RC' meet this plane, respectively, in V' and W', and let the line PA' meet the line $V'W'$ in U'. The two point sets U, V, W and U', V', W', lying in a plane, determine two point series, and these lie on a line series in this plane, determined by a construction given above.

Lastly, consider two line entities. If these have a point entity in common, they both lie on a plane entity; reciprocally, if they both lie on a plane entity, they have a point entity in common. It will be sufficient to consider the former statement. A line and a line series having a point series in common, evidently, lie on a plane. A line and a skew linear series having a point series in common, lie in a plane series having the line as axis. Two line series of which the centre points are the same point, but the planes different, these meeting in a line p, contain respectively two line sets, p, q, r and p, q', r'; the planes (qq'), (rr'), together with the plane joining p to the line of intersection of the planes (qq') and (rr'), constitute a plane set containing a set of each of the given line series, and define a plane series containing these line series. Two line series, whose centre points are different as well as their planes, which have a point series in common, lie on a plane series whose axis is the line joining the two centre points. A line series and a skew linear series, which have a point series in common, lie on a plane series containing the line series and any other point series of the skew linear series. Finally, two skew linear series having a point series in common, lie on the plane series containing this point series and two other point series, one on each of the skew linear series.

(*d*) It follows from the preceding that three point entities, not on the same line entity, determine a plane entity, and that three general plane entities determine a point entity. Further, Desargues' theorem, as a consequence of the above Propositions of Incidence, is true of two triads of point entities. And Pappus' theorem, which now becomes a theorem that three point entities lie on a line entity, can also be proved (Ex. 9, below).

The preceding aggregates in the general Abstract Geometry. In addition to Pappus' theorem in its general form, there are many interesting geometrical questions raised by the preceding constructions. And, when these have been investigated, there is the question whether the entities serve the main purpose for which they are introduced; whether, for example, given four line entities, of which no two have a point entity in common, there exist two line entities having each a point entity common with each of the four given line entities. Such questions are not only of interest in themselves, but are of theoretical logical importance if it be desired to refrain from the extension of the Abstract Geometry indicated earlier in this chapter; the extension, namely, to be quite precise, in which a system of symbols is appropriate for which the equation $z^2 = c$ is soluble for all symbols c. But, if this extension be allowed, an account can be given of the preceding point series, line series and plane series, which not only sets at rest the logical questions, but, further, removes the apparent artificiality of the theory; such an account, by introducing clearness of conception, renders the geometrical discussion, of questions not considered above, much easier. We do not enter into this, in detail. Some indications, stated as the following examples, may, however, be desirable. See Note II, at the end of the Volume.

Ex. 1. For the cubic form

$$f = (x - ay)(x - by)(x - cy),$$

shew that the Hessian form, defined as

$$\frac{\partial^2 f}{\partial x^2}\frac{\partial^2 f}{\partial y^2} - \left(\frac{\partial^2 f}{\partial x \partial y}\right)^2,$$

is, save for a numerical factor,

$$(x - ay)^2 (b - c)^2 + (x - by)^2 (c - a)^2 + (x - cy)^2 (a - b)^2.$$

Ex. 2. Shew that if two triads of points on a line be given by

$$A = O + aU, \quad B = O + bU, \quad C = O + cU,$$
$$A' = O + a'U, \quad B' = O + b'U, \quad C' = O + c'U,$$

the necessary and sufficient condition that the ranges (A', A, B, C), (B', B, C, A), (C', C, A, B) should be related, is that the two cubic forms

$$f = (x - ay)(x - by)(x - cy), \quad f' = (x - a'y)(x - b'y)(x - c'y),$$

should have Hessian forms whose (three) coefficients are proportional. The result can be obtained from what was proved above (p. 154), that the condition, for two ranges, $(P, Q, P + \rho Q, P + \sigma Q)$ and $(P, Q, P + \rho' Q, P + \sigma' Q)$, to be related, is that $\rho^{-1}\sigma = \rho'^{-1}\sigma'$.

Ex. 3. If ω be a symbol for which $(2\omega + 1)^2 = -3$, and the Hessian form of Ex. 1 be brought to the form $(x - ty)(x - uy)$, save for a factor independent of x and y, prove that, with proper distinction of t and u,

$$(t - a)(b - c)\,\omega^{-2} = (t - b)(c - a)\,\omega^{-1} = (t - c)(a - b),$$
$$(u - a)(b - c)\,\omega^{-1} = (u - b)(c - a)\,\omega^{-2} = (u - c)(a - b).$$

Ex. 4. In the preceding example, when ω is a particular one of the two symbols for which $(2\omega + 1)^2 = -3$, agreed upon, there is a distinction between t and u. And the point series of which a set consists of the points represented by $O + aU$, $O + bU$, $O + cU$, taken in a certain order, can thus be associated with a particular one of the two points $O + tU$, $O + uU$, which are determined when a, b, c are given; the other series, formed from the points of the same set differently arranged, will then be associated with the other of these two Hessian points. A similar remark is then applicable to a plane series, or to a line series. For a skew linear series an adequate statement requires the theory of quadric surfaces. But see Note II, at the end of the Volume.

Ex. 5. It has already been remarked, in the introductory article of this chapter, in anticipation of subsequent work, that, upon the plane curve called a conic section, a theory of related ranges can be set up; and the points of the conic can be put into unambiguous correspondence with the points of a line. We may then have point series upon such a conic, defined by equivalent sets each of three points, just as upon a line; and the two series, arising from the three points of a set taken in different orders, will be associated, respectively, with the two Hessian points of the cubic form belonging to any one of the equivalent sets. Although an anticipation, the geometrical form of this is so simple, that it may be mentioned: If the tangent lines to the conic at three points, A, B, C, be drawn, and meet the lines BC, CA and AB, respectively, in P, Q and R; then these points P, Q, R lie upon a line; and this line meets the conic in the two points, say U and V, which are the Hessian points of the three points A, B and C. Conversely, to an arbitrary line UV, there corresponds a series of sets A, B, C. With a further anticipation, it may be added, that when the line is what is sometimes called the line at infinity, and the conic is a 'circle,' the points A, B, C are the angular points of an arbitrary 'equilateral' triangle inscribed in the circle.

The points U, V are the common corresponding points of two ranges related by the fact that A, B, C, of one range, correspond, respectively, to B, C, A, of the other.

Ex. 6. If the theory of point series, etc., above given, is competent to represent all possibilities (as it is), then statements must be true which can be described, in a usual phraseology, not adopted here, as follows: An imaginary point lies on one real line; an imaginary plane contains one real line; there are imaginary lines of such kind that each contains a real point and lies in a real plane; and there are imaginary lines of another kind, upon which is no real point, through which passes no real plane. For the present we do not enter further into these questions; the precise discrimination of what is to be understood, in the Abstract Geometry, by a *real* point, and by an *imaginary* point, comes more naturally later.

Ex. 7. In the above account of point series, etc., regarded as aggregates of elements of the Real Geometry when this is extended by the adjunction of the postulated points, etc., we have remarked that three point series, of general position, determine a plane series. This is equivalent to saying that, if P, Q, R be three points of one line, and O, U, W be three points of another line, and O', U', W' be three points of a third line, all in general position, then three points, O_1, U_1, W_1, can be found upon the second line, equivalent to O, U, W in the sense explained, and three points O_1', U_1', W_1', can be found upon the third line, equivalent to O', U', W' in the sense explained, such that the three planes, PO_1O_1', QU_1U_1', and RW_1W_1', meet in a line. We can regard the four points O, U, O', U' as fundamental for the threefold space of the figure; and, without loss of generality, we can choose the symbols for the points so that

$$W=O+U, \quad W'=O'+U', \quad R=P+Q;$$

if then the points P, Q be determined from O, U, O', U' by the syzygies

$$P=m_1O+n_1U+m_1'O'+n_1'U',$$
$$Q=m_2O+n_2U+m_2'O'+n_2'U',$$

it can be shewn that the line of intersection of the three planes, the axis of the plane series, contains the two points

$$pO+rU+p'O'+r'U',$$
$$-rO+qU-r'O'+q'U',$$

where

$$p=m_1+m_2-n_2, \quad q=-n_1-n_2+m_1, \quad r=m_2+n_1,$$
$$p'=m_1'+m_2'-n_2', \quad q'=-n_1'-n_2'+m_1', \quad r'=m_2'+n_1'.$$

Ex. 8. It can be shewn that the general set of three points, O', U', W', equivalent to a set, O, U, W, upon the same line, in the sense explained above, the symbols of these being chosen so that $W=O+U$, $W'=O'+U'$, is found by taking

$$(O', U')=\xi(O, U),$$

where ξ denotes
$$\xi=\begin{pmatrix} a, & a-b \\ b-a, & b \end{pmatrix},$$

this notation meaning that

$$O'=aO+(a-b)\,U, \quad U'=(b-a)\,O+bU.$$

Here a, b are arbitrary symbols subject to $ab=ba$. Thus, if ξ' be a matrix of the same form constructed from a' and b', we easily find, from the law of multiplication explained above (p. 67), that $\xi\xi'=\xi'\xi$. We can write ξ in either of the two forms

$$\xi=\tfrac{1}{2}(a+b)+\tfrac{1}{2}(a-b)\,\epsilon, \quad \xi=b+(a-b)\,\tau,$$

where
$$\epsilon=\begin{pmatrix} 1, & 2 \\ -2, & -1 \end{pmatrix}, \quad \epsilon^2=-3,$$

$$\tau=\begin{pmatrix} 1, & 1 \\ -1, & 0 \end{pmatrix}, \quad \tau^2-\tau{}^{+}1 \quad 0.$$

Hence shew that the general point series contained on a skew linear series defined by the two (not equivalent) sets, O, U, $O+U$ and O', U', $O'+U'$, consists of sets of points, P, Q, $P+Q$, where P, Q are given by

$$(P, Q)=\xi(O, U)+\xi'(O', U'),$$

ξ and ξ' being any two matrices of the form above. Thus

$$\begin{aligned} P&=aO+(a-b)\,U+a'O'+(a'-b')\,U', \\ Q&=(b-a)\,O+bU+(b'-a')\,O'+b'U', \\ R&=bO+aU+b'O'+a'U'. \end{aligned}$$

This is a generalisation of the symbolic expression of any point on a line determined by two points.

Ex. 9. Let l, m, n be three skew lines, and p a line met by all transversals of l, m, n; let l', m', n' be three other skew lines such that all transversals of these equally meet p. From any point, P, of p, draw the transversal of l, m, n, meeting these, respectively, in A, B, C; and from P draw the transversal $A'B'C'$ of l', m', n'. Let U, V, W denote, respectively, the points $(BC', B'C)$, $(CA', C'A)$, $(AB', A'B)$, which, by Pappus' theorem, are in line. Prove (pp. 20, 21, above) that the locus of each of U, V, W is a line. And, by taking three positions of P upon p, hence prove Pappus' theorem, for two triads of imaginary points lying respectively on two intersecting imaginary lines of the most general kind, in terms of the representation of this Chapter.

This representation assumes Pappus' theorem for real points; the theorem of pp. 20, 21 is independent of this.

BIBLIOGRAPHICAL

It is possible to distinguish seven main sources of the theory of this volume: (*a*) The writings of the Greek geometers, and in particular the Collection of Pappus. Beside the particular result, here called Pappus' theorem, which is made to play an important part in the theory, the notion of the fourth harmonic point, the notion of six points in involution, developed by Desargues, and, essentially, what in the hands of Chasles and Steiner became the anharmonic ratio, here replaced by the theory of related ranges, are all to be found there, dealt with on a metrical basis; (*b*) The writings of Kepler and Desargues, who, both, from different points of view, regarded points at infinity as particular cases of finite points, and so made (or adopted from others) a momentous advance from the point of view of the Greeks; (*c*) The unpretentious but imperishable volumes of von Staudt. Though Desargues used the method of projection to prove the theorem we have here called by his name in the case of two triangles not in the same plane, he had no scruple in employing the metric methods of the Greeks for the case of two triangles in the same plane; not forgetting the inspiration of the great work of Poncelet, and his wonderful discovery of the imaginary elements of metric space, nor the far reaching character of the work of Chasles and Steiner, it is still to be remarked that for none of these did there exist any doubt of the obviousness of the notion of distance. It was von Staudt to whom the elimination of the ideas of distance and congruence was a conscious aim, if, also, the recognition of the importance of this might have been much delayed save for the work of Cayley and Klein upon the projective theory of distance. Generalised, and combined with the subsequent Dissertation of Riemann, v. Staudt's volumes must be held to be the foundation of what, on its geometrical side, the Theory of Relativity, in Physics, may yet become; (*d*) To von Staudt, however, the conceptions of the theory of aggregates, due to G. Cantor and others, were not clear; and his definition of related ranges, by means of harmonic nets, assumes that points of such a net are found everywhere on the line, as was pointed out by F. Klein. Thus it is necessary either to introduce into his scheme ideas which seem alien to his point of view, as indicated here in Chapter II, or frankly to recognise the need of an assumption. The discovery of the geometrical significance of this necessity is contained in an incidental remark of H. Wiener; it is this remark which has led to the recognition of the importance to be attached to the assumption of Pappus' theorem, or some equivalent assumption. It is a hazardous, but it seems a natural forecast, that wide developments still await the detailed investigation of the geometry in which Pappus' theorem is not assumed, in which the appropriate algebraical symbols are not commutative in multiplication. The definition of related ranges given in this volume is not the same as that formally adopted by von Staudt, but seems more in harmony with his general point of view; and it is mentioned by him, *Beiträge*, II, p. 136, No. 203; for the possibility of the detailed development of this definition, the volume owes much to the work of F. Schur; (*e*) The recognition that geometry does not deal with space in itself but with definite figures, constructed from points assumed to be given, in accordance with postulated laws of construction, and that these constructions may be made in a limited accessible region. It would seem right to associate these conceptions with the names of F. Klein, Pasch and Peano; (*f*) To C. Segre and the writers of the Italian school, is due the insistence upon the logical necessity and practical utility of not limiting our outlook to space of three dimensions. Though significant papers of Cayley, Riemann and Clifford are to be named, the conviction of the increased geometrical insight obtainable by the widened outlook is to be won only by experience of the many striking successes in simplification and grasp which have been obtained in this way. (*g*) Finally, the introduction by Descartes of the equation to a curve, and the epoch-making work of Poncelet (and of Laguerre) in regard to the imaginary elements, though mainly of importance in subsequent volumes, are responsible, ultimately, for the scope here suggested for the Abstract Geometry. This extension is of quite vital importance for the development of geometry.

Some detailed references to these sources may be of interest:

(*a*) Exhaustive references to the Greek geometry must be sought elsewhere. We may name M. Cantor, *Geschichte der Mathematik*; the smaller *History of Mathematics* by F. Cajori; the German *Enzykl. d. Mathem. Wiss.*; Chasles, *Aperçu historique*, and Zeuthen, *Die Lehre von den Kegelschnitten in Alterthum* (Kopenhagen, 1886). The English reader will find the Prolegomena in Charles Taylor, *Ancient and Modern Geometry of Conics*, Cambridge, 1881, especially instructive (pp. xvii—lv deal with the Greek geometry), and will also consult T. L. Heath, *The thirteen books of Euclid's Elements, translated from the text of Heiberg with Introduction and Commentary*, 3 vols., Cambridge, 1908, also *Apollonius of Perga, Conic Sections*, Cambridge, 1896, and a *History of Greek Mathematics*, 2 vols., Oxford, 1921. The actual text of the theorem we have called Pappus' theorem may be seen in Hultsch (Fridericus), *Pappi Alexandrini Collectionis quae supersunt*, Volumen II, Berolini, 1877, and is as follows, the Latin version being by Hultsch:

pp. 884, 885 *ἐὰν παράλληλοι ὦσιν αἱ* ΑΒ ΓΔ, *καὶ εἰς αὐτὰς ἐμπίπτωσιν εὐθεῖαί τινες αἱ* ΑΔ ΑΖ ΒΓ ΒΖ, *καὶ ἐπιζευχθῶσιν αἱ* ΕΔ ΕΓ, *γίνεται εὐθεῖα ἡ διὰ τῶν* Η Μ Κ.

pp. 886, 887 *ἀλλὰ δὴ μὴ ἔστωσαν αἱ* ΑΒ ΓΔ *παράλληλοι, ἀλλὰ συμπιπτέτωσαν κατὰ τὸ* Ν *ὅτι πάλιν εὐθεῖά ἐστιν ἡ διὰ τῶν* Η Μ Κ.

si parallelae sint $\alpha\beta$ $\gamma\delta$, et in eas incidant quaedam rectae $\alpha\delta$ $\alpha\zeta$ $\beta\gamma$ $\beta\zeta$, quarum $\alpha\delta$ $\beta\gamma$ concurrant in μ, et a quovis rectae $\alpha\beta$ puncto inter α et β sumpto ducantur $\epsilon\gamma$ $\epsilon\delta$, quarum $\epsilon\gamma$ cum $\alpha\zeta$ concurrat in η et $\epsilon\delta$ cum $\beta\zeta$ in κ, rectam esse quae per η μ κ transit.

at ne sint parallelae $\alpha\beta$ $\gamma\delta$, sed convergant in puncto ν; dico rursus rectam esse quae per η μ κ transit.

(*b*) Kepler published a volume with the title *Ad Vitellionem Paralipomena, quibus Astronomiae pars Optica traditur* (Francofurti 1604, Cum privilegio S. C. Majestatis), of which the dedication to his patron, the emperor Rudolph II, is signed Joannes Keplerus, S. C. M$^{\text{tis}}$ Subjectissimus Mathematicus. In the four pages of this bearing the title *De coni sectionibus*, we find (pp. 93, 95) the two following passages, which indicate plainly enough how he was led to regard a point at infinity as a particular case of a finite point. The letters refer to a diagram given in his text.

Focus igitur in circulo unus est *A*, isque idem qui & centrum: in Ellipsi foci duo sunt *BC*, aequaliter à centro figurae remoti & plus in acutiore. In Parabole unus *D* est intra sectionem, alter vel extra vel intra sectionem in axe fingendus est infinito intervallo à priore remotus, adeò ut educta *HG* vel *IG* ex illo caeco foco in quodcunque punctum sectionis *G*, sit axi *DK* parallelos.

Oportet enim nobis servire voces Geometricas analogiae; plurimum namque amo analogias, fidelissimos meos magistros, omnium naturae arcanorum conscios: in Geometria praecipuè suspiciendos, dum infinitos casus interjectos inter sua extrema, mediumque, quantumvis absurdis locutionibus concludunt, totamque rei alicujus essentiam luculenter ponunt ob oculos.

Desargues' work with the title *Méthode universelle de mettre en perspective les objets donnés réellement ou en devis, ..., sans employer aucun point qui soit hors du champ de l'ouvrage* (à Paris 1636. *Oeuvres de Desargues, par M. Poudra*, Paris, 1864), reads (t. I, p. 82):

Quand les lignes suiet sont paralelles entr'elles et que la ligne de l'œil menée paralelle à icelles, n'est pas paralelle au tableau; les aparences des ces lignes suiet sont des lignes qui tendent toutes au poinct auquel cette ligne de l'œil rencontre le tableau....

His treatise on Conics with the title: *Brouillon proiect d'une* *atteinte aux éuénemens des rencontres d'un cone avec un plan* (Paris, 1639; *loc. cit.* t. I, p. 104) gives the definition:

Ordonnance des lignes droites.—Pour donner à entendre de plusieurs lignes droites, qu'elles sont toutes entr'elles ou bien paralleles, ou bien inclinées à mesme point, il est icy dit, que toutes ces droites sont d'une mesme ordonnance entr'elles; par ou l'on conceura des ces plusieurs droites, qu'en l'une aussi bien qu'en l'autre de ces deux espèces de position, elles tendent toutes à un mesme point.

(*c*) In the Vorwort to the *Geometrie der Lage*, by Dr Georg Karl Christian von Staudt, ord. Professor an der Univ. Erlangen (Nürnberg, 1847), we read:

Man hat in den neuern Zeiten wohl mit Recht die Geometrie der Lage von der Geometrie des Masses unterschieden, indessen gleichwohl Sätze, in welchen von keiner Grösse die Rede ist, gewöhnlich durch Betrachtung von Verhältnissen bewiesen. Ich habe in dieser Schrift versucht, die Geometrie der Lage zu einer selbstständigen Wissenschaft zu machen, welche des Messens nicht bedarf.

(*d*) H. Wiener, "Ueber Grundlagen und Aufbau der Geometrie" (*Jahresber. d. Deutsch. Math.-Verein.* I, 1892, p. 47), states:

Diese beiden Schliessungssätze (Der Satz von Desargues über perspective Dreiecke, Der auf das Geraden paar bezogene Pascal'sche Satz) aber genügen, um ohne weitere Stetigkeitsbetrachtungen oder unendliche Processe den Grundsatz der projectiven Geometrie zu beweisen, und damit die ganze lineare projective Geometrie der Ebene zu entwickeln.

v. Staudt's reference to the commutativity of multiplication of his Würfen is on p. 172, no. 268, of his *Beiträge zur Geom. der Lage* (Zweites Heft). A particular case of Pappus' theorem, considered with a view to the theory of similar triangles, is connected with commutativity of multiplication of the symbols by F. Schur, *Lehrbuch der Analytischen Geometrie* (Ers. Auf. 1898, Zw. Auf. 1912), Einleitung, p. 11. Cf. Hilbert, *Grundlagen der Geometrie*, 1899.

See also F. Schur, "Ueber den Fundamentalsatz der projectiven Geometrie," *Math. Ann.* LI (1899), pp. 401-409; "Ueber die Grundlagen der Geometrie," *Math. Ann.* LV (1902), pp. 265-292; and the volume by the same author, *Grundlagen der Geometrie*, Leipzig, 1909, pp. 1-192.

(*e*) For the many contributions of F. Klein to the foundations of geometry reference may be made to his forthcoming Collected Works. A general oversight may be found in the *Gutachten* pronounced for the first award of the Lobatschewsky prize, *Math. Ann.* L (1898), pp. 583-600.

Pasch's significant book has the title *Vorlesungen über neuere Geometrie* (Leipzig, 1882).

Peano's words may be quoted ("Sui fondamenti della geometria," *Rivista di Mat.* IV, 1894, p. 52): Ritenendo pertanto il concetto di spazio come fondamentale per la geometria, ne viene che non si potrebbe scrivere un trattato di questa scienza in una lingua che per avventura manchi di tali parole. Quindi non si potrebbe scrivere di Geometria nella lingua d'Euclide ed Archimede, ove appunto manca la parola correspondente al termine *spazio*, nel senso in cui lo si usa negli odierni trattati.

(*f*) The papers of Cayley and Clifford especially referred to are Cayley, "Chapters in the analytical geometry of *n* dimensions" (1843), *Coll. Papers*, I; Cayley, "A memoir on abstract geometry of *n* dimensions" (1869), *Coll. Papers*, VI; Clifford, "On the classification of loci" (1878), *Coll. Papers*, XXXIII; Riemann's paper, "Ueber die Hypothesen welche der Geometrie zu Grunde liegen" (see *Ges. Werke*), is of date 1854.

For references to C. Segre, see Bertini, *Introduzione alla Geom. proiett. degli iperspazi*, Pisa, 1907, pp. 1–426.

(*g*) Poncelet's statement of what constitutes in effect the Principle of Continuity in Geometry is given on p. 66, t. I, of his great work *Traité des Propriétés Projectives*, 2^me^ Ed., Paris, 1865. For his discovery in regard to the imaginary (or ideal) points of circles, see pp. 48, 64, 380, etc., of that work, and, for the corresponding theorem in regard to spheres, p. 370. For Chasles' account of pairs of imaginary points reference may be made to Chap. V of his *Traité de Géométrie Supérieure*, 2^me^ Ed., Paris, 1880. (See also the *Discours*, pp. 547–585 of the same volume, and his *Aperçu historique*.) Von Staudt's systematic justification of the use of imaginary elements occupies the Erstes Heft of his *Beiträge zur Geometrie der Lage*, 1856, pp. 1–129. In the Vorwort to this we read: Dass eine Ellipse oder Hyperbel durch ihre Brennpunkte und eine Tangente bestimmt ist, war schon den ältern Geometern bekannt. Das aber die Curve aus dem Grunde bestimmt ist, weil von ihr eigentlich fünf Tangenten gegeben sind, und dass also der erwähnte Satz nur ein besonderer Fall von einem allgemeinern Satze ist, ergab sich erst aus der Betrachtung der imaginären Elemente. A comparison of this with preceding formulations makes clear a notable advance in conception.

We pass now from these general remarks to some detailed references in regard to various points treated in the preceding pages. Explicit reference should however first be made to the two Cambridge Mathematical Tracts by Dr A. N. Whitehead, *The Axioms of Projective Geometry*, 1906, and *The Axioms of Descriptive Geometry*, 1907; also to Veblen and Young, *Projective Geometry*, Vol. I, 1910; and also to the *Bibliography of Non-Euclidian Geometry*, by Dr D. M. Y. Sommerville, St Andrews, 1911, which is a most valuable collection of exact references to geometrical literature extending far beyond its title.

pp. 6, 7. Desargues' theorem is proved as in the text by von Staudt. Desargues' proof for the case of two triangles in one plane is metrical. Mr R. J. Lyons, of the University of Sydney, remarks that the converse section (beginning at line 8 from below, on p. 7) may be shortened, using the preceding, by remarking that the joins of corresponding points of the two triads MCC', NBB' meet in the point L; hence the points (MC, NB), (MC', NB'), (CC', BB') are in line; and the first two are A and A'.

p. 11. For the origin of the fourth harmonic point, see Ch. Taylor, *Geometry of Conics*, referred to above, p. liv.

p. 14. Let a, b, c, d, e, f be imagined capable of associative and commutative multiplication, and such that

$$a^2 = b^2 = \ldots = f^2 = 1, = abcdef;$$

and let any product of two different elements, of these six, denote a point, three points being in line when the product of their three symbols is 1, as, for instance, ab, cd, ef, or ab, ac, bc. Then we have a 'geometry' of only fifteen points, thirty-five lines, and fifteen planes, such that any two points determine a line (containing three points), and every three points not in line determine a plane (containing seven points), in which every two lines have a point in common. Such a set of seven coplanar points are those represented by bc, ca, ab, ad, bd, cd, ef; the joining lines of these form a quadrangle of which the three vertices are in line, and the construction for the fourth harmonic point, given on p. 14 of the text, fails. The whole configuration may be represented by the symbol

$$15\,(\cdot, 7, 7)\; 35\,(3, \cdot, 3)\; 15\,(7, 7, \cdot),$$

meaning that there are fifteen points, each lying in seven lines and on seven planes, that there are thirty-five lines, each containing three points and lying in three planes, and fifteen planes, each containing seven points and seven lines. The reader may compare Veblen and Bussey, *Trans. Amer. Math. Soc.* VII (1906), p. 241, and *ibid.* VIII (1907), p. 266.

p. 15. See the note to p. 60, below.

p. 20. Cf. Zeuthen, *Compt. rend.* CXXV (1897), pp. 639, 858; a reference I owe to the kindness of Prof. F. Schur.

pp. 22–24. See F. Schur, *Math. Annal.* LI, 1899, pp. 406–409.

pp. 28, 29. This result, arising from Ex. 2 (p. 26), was so obtained by C. V. Hanumanta Rao, now Professor of Mathematics at Lahore.

p. 30. See K. Th. Vahlen, *Abstrakte Geometrie*, Leipzig, 1905, p. 129.

p. 47. Pappus' theorem may also be stated by saying that, if two triads of points L, L', L'' and M, M', M'' be in perspective in two ways, from centres N, N', then they are also in perspective from a third centre, N''. The three triads of points are then symmetrically related. Cf. Steinitz, *Enzykl. Math. Wiss.* III, 1, p. 491; also Rosanes and Schroeter, *Math. Annal.* II (1870), pp. 549, 553; Schroeter, *Oberflächen Zw. Ordn.* Leipzig, 1880, p. 405, and C. V. H. Rao, *Camb. Phil. Soc. Proc.* XXIII (1927), p. 496.

pp. 48, 49. See F. Schur, *Math. Annal.* LI, 1899, p. 405; F. Schur, *Grundlagen der Geometrie*, 1909, p. 37.

p. 60. The involution upon an arbitrary line by the six joins of four points, to which this work ultimately leads, is found in Pappus; see Ch. Taylor, as above, p. lii. The theorem was extended by Desargues to the intersections of a line by conics through four given points. *Œuvres de Desargues*, t. I (*Traité des coniques*, 1639), p. 268. For Desargues the relation is one among rectangles of segments on the line.

p. 61. Moebius, *Gesamm. Werke*, I, Leipzig, 1885, p. 443 (*Crelle*, III, 1828, p. 273).

p. 66. The symbols first given as example have of course the laws of combination of the complex numbers of ordinary analysis.

p. 71. In effect the symbols are here so introduced as to have the same laws of manipulation (save for commutative multiplication) as those of Moebius, in his barycentric calculus (1827. See *Ges. Werke*, I, p. 176), founded on metrical and statical considerations. In fact they were used as in the text, as the most appropriate representation of the geometry, before this was realised.

pp. 74 f. For such diagrams cf. F. Schur, *Math. Annal.* LV (1902), p. 281, or *Grundlagen der Geometrie* (1909), p. 51; Hilbert, *Grundlagen* (1899); Vahlen, *Abstrakte Geometrie* (1905); Veblen and Young, *Proj. Geom.* (1910). See also Hessenberg, *Acta Math.* XXIX (1905), p. 1; Hölder, *Leipzig. Ber.* LXIII (1911), p. 65; Mehmke, *Punkt- u. Vectorenrechnung*, 1913; von Staudt, *Beiträge*, No. 276, p. 175, etc.

p. 86. Moebius, *Ges. Werke*, I (Leipzig, 1885), p. 247, constructs the point $\alpha A+\beta B+\gamma C$, given $D=A+B+C$.

p. 96. Cf. Pasch, *Vorlesungen über neuere Geometrie* (1882); Peano, *I principii di geometria logicamente esposti* (Torino, Bocca), 1889; Peano, "Sui fondamenti della Geometria," *Rivista di Mat.* IV, 1894, pp. 51–90; Pieri, "I principii della Geometria di posizione," *Mem. Acc. Torino*, XLVIII (1898); also, Pieri, "Un sistema di postulati per la geometria proiettiva," *Rev. mathém. Torino*, VI (1896), and *Atti Torino*, 1904, 1906; *Mem. Torino*, 1905; Fano, "Sui postulati fondamentali della geometria proiettiva," *Giorn. di mat.* XXX (1892), pp. 106–132; Hilbert, *Grundlagen der Geometrie* (1899); F. Schur, *Grundlagen der Geometrie* (1909); Moore, "The projective axioms of geometry," *Trans. Amer. Math. Soc.* III (1902); Veblen, "A system of axioms for geometry," *Trans. Amer. Math.*

Soc. v (1904); Veblen and Young, "A set of assumptions for projective geometry," *Amer. J. Math.* xxx (1908); Robb, *Mess. of Math.* XLII, 1912, p. 121; Enriques, the German *Enzykl. Math. Wiss.* III, *Prinzipien*; and *Questioni riguardanti le matematiche elementari* (2 vols., Bologna, 1912); and many other writings (see the Bibliography of Sommerville, above referred to).

pp. 108–113. Cf. F. Schur, *Grundlagen der Geometrie*, pp. 16–18.

p. 125. In the hope that the geometrical reader may be willing to examine the theory of an abstract order, given in the text, on its own merits, references to, and the technical terms of, the theory of the so-called arithmetical continuum, have been avoided. For these the reader may consult authorities on the Theory of Functions. The reference to Dedekind might quite well be accompanied by references to Weierstrass, G. Cantor, and others.

p. 137. For Archimedes' axiom see the writings of Stolz; Hölder; Enriques, "Prinzipien der Geom." *Enzykl. der Math. Wiss.*; and Veronese, *Fondamenti di geometria a più dimensioni ed a più spezie di unità rettilinee esposti in forma elementare*, Padova, 1891, pp. 1–628, which has given rise to an extensive literature. For the use of the result stated on p. 137, instead of the axiom (3) of p. 122, to prove Pappus' theorem, see Newman, *Proc. Camb. Phil. Soc.* XXII (1925), p. 919; also Hilbert, *Grundlagen der Geom.* § 14.

p. 153. The argument of the text was suggested by F. Enriques, *Proj. Geom.*, Leipzig, 1903, Anhang, pp. 349–354.

pp. 165–175. Von Staudt's systematic treatment of imaginary elements is contained in the *Beiträge zur Geometrie der Lage* (1856); see, in particular, p. 76. An exposition of von Staudt's theory was given by Ch. An. Scott, *Math. Gazette*, 1900, and *Bulletin of the American Math. Soc.* VI, 1900, p. 163. For this and the theory of the text the following may be consulted: Stolz, *Math. Annal.* IV (1871), p. 416; August, "Untersuch. ü. d. Imag. in Geom." (*Prog. d. Fr. Realschule in Berlin*, 1872); Klein, *Gött. Nachr.* 1872, p. 373, *Ges. Abh.* I, p. 404; Lüroth, *Math. Annal.* VIII (1875), p. 145; Sturm, *Math. Annal.* IX (1876), p. 333; Schroeter, *Math. Annal.* X (1876), p. 420; Harnack, *Zeitschr. f. Math. u. Phys.* XXII (1877), p. 38; Lüroth, *Math. Annal.* XI (1877), p. 84; Lüroth, *Math. Annal.* XIII (1878), p. 305; Klein, *Math. Annal.* XXII (1883), p. 242; Grünwald, *Zeitschr. f. Math. u. Phys.* XLV (1900), p. 10; and K. Th. Vahlen, *Abstrakte Geometrie*, Leipzig, 1905, pp. 163–169.

NOTE I, to pp. 148–152.

On the condition that two spaces be related; and on the assignment of the symbols to the points of an Abstract Space.

§ 1. It has been shewn in the text (pp. 148–152), in particular for $n=2, 3$, that if, of two n-fold spaces, there be given $(n+2)$ points of one, to correspond respectively to $(n+2)$ given points of the other, then the spaces may be regarded as *related*. But the proof assumes that if, of a range of points (or pencil of lines) in one space, four points (or rays) be given, and, of the corresponding range (or pencil) in the other space, three points correspond to three of the four points of the former range, then the fourth point of the latter range which is to correspond to the fourth point of the former, is determinate. In other words it is assumed, as stated in the text, that we have agreed on some method of knowing when a range of one space is related to a range of the other (as by a sequence of perspectivities, for example).

§ 2. The geometrical correspondence, between two spaces of n dimensions, set up by means of $(n+2)$ points given in each space, may be obtained by a sequence of $(n+1)$ successive perspectivities, if the two n-fold spaces be supposed to lie in the same space of $(2n+1)$ dimensions. Such a succession of $(n+1)$ perspectivities is in fact equivalent to a projection from a single n-fold space (cf. p. 43, above); and we state the theorem first in this way. Suppose we have two n-fold spaces, lying in a space of $(2n+1)$ dimensions, S_{2n+1}, in general relative positions, the former space, S_n, containing the $(n+2)$ points $O, A, B, \ldots, D$, and the latter space, S_n', containing the $(n+2)$ points $O', A', B', \ldots, D'$, no set of $(r+1)$ points of either of these sets lying in a space of less than r dimensions (for $r < n+1$). It has been shewn (above, p. 39) that, through an arbitrary point of the line OO', a definite space, Σ_n, of n dimensions, can be drawn to meet all the $(n+1)$ lines $AA', BB', \ldots, DD'$. Take one such space Σ_n. Any point, P, of the space S_n determines then, with Σ_n, a space of $(n+1)$ dimensions; and this Σ_{n+1} meets S_n', in the space S_{2n+1}, in a single point, P'; and, conversely, P is thus determinable from P'. The line PP' then meets Σ_n. There is thus a (1, 1) correspondence between the points of the spaces S_n, S_n', in which, in particular, $O, A, B, \ldots, D$ correspond, respectively, to $O', A', B', \ldots, D'$. The correspondence can be shewn to transform a line, plane, ... of one space into a line, plane, ... of the other space, and evidently transforms any incidence of two spaces in S_n into an incidence of the two corresponding spaces of S_n'—so that, in particular, when $n \geqq 2$, it transforms a harmonic range into a harmonic range. And, if we assume Pappus' theorem, it can be shewn that the correspondence is the same whatever be the space Σ_n chosen (of the ∞^1 such that exist), and the same as if some other construction be used, likewise of (1, 1) character, which transforms $O, A, B, \ldots, D$ respectively into $O', A', B', \ldots, D'$. The construction is the direct generalisation of that followed, for the case $n=1$, to define two related ranges upon two straight lines which do not intersect (p. 18, above).

Essentially, as a sequence of $(n+1)$ successive perspectivities, the construction is due to Grassmann (*Crelle*, XLIX (1855), p. 55, for the case $n=2$. See further references in Segre, *Mehrd. Räume*, *Enzykl. Math. Wiss.*, III C. 7, pp. 820–822). We may indicate briefly this mode of statement, for the case $n=3$, supposing that the first projection, from an arbitrary point of the line

OO', has already been made, upon an arbitrary sixfold space containing O, A, B, C, D. We then have two threefold spaces, O, A', B', C', D' and O, A, B, C, D, in this sixfold space, with the point O in common. If we denote the points by symbols, for brevity, and suppose, for these, that

$$O = A + B + C + D = A' + B' + C' + D',$$

it can be shewn that there is a definite plane meeting the four lines AA', BB', CC', DD'; the points of meeting are the points of symbols $A - A'$, $B - B'$, $C - C'$, $D - D'$. We may then first project the points O, A', B', C', D' from the point $(A - A')$ on to the threefold space O, A, B', C', obtaining thus, respectively, the points $O, A, B', C', (-A + A' + D')$. This operation we can denote by

$$(-A + A')\{O, A', B', C', D'\} = \{O, A, B', C', -A + A' + D'\}.$$

We may then project from the point $(B - B')$ upon the threefold space O, A, B, C', giving the operation expressed by

$$(-B + B')\{O, A, B', C', -A + A' + D'\} = \{O, A, B, C', -B + B' - A + A' + D'\}.$$

If now we project from $(C - C')$ upon the space O, A, B, C, we obtain

$$(-C + C')\{O, A, B, C', -B + B' - A + A' + D'\} = \{O, A, B, C, D_1\},$$

where D_1, arising as

$$-C + C' - B + B' - A + A' + D',$$

is in fact D. We have thus passed from O, A', B', C', D' to O, A, B, C, D, respectively.

§ 3. We have in the text (p. 153) justified the use of the symbols, for the points of a space, by comparing the process by which two spaces are related with the process by which the symbols are assigned to the points of a given space. It appears worth while to remark in more detail upon the step of the latter process which corresponds to the condition, in relating two spaces, that a definite range of one of these shall be supposed, by some construction, related point by point, to the corresponding range of the other space. The step in question consists in supposing that the symbol for every point of a single definite line of the space is assigned, and conversely that the point of the line represented by every appropriate symbol is likewise supposed given. The explanation serves to emphasise further the point of view here taken in regard to the so-called imaginary (or abstract) points.

It has been assumed (p. 71, etc.) that if A, B be the symbols of two points, made definite by the assignment of the symbol of some other point of the line joining these, for instance the point $A + B$, then every symbol of the form $mA + nB$ represents a point of the line, and conversely that every point of the line can be represented by such a symbol. When m, n are iterative symbols we have shewn how to construct the point represented by $mA + nB$, in certain cases (p. 86); the two assumptions may then need no detailed justification when we are considering only the points in which m and n are real symbols (that is, the iterative symbols and the symbols arising from these as the irrational numbers of arithmetic arise from the rational numbers). But our aim is to set up an Abstract Geometry, admitting the existence of points whose geometrical relations are suggested by the relations of symbols which are of the form $A + iB$, where i is an algebraic symbol such that $i^2 = -1$ (cf. p. 143). For such points the case is different, the point $A + iB$ not being in linear order with the points $mA + nB$, in which m, n are iterative symbols.

Consider the case of a plane. Say that a line is *determinate by construction* when two points of it are supposed given, and a point is likewise determinate when two lines through it are given. Suppose that the four points of the plane of which the symbols are A, B, C, $A+B+C$, are given. Suppose further that for one definite line of the plane we know the symbol, $U+\lambda V$, of every point existing on this line, and, for every symbol of the form $U+\mu V$, we know the point of the line of which this is the symbol. We wish to make it clear that then the symbol $xA+yB+zC$, of every point of the plane, is determined, and conversely that the point is determined which is represented by any given symbol of this form, in which x, y, z are any algebraic symbols of the system we are using. It is sufficient to suppose that the line UV, upon which the correspondence of points and symbols is known, is one of the lines joining two of the points A, B, C, $A+B+C$. We will suppose that it is the line BC. Then the correspondence upon any other line of the plane is determined by projection. For instance upon the line AB: any given point, Q, of AB, joined to O, gives a point, P, of the line BC, of which then, by hypothesis, the symbol $B+\lambda C$ is known; the symbol of Q is then

$$-(B+\lambda C)+\lambda(A+B+C),$$

or $\lambda A+(\lambda-1)B$. Conversely, any symbol $A+\mu B$, wherein μ is given, by taking $\lambda-1=\mu\lambda$, or $\lambda=(1-\mu)^{-1}$, determines a symbol $B+\lambda C$, or $(1-\mu)B+C$; by the hypothesis made this determines a definite point, P, upon BC, and, from this, the point, Q, of AB, given by $A+\mu B$, is determined by the intersection of PO with AB. Similarly for the line AC, or for the lines OB, OC (using A instead of O); and similarly for AO, points of which can be projected upon AB from C. For a point, P, of the plane which does not lie on any of the lines joining A, B, C, $A+B+C$, let the lines joining P to A and O meet BC in A' and O', respectively. Then if P is given, both A' and O' are determinate, and conversely. If P be $xA+yB+zC$, the points A', O' are, respectively, $yB+zC$ and $(y-x)B+(z-x)C$; whence, if P is given, the ratios y/z and $(y-x)/(z-x)$ are known, and hence the ratios of x, y, z. Conversely if these latter are given, so, by the hypothesis, are the points A' and O', and hence the point P.

It is sufficiently clear that the general proposition is that if, in an n-fold space, the symbols O, A, B, ..., D, of $(n+2)$ given points, be given, with the expression of O in terms of A, B, ..., D (say $O=A+B+\ldots+D$); and also the correspondence be given between the symbols and the points, including the abstract points, upon one of the lines, say AB, joining two of the $(n+2)$ given points, then the correspondence of points and symbols is determinate by construction for every point of the space, and every allowable symbol.

This assignment of the correspondence between the symbols and the points of one line serves the purpose of shewing what is involved in regarding the operations of the geometry as controlled by the behaviour of the symbols. But, by its merely theoretical character, it serves also to explain the sense in which we say that certain processes are not geometrically possible, by construction, except with the supposition that this assignment has been made. For instance, it is true in the Abstract Geometry that two related ranges on the same line have two common corresponding points; but as appears under (vi), p. 159, above, these are not always separately determinable by construction. Or, to take another illustration: later on (Vol. ii, Chap. iv) we identify the iterative symbols with the real numbers of arithmetic, utilising the notion of order in the real geometry for the points of a line. Then we are able to identify the algebraic symbols with the numbers of ordinary Analysis, regarding any symbol as being of the form $\lambda+i\mu$, with $i^2=-1$, in which λ, μ are real numbers, which are then known when the symbol is given. Thereby also the symbol $\lambda-i\mu$, and a point defined by this, are determinate, when the symbol $\lambda+i\mu$ is given. A set of points with coordinates of the forms $\lambda+i\mu$, determines then, in this sense, a corresponding set of points with coordinates of the forms $\lambda-i\mu$;

and every incidence of elements of the former set determines an incidence of the latter. But the two sets of points are not corresponding parts of two spaces which are *related*; nor are the points of the second set determinate by *construction* from the points of the former set, except with the supposition that the assignment of the correspondence of the points and symbols for a line, referred to above, has been made. Such a construction would in particular involve that a symbol $x-iy$ was an analytic function of $x+iy$, which is not the case. It would seem then to add to clearness to distinguish between (1, 1) correspondences of two spaces which are *arithmetical*, in the sense explained, and those which may be called *geometrical*. For the questions here discussed, cf. von Staudt, *Geom. d. Lage, Beiträge*, Nos. 225, 226, pp. 147, 148; also Nos. 276, 283, pp. 174, 177. See also Segre, *Un nuovo campo di ricerche geometriche, Atti...Torino*, xxv (1890), pp. 276, 430, and xxvi, pp. 35, 592.

NOTE II, to pp. 165–175.

On the representation of imaginary elements by sets of real elements.

The following remarks, though in logic belonging to a subsequent stage of the geometrical theory, may explain the meaning of and establish confidence in the representation given in the text.

If, in space of three dimensions, A, B, C, D be the symbols of four points, of general positions, regarded as real, an 'imaginary' point, with respect to these, is a point of symbol

$$(a+i\alpha)A+(b+i\beta)B+(c+i\gamma)C+(d+i\delta)D,$$

or $P+iQ$, where $i^2=-1$, and P, Q are the real points given respectively by

$$P=aA+bB+cC+dD, \quad Q=\alpha A+\beta B+\gamma C+\delta D.$$

Thus an imaginary point lies on a real line, joining two real points P, Q. The same point is represented, if l, m be real, by the symbol $(l+im)(P+iQ)$, or

$$lP-mQ+i(mP+lQ);$$

the pairs of real points $lP-mQ$, $mP+lQ$ belong to an involution upon the line, of which the double points are $P+iQ$ and $P-iQ$. These points coincide when P, Q represent the same point, in which case $P+iQ$ is a real point.

An imaginary line of the most general kind is that joining two general imaginary points. The points of such a line have then a symbol of the form

$$A+iB+(p+iq)(C+iD),$$

in which A, B, C, D represent real points, and p, q are real symbols which vary from point to point of the line. As an imaginary point depends upon six real symbols, it follows that a general imaginary line depends upon eight real symbols. The symbol of a general point of the line being

$$A+pC-qD+i(B+qC+pD),$$

it follows that the line does not contain a real point unless, for proper values of p and q, the symbols $A+pC-qD$, $B+qC+pD$ represent the same point. For this, the necessary and sufficient condition is that the four points A, B, C, D should lie in a plane. Then the line lies in this plane. Through the general point of a general imaginary line there passes a definite real line; that, namely, joining the points $A+pC-qD$, $B+qC+pD$; this line does not intersect the real line passing through another point of the imaginary line, or, again, the points A, B, C, D would be in a plane. All these real lines evidently meet also the imaginary line which joins the points $A-iB$, $C-iD$, the real line spoken of passing through the point

$$A-iB+(p-iq)(C-iD);$$

we may regard this last as the symbol of the general point of the second line, and speak of this line as the conjugate imaginary of the former. The real lines meeting a general imaginary line are thus, in a subsequent phraseology, the real lines of a linear congruence of lines. As stated in the text (p. 170), one of the real lines meeting a general imaginary line passes through an arbitrary real point, the real line through $xA+yB+zC+tD$ which meets the imaginary line being that through the point

$$(x-iy)(A+iB)+(z-it)(C+iD)$$

of the imaginary line. From the abstract point of view, if the given real point be joined by planes to the imaginary line and its conjugate, these conjugate imaginary planes meet in the real line in question.

Now take any three of the real lines meeting the given general imaginary line, say the lines a, a', a''; and consider the common transversals of the lines a, a', a'', among which are the original line and its conjugate imaginary. Let these latter meet the line a in the points I and J, respectively, and similarly meet a' in I', J', and meet a'' in I'', J''. Also, from a point P, in the line a, let the transversal to a' and a'' meet these in P' and P'', respectively; and, similarly, let Q, Q', Q'' be another transversal, R, R', R'' another, and so on. It can be shewn that the ranges $I, J, P, Q, R, \ldots$; $I', J', P', Q', R', \ldots$; $I'', J'', P'', Q'', R'', \ldots$ are related. We may suppose P, Q, R so taken on a that I, J are the common corresponding points of the two related ranges on a which are defined by the condition that P, Q, R of one range correspond respectively to Q, R, P of the other range; then exactly similar relations hold on a' and a''. The condition stated is the same as that I, J are the Hessian points of the triad P, Q, R (see Ex. 5, p. 174). If, further, another triad of real points X, Y, Z, be taken on a, such that the three ranges X, P, Q, R; Y, Q, R, P; Z, R, P, Q are related, then triads X', Y', Z' and X'', Y'', Z'' exist on a', a'', respectively, for which similar relations hold. Conversely, three real lines PP', QQ', RR', in which the real points P, Q, R are on a line a, and the real points P', Q', R' are on a line a', determine conjugate imaginary points I, J on a, and conjugate imaginary points I', J' on a' (cf. Ex. 1, p. 173), and so determine the conjugate imaginary lines II', JJ'; also ∞^1 real lines, such as a'', meeting PP', QQ', RR', are determinate, as well as sets of lines such as XX', YY', ZZ', all equally meeting the line a''. We may, however, regard as given, not the lines PP', QQ', RR', but, for example, the lines PX', QY', RZ'; then the same pair of imaginary lines II', JJ' will be determined by these as by the triad PP', QQ', RR', but the line a'' is not a transversal, in general, of PX', QY', RZ'; the real lines meeting PX', QY', RZ' will be another ∞^1 of real lines, than those meeting PP', QQ', RR', also belonging however to the ∞^2 real lines which meet II' and JJ'. In a phraseology employed in Vol. III, there are two quadric surfaces involved, which have four lines in common, namely, the two real lines a, a', and the two conjugate imaginary lines II', JJ'. More generally, varying the set X', Y', Z' upon the line a', we obtain ∞^1 real quadric surfaces, every one of which contains the lines II', JJ' as well as ∞^1 real lines which meet these. We may, in fact, verify that, with coordinates relative to the fundamental points A, B, C, D of our discussion, the equation

$$\begin{vmatrix} x^2+y^2, & xz+yt, & yz-xt, & z^2+t^2 \\ 1, & p, & q, & p^2+q^2 \\ 1, & p', & q', & p'^2+q'^2 \\ 1, & p'', & q'', & p''^2+q''^2 \end{vmatrix} = 0$$

represents the quadric surface containing all points, $(1, i, \theta, i\theta)$, of the imaginary line II', and all points, $(1, -i, \phi, -i\phi)$, of the line JJ', as well as all points, $(1, \sigma, p+q\sigma, p\sigma-q)$, of the line a, and, similarly, all points of the lines a', a''. A set of points such as P, Q, R (or X, Y, Z) above, corresponds to three values of σ satisfying an equation of the form

$$\sigma^3+3h\sigma^2-3\sigma-h=0,$$

where h is variable as we pass from set to set; the Hessian of this form is $(\sigma^2+1)(h^2+1)$, and the points I, J arise for $\sigma=i$ and $\sigma=-i$. If we choose P, Q, R corresponding to the three values of σ satisfying this equation for any given value of h, and choose P', Q', R' corresponding to the three values of σ arising when h' is put for h, then there are ∞^1 lines a'' for which the quadric surface, with the equation above, contains all the sets of lines equivalent to PP', QQ', RR'. These sets form one of the *skew linear series*, in the phraseology of the text, which, with a proper order for P, Q, R, represent the line II'.

The statement in the text (p. 168), that of a given skew linear series, there is one set of which one line is an arbitrary line, follows at once. For, from two real points taken on the arbitrary line l, draw the real lines which meet II'; these are such as the lines a, a' of the preceding discussion; and two lines can be taken meeting a and a', which, with l, form three lines whose intersections with a (or with a') have as their Hessian pair the intersections of a with II' and its conjugate imaginary.

Beside the most general imaginary line thus considered, there are imaginary lines each containing only one real point. If H be this point, the points of such a line have symbols of the form $A+iB+(p+iq)H$, where p, q are real variable symbols. Such a line lies in the real plane determined by the points A, B, H. The conjugate imaginary of a general point, $(1, i, p+iq, 0)$, of this line, is the point $A-iB+(p-iq)H$, which does not lie on the line. The *line series* of the text consists then of sets of three lines through the point H, one such set being, relatively to A, B, H, expressed by an equation

$$y^3+3hy^2x-3yx^2-hx^3=0,$$

with an appropriate value for h.

By von Staudt, the general imaginary line was said (*Beiträge*, pp. 76, 77, Nos. 116, 117) to be of the second kind, the lines containing one real point being of the first kind. A line containing two real points is real.

It is very usual to represent a line by means of the ratios of the coefficients in the equations of the planes which join the line to four fundamental points, which we shall consider as real; of these planes two are in general sufficient. If their equations be taken to be

$$l't+mz-ny=0=m't+nx-lz=n't+ly-mx=l'x+m'y+n'z,$$

with $ll'+mm'+nn'=0$, then l, m, n, l', m', n' are the homogeneous coordinates of the line. An imaginary line of the most general kind will then be given by such coordinates, with the condition that two at least have a ratio which is not real; or, if we write $l=l_1+il_2, \ldots, n'=n_1'+in_2'$, not all of $l_2, \ldots, n_2'$ are zero. The conditions that such a line should contain a real point are that two of the four planes above (and, therefore, the other two) should contain this point; and, for one of these planes to contain a real point, two conditions, in real symbols, must be satisfied. The elimination of the coordinates of the real point, from the four conditions so arising, leads to one condition as necessary among the line coordinates. For a general imaginary line we have the relations

$$l_1l_2'+l_2l_1'+m_1m_2'+m_2m_1'+n_1n_2'+n_2n_1'=0,$$
$$l_1l_1'+m_1m_1'+n_1n_1'=l_2l_2'+m_2m_2'+n_2n_2';$$

the condition that the line should contain a real point is found to be that both the last written expressions should vanish. If a general imaginary line be described, as above, as joining the two points $A+iB$, $C+iD$, its coordinates relatively to A, B, C, D are easily seen to be $(i, -1, 0; -i, 1, 0)$; the real lines meeting the imaginary line are then such that $l=l'$, $m=m'$.

Von Staudt's theory uses (*Beiträge*, § 15, p. 137) the notion of a *chain* of points upon a general imaginary line, determined by three arbitrary points thereon. If, as above, a, a', a'' be the real lines through these points, the chain consists of the points, U, of the line, such that the real line through U is met by all the transversals of a, a', a''. Thus, also, from what we have said, it consists of all points $A+iB+(p+iq)(C+iD)$, where p, q satisfy a relation of the form $a+bp+cq+d(p^2+q^2)=0$, in which a, b, c, d are real. Or, again, it consists of all points $P+n\omega Q$, where P, Q are the symbols of two points of the line, ω is a definite imaginary symbol, and n is a variable real symbol. From the theory of quadric surfaces it is clear that two chains with one common point have in general another common point. But also, if one quadric surface have the conjugate imaginary lines II', JJ' as generators, and have the real generator a, meeting these, as another generator; and if u be a real line meeting II', JJ', not lying on the quadric surface, another quadric surface can be constructed, having II', JJ', a and u as generators, to touch the former at every point of a; so that (von Staudt, *Beiträge*, p. 139, No. 208), there is one chain containing one given point of a given chain, and another assigned point of the line not belonging to the first chain, which contains no other point of the first chain. If the first chain be given by $A+iB+n\omega(C+iD)$, and the point U be $A+iB+\mu(C+iD)$, in which μ/ω is not real, the second chain is $\mu(A+iB)+p\omega U$, for variable real p; namely, is $A+iB+\omega\nu(C+iD)$, where $\nu^{-1}=p^{-1}+\omega/\mu$; and ν can be real for no real value of p other than $p=0$. (Cf. Veblen, *Projective Geometry*, II, p. 30, Assumption I.)

NOTE III, to p. 118.

On onesidedness.

The statement referred to, that the plane is a onesided surface, retains from the limited real geometry the notions, (i) of a segment of a line, to which a definite direction, or sense, is assigned; (ii) of a region of a plane bounded by segments; but uses also the notion, (iii) that two points of a line determine two segments thereon, the line being continued, *with its direction*, through the inaccessible point of the line. The property of onesidedness arose however for surfaces of which all the points are accessible, and may first be explained for such a case (given by Moebius, *Ges. Werke*, II, p. 482).

Suppose we have, in space of three dimensions, a set of triangular pieces of paper, joined together along sides, so that any side of any triangle is also a side of another triangle, such for instance as the four triangles bounding a tetrahedron. By assigning a direction to one side of one triangle we may establish a direction of circulation round the sides of the triangle, each of the other two sides acquiring thus also a direction. Taking now a particular one of the three sides of this triangle, and regarding it as a side of the other triangle of the figure to which it belongs, we may attach to it, in this other triangle, the reverse direction to that formerly assigned, and so establish a direction of circulation round the sides of the second triangle. The same process may now be applied to the other sides of the first and second triangles, and so on continually. It may then be the case that it is possible to assign a direction of circulation for all the triangles of the figure, in such a way that the two directions thus arising in any segment (which belongs by hypothesis to two triangles) are opposite. This is the case, for instance, for the four triangles of a tetrahedron whose vertices are A, B, C, D: we may take for ABC the circulation indicated by the order of the letters, with the other respective circulations DCB, DAC, DBA; then BC in ABC arises as CB in DCB, and DA in DAC arises as AD in DBA, and so on.

But such an assignment of circulations may be impossible. Take, for instance, five points, which we denote in order by 1, 2, 3, 4, 5; let the five segments 12, 23, 34, 45, 51 be called the sides, and the five segments 13, 24, 35, 46, 51 be called the diagonals; two consecutive sides such as 12, 23 together with the associated diagonal 13 form a triangle, and there are five such triangles; two of these which are consecutive have in common one of the five original sides of the figure, but we neglect the possibility of other common points of any two of these triangles. Now take an arbitrary sixth point, say 6; and let the two segments joining it to the two ends of a diagonal, together with that diagonal, be regarded as forming another triangle. Thereby we have five new triangles; and the whole ten triangles are such that any bounding side of one of them is equally a bounding side of another triangle. It can easily be seen that the figure now obtained is symmetrical in its description, whichever five of the six points be regarded as first taken; the description may be represented by

$$6(\cdot\,, 5, 5)\,15\,(2, \cdot\,, 2)\,10\,(3, 3, \cdot\,),$$

meaning that there are six points each an end point of five segments, or edges, and a corner of five triangles, or faces; that there are fifteen edges, each with two corners and lying in two faces; and that there are ten faces, each containing three corners and three edges. To avoid the possible intersections of the faces, save along the assigned edges, we may suppose the figure constructed in space of four dimensions. For this figure, now, it will be found impossible to assign such a circulation to every one of the ten triangles that the two directions thus arising in any edge, regarded as belonging in turn to the two faces of which it is a bounding edge, shall in all cases be opposite. In fact this condition applied to the five triangles 613, 624, ..., 651 necessitates the assignment of a uniform sense to the diagonals 13, 35, 52, 24, 41 (one of two senses); but the sense 31 of the diagonal edge of the face 123, involves the sense 23 in the side edge, while the sense 42 of the diagonal edge of the face 234 also involves the sense 23 in the side edge; and thus the two senses arising in the edge 23 are not opposite, as they should be. The figure may then be spoken of as a closed one-sided polyhedron.

Now consider, in a plane, four points A, B, C, D; let the pair of opposite joins BC, AD meet in P, and similarly CA, BD meet in Q, and AB, CD meet in R. On each of the six joining lines, regarded as divided into two segments by the two points of A, B, C, D which lie upon it, take the segment which does not contain the respective point, of P, Q, R, which lies on this line. Denote the segments so obtained, respectively on AB, BC, CD, DA, BD, AC by 1, 2, 3, 4, 5, 6. Thereby we may regard the whole plane as divided into three regions each bounded by four segments; one region by the segments 1, 2, 3, 4; another by the segments 2, 4, 5, 6; and the third by the segments 1, 3, 5, 6. In a phraseology which will be understood the connection of two of these regions is secured by using inaccessible points of the region. Each segment contains two points and is a boundary of two regions. It will be found then that it is impossible to assign a direction of circulation for every region, round the four segments bounding the region, in such a way that the directions so obtained, along any segment separating two regions, are opposite. It is understood, as has been stated, that for a segment containing the inaccessible point of the line on which the segment lies, the direction of the segment, regarded as part boundary of one of the regions, is continued through the inaccessible point.

The origin of the peculiarity evidently is that the points of the plane are obtainable from the lines passing through an arbitrary point not in the plane; the dissection of the plane which we have considered may be obtained by projecting the surface of, say, a cube, from its centre, upon a plane not passing through this; then two opposite points of the surface of the cube, upon the same line through the centre, give rise to the same point of the plane. The same peculiarity arises for any dissection of the complete plane; and for this reason the plane is said to be one sided.

It is interesting to remark that the extension of similar considerations to the complete space of three dimensions leads us to regard this as *two* sided. For brevity employ the description of the real metrical geometry. Consider a rectangular parallelepiped. Let the corners of one face be named in order A, B, C, D, and the diametrically opposite corners of the opposite face be named, respectively, A', B', C', D'. Consider the segment of the diagonal AA' which does not contain the centre of the figure; this may be regarded as beginning at A, passing through a point X, then through the inaccessible point and then to A' through a point X'. Similarly let the exterior segment of the diagonal BB' be $BYY'B'$, the inaccessible point being passed between Y and Y'; and we likewise consider the other two exterior diagonal segments, $CZZ'C'$ and $DTT'D'$. The whole threefold space may now be divided into four regions. One of these is within the original parallelepiped; another is bounded by the two faces $ABCD$, $A'B'C'D'$, the two faces $ABYY'B'A'X'X$, $CDTT'D'C'Z'Z$, and the two faces $DAXX'A'D'T'T$, $BCZZ'C'B'Y'Y$; and there are two other regions, each of which has, as two of its six boundary faces, two opposite faces of the original solid. There are thus, in all, twelve faces, each a boundary of two of the regions; and there are sixteen edge segments each lying in the boundary polygon of four faces. The whole figure may be represented by

$$8(\cdot, 4, 6, 4)\,16(2, \cdot, 3, 3)\,12(4, 4, \cdot, 2)\,4(8, 12, 6, \cdot),$$

meaning that there are eight corner points, each an end of four segments, lying in six faces and belonging to four of the regions; that there are sixteen edge segments, each containing two corners, lying in three faces and belonging to three of the regions; and so on. It can be verified, (i) that, considering any one of the regions, we can assign, for each of its faces, a direction of circulation of its edge segments, so that for every two of the faces the directions in their common edge are opposite, (ii) that this can be done so that the directions of circulation for any polygon face common to two regions, arising in this way for the two regions, are opposite. The complete threefold space may then be regarded as two sided.

We have said that the dissection of the plane we have employed may be regarded as obtained by projecting the faces of a cube from its centre. The centres of the faces of the cube define an octahedron. If this be projected from its centre we obtain a dissection of the plane into four triangular regions: let A, B, C be three points of the plane, let a, b, c denote, respectively, the segments BC, CA, AB which do not contain a point of some line drawn in the plane, and let a', b', c' be the complementary segments of the lines BC, CA, AB. The four regions are then bounded, respectively, by the segments

$$(a, b, c), \quad (a, b', c'), \quad (b, c', a'), \quad (c, a', b').$$

The numerical schemes which describe the former dissection and the latter respectively are

$$4(\cdot, 3, 3)\,6(2, \cdot, 2)\,3(4, 4, \cdot), \quad 3(\cdot, 4, 4)\,6(2, \cdot, 2)\,4(3, 3, \cdot)$$

in which the numbers come in the reverse order. The diagrams are in fact 'reciprocal' in the sense employed in the theory of force diagrams (cf. Maxwell, *Sc. Papers*, I, p. 514, II, p. 161 and II, p. 492).

In the same way for the subdivision of the complete space of three dimensions, instead of a cube we may employ a tetrahedron, so dividing the space into eight tetrahedra. It will be found that in the numerical scheme for the figure obtained the numbers come in the reverse order to that in the scheme obtained above. But the two sidedness is obtainable also by this figure; or indeed by any other subdivision.

In connection with this note the reader may consult Dénes König, *Archiv d. Math. u. Phys.* XIX (1912), p. 214, and the references there given; in particular, Möbius, *Ges. Werke*, II. A drawing of a closed onesided surface is given in Klein, *Ges. Abh.* II, p. 76.

PRINTED IN GREAT BRITAIN

PREFACE

THE present volume has in effect two aims: In the first place, in pursuance of the general purpose of the book, it seeks to put the reader in touch with the main preliminary theorems of plane geometry. Chapter I is devoted to a deduction, with synthetic methods, of the fundamental properties of conic sections; it is an introduction to what is usually called Projective Geometry, in the plane, in which, however, the notions of distance and congruence are not assumed. Chapter II, also without help of these notions, develops results that arise by considering conics in relation to two Absolute points, including, for instance, the properties of circles, and of confocal conics; the matter here contained is usually found in sequels to Euclid, books on Pure Geometry, and books on Geometrical Conics. Chapter III is designed to explain the application of the algebraic symbols to plane geometry; it contains methods and formulae found in works on Analytical Geometry of the Plane. Chapter IV is a brief consideration of some logical questions, and marks the recognition of a limitation in the symbols employed; it deals with the sense in which the words real and imaginary are used, and calls attention to the elements of Analysis assumed in the following chapter. Chapter V deals with the theory of measurement, of length and angle, with the help of an Absolute conic, shewing how the so-called non-Euclidean geometries may be regarded as included in our general formulation. It considers the metrical plane also as deduced from the geometry of a quadric surface, incidentally dealing with the fundamental properties of this surface and, in particular, with Spherical Trigonometry. As a corollary from this point of view, Riemann's space of constant curvature is seen not to require the assumption of absolute coordinates; and further, that form of the hyperbolic geometry in which lines are replaced by circles cutting a fixed circle at right angles (which, for instance, was an inspiration to Poincaré in his development of the theory of automorphic functions) is seen to arise naturally. Notes I and II deal with the theorems of incidence which were developed very gradually for the complete Pascal figure and appeared very intricate; from the point of view here explained they are natural, if particular, properties of a figure which arises otherwise, and will much concern us in a later volume. Note III gives some indications of the literature of non-Euclidean geometry. Note IV contains remarks and corrections for Volume I, for many of which I am indebted to friends. There is also an Index; but it is possible that the extensive Table of Contents may be more useful. No attempt is made to give a general Bibliography for the contents of the volume.

It will be seen that the volume deals with a wide range of theory; in other conditions than the present, a less condensed treatment might have been desirable. The order in which the ideas are taken has been chosen largely in view of the second aim of the volume; it will not be difficult, with the help of the Table of Contents, for the reader to modify this order. It is believed, however, that a large amount of the time usually spent, at present, in learning geometry, could be saved by following, from the beginning, after an extensive study of diagrams and models, the order of development here adopted; and such a plan would make much less demand upon the memory.

But the second aim of the volume may, I hope, appeal to attentive readers. It is an attempt, tempered indeed by practical considerations, to test the application in detail of the logical principles explained in Volume I. It seeks to bring to light the assumptions which underlie an extensive literature in which coordinates are freely used without attempt at justification. It suggests the question whether, in the case of distance, as in many other cases, we may not have derived from familiarity with physical experiences, a confidence which a more careful scrutiny can only regard as an illusion. When this view, which seems sure, shall win acceptance, the change in scientific thought will be rapid and momentous. As the first step in this sense was made in the development of the theory of our geometrical conceptions, it is proper that the matter should be dealt with here. It will be of importance if the reader come to see how deep lying are the questions involved in the use of coordinates, and the assumption of distance as a fundamental idea.

As in the case of the first volume, I desire to express my thanks to the Staff of the University Press for their care and courtesy, and to Mr J. B. Peace, M.A., for the great trouble he has taken with the numerous diagrams.

H. F. B.

2 *September* 1922

To the present Reprint are added, at the end of the Volume, various remarks and examples; these are referred to in the text by the abbreviation [Add.]. To many friends who have made suggestions I offer my best thanks.

H. F. B.

TABLE OF CONTENTS

PRELIMINARY

PAGES

Related ranges on the same line 1

Involution . . . . 2—4

Symbolical expression of the preceding results . . . . 4—6

Examples of involution . . . . 6—8

A general abbreviated argument for relating two ranges . . 8, 9

Of the distinction between the so-called real and imaginary points 9

CHAPTER I. GENERAL PROPERTIES OF CONICS

Definition of a conic . . . . 10—12

Involution on a line by conics having four common points . . 12, 13

Maclaurin's definition of a conic. Pascal's theorem . . . 13, 14

Ranges of points on a conic 14

Involution of pairs of points of a conic 14, 15

Pascal's theorem and related ranges of points upon a conic . . 15, 16

Converse of Pascal's theorem 16

Introduction of the algebraic symbols . . . . 16—20

Geometrical theory resumed. Polar lines 20, 21

Duality in regard to a conic 21

Dual definition of a conic 22, 23

Examples of the application of the foregoing theorems (Exx. 1—36) 23—62

Ex. 1. *The self-polar triad of points for conics through four points; the self-polar triad of lines for conics touching four lines* . . 23—25

Ex. 2. *Dual of Pascal's theorem* 25, 26

Ex. 3. *The director conic of a given conic in respect of two arbitrary points* 26, 27

Ex. 4. *The polars of three points determine a triad of points in perspective with the original triad* 27

Ex. 5. *A construction for two points conjugate in regard to a conic* 27, 28

Ex. 6. *Range determined by a conic, and by the joins of three points of the conic, upon any line drawn through a fixed point of the conic* 28, 29

Ex. 7. *The six joins of two triads of points of a conic touch another conic* 29

Ex. 8. *The pedal line of three points of a conic in regard to three other points of the conic, taken in a particular order* . . . 29, 30

Ex. 9. *The Hessian line of three points of a conic. The Hessian point of three tangents of a conic* 30, 31

PAGES

Ex. 10. *Polar triads in regard to a conic. Hesse's theorem* . . 31—33

Ex. 11. *Outpolar conics* . . . . 33—35

Ex. 12. *Two self-polar triads of one conic are six points of another conic* 35, 36

Ex. 13. *Particular cases of outpolar, or of inpolar, conics* . . 36

Ex. 14. *The joins of four points of a conic and the intersections of the tangents at these points. The common points, and the common tangents, of two conics* 36, 37

Ex. 15. *The polar lines of any point in regard to the conics through four given points all pass through another point* . . . 37, 38

Ex. 16. *A point to point correspondence in regard to four given points* 38, 39

Ex. 17. *Four conics can be drawn through two given points to touch three given lines* . . . . 39—41

Ex. 18. *The poles of a line, in regard to conics with four common points, lie on a conic* 41, 42

Ex. 19. *Two conics of which the tangents at their common points meet, in fours, at two points* . . . . 42—44

Ex. 20. *A conic derived from two given conics* 44, 45

Ex. 21. *To construct a conic in regard to which two triads of points of a given conic shall both be self-polar* 45, 46

Ex. 22. *To construct a conic for which a given triad of points shall be a self-polar triad, and a given point and line shall be pole and polar* 46

Ex. 23. *To construct a conic for which a given triad of points shall be self-polar, to pass through two given points* 46, 47

Ex. 24. *The polar reciprocal of one conic in regard to another. A particular case* 47, 48

Ex. 25. *Gaskin's theorem for conics through two fixed points outpolar to a given conic* . . . . 48—50

Ex. 26. *Two related ranges upon a conic obtained by composition of two involutions* . . . . 50—52

Ex. 27. *Three triads of points of a conic are all in perspective with another triad of points of the conic* 52

Ex. 28. *The envelope of the line joining two corresponding points of two related ranges on a conic* 52, 53

Ex. 29. *The tangents from three points, A, B, C, to a conic, meet BC, CA, AB in six points of a conic* 53, 54

Ex. 30. *Two tangents of one conic meet two tangents of another in four points lying on a conic through the common points of the two conics, if the four points of contact are in line* 54, 55

Ex. 31. *Poncelet's theorem, for sets of points A, B, C, ... of one conic, of which the joins AB, BC, ... separately touch other fixed conics, all the conics having four points in common* . . . 55—58

Ex. 32. *Construction of a fourth tangent, with its point of contact, of a conic touching three lines at given points* 58, 59

PAGES

Ex. 33. *Hamilton's extension of Feuerbach's theorem* . . . 59, 60
Ex. 34. *Theorem in regard to the remaining common tangents of three conics, which touch three given lines* 60, 61
Ex. 35. *The four conics through two points of which each contains three of four other given points* 61
Ex. 36. *The polars of any point in regard to the six conics which can be drawn through the sets of five, from six arbitrary points of a plane, touch a conic* 61, 62

CHAPTER II. PROPERTIES RELATIVE TO TWO POINTS OF REFERENCE

Introductory 63
Middle points, Perpendicular lines, Centroid, Orthocentre . . 63, 64
Circles. Circles at right angles 65, 66
Coaxial circles 66, 67
Inversion in regard to a circle 67, 68
Examples of inversion in regard to a given circle . . . . 68—70
Examples in regard to circles (Exx. 1—9) . . . . . . 70—75
Miquel's theorem, pedal (Wallace) line, property of four circles . 70—72
Proof of Feuerbach's theorem by inversion . . . . . . 73—75
Angle properties for a circle . . . . 75—77
Foci and axes of a conic . . . . 77—79
Confocal conics 79
Common chords of a circle with a conic 79, 80
The director circle of a conic. The director circles of conics touching four lines are coaxial 80, 81
Parabolas. The directrix of a parabola 81
Examples in regard to a parabola (Exx. 1—5) . . . . . 81—83
Definition of a rectangular hyperbola 83, 84
Examples in regard to a rectangular hyperbola (Exx. 1—3) . . 84, 85
Auxiliary circle of a conic 85, 86
Examples in regard to auxiliary circle, and pedal circle (Exx. 1—5) 87, 88
The locus of the centres of rectangular hyperbolas passing through three given points . . . . 88—90
The polars of a point in regard to a system of confocal conics touch a parabola. Four normals can be drawn from a point to a conic 90, 91
A particular theorem for intersection of a conic with a rectangular hyperbola 91, 92
The normals of a conic which pass through a given point. The feet of three of these, and the opposite of the other foot, lie on a circle. Case of the parabola also. Examples (Exx. 1, 2) . 92—94
The dual of the director circle of a conic. Sets of four points of one conic whose joins in order touch another conic . . . 94—96

CHAPTER III. THE EQUATION OF A LINE, AND OF A CONIC

PAGES
Preliminary remarks 97
The coordinates of a point in a plane 97, 98
The equation of a line 98, 99
The coordinates of a line. Symbol of a line 99, 100
The equation of a point 100
The equation of a conic. The expression by a parameter . . 101—104
A particular form of the equation of a conic. Equation of tangent. Tangential equation of a conic. Conic referred to self-polar triad 104—107
Equation of a circle. Of circles of coaxial system. Condition that two lines or two circles should cut at right angles . . . 107—110
Examples of the algebraic treatment of the theory of conics (Exx. 1—29) . . . . 110—152
Ex. 1. *Condition that a pair of points should be harmonic conjugates in regard to another pair* 110, 111
Ex. 2. *A result in regard to involutions* 111
Ex. 3. *Representation of all the pairs of an involution* . . . 111
Ex. 4. *A general result for two pairs of points* 111
Ex. 5. *Condition that two circles, in general form, should cut at right angles* 111
Ex. 6. *The radical axis of two circles; the radical centre of three circles* 111, 112
Ex. 7. *The common tangents and centres of similitude of two circles* 112
Ex. 8. *Feuerbach's theorem. Apolar triads* . . . . . 112—114
Ex. 9. *Continuation of the preceding example* . . . . 114—116
Ex. 10. *Hamilton's modification of Feuerbach's theorem. Introductory results* 116, 117
Ex. 11. *Hamilton's modification of Feuerbach's theorem* . . 117, 118
Ex. 12. *Conic referred to its centre and axes* 118, 119
Ex. 13. *Confocal conics* . . . . 119—121
Ex. 14. *Conics derived from a conic intersecting the joins of three points. Bipunctual conics* . . . . 121—123
Ex. 15. *Two triads reciprocal in regard to a conic are in perspective* 123, 124
Ex. 16. *The Hessian line of three points of a conic* . . . 124
Ex. 17. *The director circle of a conic, and generalisations* . . 124—127
Ex. 18. *Envelope of a line joining points of two conics which are conjugate in regard to a third, with particular applications* . 127—134
Ex. 19. *Indication of a generalisation of the preceding results* . 134
Ex. 20. *Of correspondences, in particular of general involutions, upon a conic* . . . . 134—139
Ex. 21. *Reciprocation of one conic into another when they have a common self-polar triad* 139, 140

PAGES
Ex. 22. *The determination of the common self-polar triad of two conics in general* 140, 141
Ex. 23. *Fundamental invariants for two conics* 141, 142
Ex. 24. *The algebraical condition for one conic to be outpolar to another, or to be triangularly circumscribed to another* . . 142—146
Ex. 25. *Enumeration of reduced forms for the equations of any two conics* 146, 147
Ex. 26. *A particular involution of sets of three points. Apolar triads* 147—149
Ex. 27. *Three conics related in a particular way* . . . 149—151
Ex. 28. *The director circle of a conic touching three lines is cut at right angles by a circle, for which the three lines form a self-polar triad* 151
Ex. 29. *A transformation of conics through four points into conics having double contact* 152

CHAPTER IV. RESTRICTION OF THE ALGEBRAIC SYMBOLS. THE DISTINCTION OF REAL AND IMAGINARY ELEMENTS

Review of the development of the argument. Real and imaginary symbols . . . . 153—155
The distinction of positive and negative for the real symbols . 155, 156
Order of magnitude for the real symbols 156, 157
The roots of a polynomial 157
The exponential and logarithmic functions 157
A simple application to the double points of an involution. Reality of double points of involution defined by two pairs . . 157—160
General statement of the meaning of real and imaginary points in a plane 160, 161
Some applications of the definition. Imaginary points and lines . 161, 162
Real and imaginary conics . . . . 162—164
The interior and exterior points of a real conic 164
The reality of the common points, and of the common self-polar triad, of two conics 164, 165
Example. Construction of a conic given three points and two pairs of conjugate points 165

CHAPTER V. PROPERTIES RELATIVE TO AN ABSOLUTE CONIC. THE NOTION OF DISTANCE. NON-EUCLIDEAN GEOMETRY

The interval of two points of a line relatively to two given points of the line 166, 167
Angular interval in regard to two absolute points 167
Interval in regard to an absolute conic. Meaning of movement . 167—170

PAGES

Case of an imaginary conic as Absolute . . . . . 170—172
Application to a triangle, in particular a right-angled triangle . 172—177
The sum of the angular intervals for a triangle 177
Formulae for a general triangle 177, 178
The case of a real conic as Absolute . . . . 178—180
The sum of the angles of a triangle and a quadrangle of three right angles 180, 181
Comparison with the Lobatschewsky-Bolyai geometry resumed . 181—183
Case of degenerate conic as Absolute . . . . 183—186
The arbitrariness and comparison of the several methods of measurement. Extent between two lines, of a triangle, of a circle, in the elliptic geometry . . . . 186—189
Plane metrical geometry by projection from a quadric surface. Spherical geometry. Elementary properties of a quadric surface 189—195
Metrical geometry in regard to an absolute conic. Cayley's measure of distance deduced from Laguerre's . . . . . . 195—197
Representation of the original plane upon another plane. Riemann's space of constant curvature. Lobatschewsky lines as circles cutting a fixed line at right angles . . . . . . 197—204
Remark, comparison of the two cases considered 204
Examples of the preceding considerations (Exx. 1—9) . . . 204—211
Ex. 1. *Delambre's formulae in spherical trigonometry* . . . 204—206
Ex. 2. *Napier's analogies* 206
Ex. 3. *A particular triangle corresponding to the division of a sphere into four congruent triangles* . . . . . . 206—209
Ex. 4. *General form of the theorem for the sum of the focal distances of a point of a conic. Circular sections and focal lines of a cone* 209, 210
Exx. 5, 6. *Particular theorems of importance* 210
Exx. 7, 8. *Generalisation of result of Ex.* 4 . . . . . 210, 211
Ex. 9. *Elliptic integral for porism of two conics* 211

NOTE I. ON CERTAIN ELEMENTARY CONFIGURATIONS, AND ON THE COMPLETE FIGURE FOR PAPPUS' THEOREM

The simpler Desargues' figure 212, 213
The figure of three desmic tetrads of points in space of three dimensions 213, 214
The figure formed from three triads of points which are in perspective in pairs, with centres of perspective in line . . . 214, 215
The complete figure for Pappus' theorem 215, 216
The figure formed from six points in four dimensions . . . 216—218
Exx. 1—4. *The configuration in space of* n *dimensions, formed from* $(n+2)$ *points, or from* $(n+2)$ *spaces of* $(n-1)$ *dimensions; it is self-polar* 218

NOTE II. ON THE *HEXAGRAMMUM MYSTICUM* OF PASCAL

PAGES
Introduction, and arrangement of note 219, 220
Sylvester's synthemes from six elements. The combinatorial identity with the Pascal figure . . . . 220—224
The geometrical interpretation of the relations, in space of four dimensions (see also the Frontispiece of the volume). Statement and proof of the Pascal incidences . . . . . 224—229
Direct deduction of Pascal's figure from a cubic surface with a node 229—231
Examples of particular properties of the figure (Exx. 1—6) . . 231—235
Ex. 1. *The pairs of conjugate Steiner planes* 231, 232
Ex. 2. *The Steiner planes and Steiner-Plücker lines* . . . 232
Ex. 3. *The separation of the complete figure into six figures* . . 232
Ex. 4. *Tetrads of Steiner points each in threefold perspective with a tetrad of Kirkman points* 232, 233
Ex. 5. *Relation of the Cayley-Salmon lines and the Salmon planes* 233
Ex. 6. *Proof of the relations by plane geometry* . . . . . 233—235
References to the literature of the matter 235, 236

NOTE III. IN REGARD TO THE LITERATURE FOR NON-EUCLIDEAN GEOMETRY 237

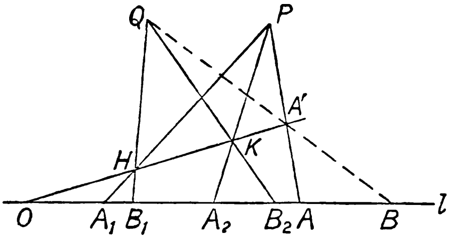
ADDITIONS 239

INDEX 254

PRELIMINARY

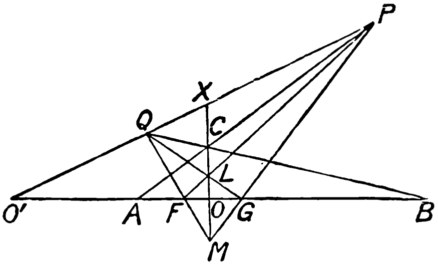
There are several matters, readily understood by the reader of Volume I, in regard to which we have not there entered into the detail which may be desirable for the purposes of the present volume.

Related ranges on the same line. With the purpose of avoiding the use of points whose existence could only be assumed after the consideration of the so-called imaginary points, we have (Vol. I, pp. 18, 25) defined two ranges on the same line as being *related* when, one of them is in perspective with a range on a second line which is related to the other range of the first line. From this definition we have shewn (Vol. I, p. 160) that in the abstract geometry two such related ranges on the same line have two corresponding points in common, though these may coincide. Assuming this, we may now formally prove that two such ranges also satisfy the general definition, namely that they are both in perspective with the same other range on another line, from different centres.



Let the ranges (a), (b), on the same line, l, be such that (a) is in perspective with a range (c), while (c) is related to (b). Let O be a point of the line l which corresponds to itself whether regarded as belonging to the range (a) or to the range (b); let A_1, A_2, A be other points of the range (a), respectively corresponding to the points B_1, B_2, B of the range (b). Let H, K be any two points in line with O; let A_1H, A_2K meet in P, and B_1H, B_2K meet in Q, and let PA meet the line OHK in A'. Then the range O, H, K, A' is in fact related to O, B_1, B_2, B. For the former is in perspective, from P, with the range O, A_1, A_2, A; this is, by hypothesis, in perspective with a range (c), which is itself related to O, B_1, B_2, B; so that the result follows from Vol. I, pp. 22–24. Thence, as the ranges, O, H, K, A' and O, B_1, B_2, B, have the point O in common, they are in perspective (Vol. I, p. 58, Ex. 2 (c)). Thus the line QB passes through A', and the two ranges (a), (b) are in perspective with the same range on the line OHK, respectively from P and Q. This is what we were to prove.

It is clear that the line PQ meets the line l in another common corresponding point of the two ranges (*a*), (*b*), which may however coincide with *O*.



Involution. Considering two related ranges upon the same line, it does not generally follow that, if *K* be the point of the second range corresponding to a point *H* of the first range, then to the point *K*, considered as belonging to the first range, there corresponds the point *H*, considered as belonging to the second. We proceed to shew, however, that, if this be true for one position, *F*, of *H*, and the corresponding position, *G*, of *K*, then it is true for every pair of corresponding points *H*, *K*.

For, in accordance with the preceding, let the ranges be in perspective, respectively from the points *P* and *Q*, with the same range; let *X* be the point of this range which lies on the line *PQ*, and *O′* the common corresponding point of the two ranges arising by perspective from *X*; let *L* be the point of this range which gives rise, respectively from *P* and *Q*, to the two particular corresponding points *F*, *G* of the two ranges, the points *P*, *L*, *F*, and also the points *Q*, *L*, *G*, being in line. Then, by hypothesis, the lines *PG*, *QF* meet in a point, *M*, of the line *XL*. Let *O* be the intersection of the line *XL* with the original line, so that *O* is also a common corresponding point of the two ranges.

It is clear from the construction that the points *O*, *O′* are harmonic conjugates in regard to *F* and *G*, and therefore do not coincide with one another; unless, indeed, they both coincide either with *F*, or with *G* (I, pp. 14, 119), in which case, as *O′* is a self-corresponding point, *G* would coincide with *F*, which we suppose not to be the case. Thus, when the two common corresponding points of the two given ranges are coincident, the case of two such different reciprocally related points *F* and *G* as we are now considering does not arise. Further, the points *O′*, *X* are harmonic conjugates in regard to *P* and *Q*.

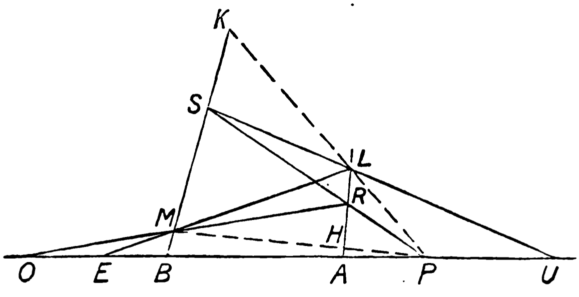
Now let *A*, *B* be any two other corresponding points, respectively of the two given ranges, arising from the point *C* of the line *XL*, by perspective from *P* and *Q*, respectively, so that *P*, *C*, *A*, and also *Q*, *C*, *B* are in line. Then, as *O′*, *X* are harmonic conjugates in regard to *P* and *Q*, it follows that *O′*, *O* are harmonic conjugates in regard to *A* and *B*. From this it follows that *PB* and *QA* meet on the line *XL*, and, therefore, that, to the point *B*, of the first range, corresponds the point *A*, of the second; as we desired to prove.

Conversely, any two points of the original line which are harmonic conjugates in regard to O' and O are a pair of reciprocally corresponding points of the two ranges. The aggregate of such pairs is called an *involution* of pairs of points; the points O', O are called the *double points* of the involution.

It is clear that if three pairs of points of a line, (A, B), (F, G) and (U, V), be pairs of an involution, then the range A, F, G, U, consisting of two points of one pair, and a point from each of the other two pairs, is related, point to point, to the range B, G, F, V, consisting of the respectively complementary points of the various pairs. For we can define two related ranges by the fact that the points A, F, U, of the one, correspond, respectively, to the points B, G, V, of the other; then, to the point G, of the former, corresponds the point F, of the latter. Conversely, if six points of a line be such that the range A, F, G, U is related, point to point, to the range B, G, F, V, then (A, B), (F, G) and (U, V) are three pairs of an involution. Also, an involution is established when two pairs are given; for, if these be (A, B) and (F, G), we have only to associate, to any point U, a point V for which the range B, G, F, V is related, point to point, to the range A, F, G, U.

Thus, further, a pair of points, O and O', exists, which are harmonic conjugates both in regard to one arbitrary pair of points, A, B, and also in regard to another arbitrary pair, F, G, which lie in the line AB. These points, O, O', are the double points of the involution determined by the pairs A, B and F, G.

From this it follows, also, that if there be two involutions of pairs of points upon the same line, there is a pair of points common to both involutions. This pair consists of the two points which are harmonic conjugates in regard to the double points of the first involution, and also harmonic conjugates in regard to the double points of the second involution.



The definition of an involution of pairs of points on a line may be approached differently, in connexion with a figure previously employed (Vol. I, pp. 76, 77).

Let A, B, O, U, E be arbitrary points of a line; in a plane through the line draw two lines AL, BM, met by a line through E respectively in L and M; let UL and BM meet in S, and OM meet AL in R. Let SR meet AB in P.

If, then, PL, PM, respectively, meet BM and AL in K and H, the range O, A, E, P is in perspective, from M, with the range R, A, L, H; this last is in perspective, from P, with the range S, B, K, M, and this, again, in perspective, from L, with the range U, B, P, E. As, then, the ranges O, A, E, P and U, B, P, E are proved to be related, it follows, from what is said above, that the pairs (O, U), (A, B) and (E, P) are in involution.

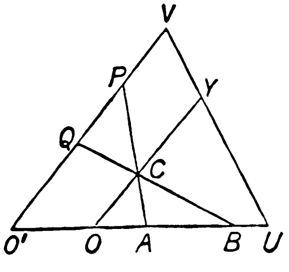
Thus the three pairs of joins of any four points of a plane (in this case M, R, L, S) meet an arbitrary line, of the plane, in three pairs of points of the same involution. As has been remarked in Vol. I (p. 181), the significance of the fact that five of these points determine the remaining one was noted by the Greeks.

Every result relating to pairs of points of a line corresponds, by the principle of duality, to a result relating to pairs of lines, in a plane, passing through a point. We may therefore consider pairs of lines, in a plane, through a point, forming a pencil in involution; these meet an arbitrary line of the plane, not passing through the centre of the pencil, in pairs of points of a range in involution. In particular, if four arbitrary lines be given in a plane, these, divided into two pairs in each of the three possible ways, determine, by the intersections of lines of a pair, three pairs of points. The lines which join an arbitrary point of the plane to these three pairs of points, are three pairs of lines belonging to the same involution.

Symbolical expression of the preceding results. We have in Vol. I (pp. 140, 154) reached the result that if a range of points represented by symbols $O + xU$, for different values of x, be related to a range of points represented by symbols $O + yU$, for different values of y, then there is a relation of the form

$$ayx + by + cx + d = 0,$$

wherein the symbols a, b, c, d are independent of x and y. We are, throughout, assuming Pappus' theorem, and there is no question of the commutativity of the multiplication of the symbols. It may be interesting, in the first place, to obtain this result by regarding the ranges as being in perspective, from different centres, with the same range on another line.



For this, let the ranges $(A\ldots)$, $(B\ldots)$, on a line $O'U$, be in perspective with a range $(C\ldots)$, on a line OY, respectively, from centres P and Q. Let the line PQ

meet $O'U$ in O'; let V be any point of this line, and let any line from V meet the line of the range $(C\ldots)$ in the point Y, and meet the line $O'U$ in the point U; let the line of the range $(C\ldots)$ meet the line $O'U$ in O. Then, regarding the points O', U, V as fundamental points of the plane, we may suppose, for the symbols of the points concerned, the following expressions

$$P = O' + pV, \quad Q = O' + qV, \quad O = O' + mU, \quad Y = U + V.$$

Thence, if we take for different points C,

$$C = O + cY,$$

with different values of c, that is

$$C = O' + mU + c(U + V), = O' + (m + c)U + cV,$$

we infer, for the points A, B, of the ranges on OU, which arise from C, respectively the symbols

$$(c^{-1} - p^{-1})O' + (c^{-1}m + 1)U, \quad (c^{-1} - q^{-1})O' + (c^{-1}m + 1)U;$$

if we write, then, $A = O' + xU$, $B = O' + yU$,

this gives $$\frac{1 + mp^{-1}}{1 - mx^{-1}} = 1 + mc^{-1} = \frac{1 + mq^{-1}}{1 - my^{-1}}$$

and, hence, $(p - q)xy + q(p + m)x - p(q + m)y = 0.$

This is of the form in question. It shews, putting $x = 0$, $y = 0$, that O' is a common corresponding point of the two ranges $(A\ldots)$ and $(B\ldots)$; and, putting $x = m$, $y = m$, that O is the other common corresponding point. It coincides with O' when $m = 0$.

Passing now to the condition for an involution: If, when A takes the present position of B, this takes the present position of A, we must have, beside the previous relation, also the relation

$$(p - q)xy + q(p + m)y - p(q + m)x = 0;$$

from these two relations we obtain, by subtraction,

$$[p(q + m) + q(p + m)][x - y] = 0,$$

and hence, A and B being any particular pair of corresponding points which do not coincide,

$$p(q + m) + q(p + m) = 0.$$

When this is satisfied the relation connecting the values of x and y, in general, is at once seen to reduce to

$$2xy - m(x + y) = 0.$$

We may, however, write

$$(x - y)O = (m - y)(O' + xU) - (m - x)(O' + yU),$$
$$= (m - y)A - (m - x)B;$$

thus the harmonic conjugate of O, in regard to A and B, is (Vol. I, p. 74) of symbol

$$(m - y)A + (m - x)B,$$

or $$(2m - x - y)O' + [m(x + y) - 2xy]U,$$

and coincides with O' whatever pair of corresponding points A and B may be. Thus O and O' must be different, and the general pair of points of the involution is a pair of points harmonically conjugate in regard to these.

Examples of involution. *Ex.* 1. The condition that the pair of points represented by $O'+xU$, $O'+yU$, should be harmonic conjugates of one another in regard to the pair of points represented by $O'+aU$, $O'+bU$, being the condition that, for proper symbols p, q,

$$x = (pa+qb)/(p+q), \quad y = (pa-qb)/(p-q),$$

is

$$(x-a)(y-b)+(x-b)(y-a)=0,$$

or

$$xy-\tfrac{1}{2}(x+y)(a+b)+ab=0.$$

This remark, (a), gives the pair of points which are harmonic conjugates of one another in regard to each of two other given pairs of points. In particular, the pair of points harmonically conjugate both in regard to O', U, and in regard to $O'+aU$, $O'+bU$, is given by $O'+kU$, $O'-kU$, where $k^2=ab$. It also gives, (b), the relation for a pair of points belonging to a given involution, and, (c), shews that two given involutions, on the same line, have a common pair of points.

Ex. 2. When $O'+xU$, $O'+yU$, are, as above, corresponding points of two related ranges, of which O' is a common corresponding point, the relation connecting x and y,

$$(p-q)xy+q(p+m)x-p(q+m)y=0,$$

is capable of one of the two following forms:

$$\frac{y-m}{x-m}=\sigma\frac{y}{x}, \qquad \frac{1}{y}=\frac{1}{x}+\frac{1}{\lambda},$$

where

$$\sigma=\frac{p(q+m)}{q(p+m)}, \qquad \frac{1}{\lambda}=\frac{1}{p}-\frac{1}{q},$$

according as m is not zero, or m is zero. In general, the relation

$$ayx+by+cx+d=0,$$

if the equation

$$ax^2+(b+c)x+d=0,$$

for which $y=x$, have two different roots α, β, is capable of the form

$$\frac{y-\beta}{x-\beta}=\sigma\frac{y-\alpha}{x-\alpha},$$

where

$$\frac{(\sigma+1)^2}{\sigma}=\frac{(b-c)^2}{ad-bc};$$

but, if $\beta=\alpha$, or $(b+c)^2=4ad$, the relation is capable of the form

$$\frac{1}{y-\alpha}=\frac{1}{x-\alpha}+\frac{1}{\lambda},$$

where

$$\lambda=\tfrac{1}{2}(b-c)/a.$$

The general condition for a pair of points, represented by $O' + xU$, $O' + yU$, to belong to an involution is of the form

$$axy + b(x+y) + c = 0.$$

If we choose U for one of the two double points, we have $a = 0$. If then, also, O' be the other double point, we have also $c = 0$. If O' and U be any pair of the involution, we have $b = 0$.

In general, the double points are given by the values of x for which

$$ax^2 + 2bx + c = 0;$$

if these coincide ($b^2 = ac$), the involution reduces to one fixed point, for which $x = -b/a$, taken in turn with every other point of the line. This very degenerate case has been excluded from consideration in what has preceded.

Ex. 3. If P, Q and P', Q' be any two pairs of points of a line, and P'' be the harmonic conjugate of P in regard to P' and Q', while Q'' is the harmonic conjugate of Q in regard to P' and Q', the pairs (P, Q), (P', Q'), (P'', Q'') are in involution.

For, by construction, P, P'' and Q, Q'' are pairs of an involution with P', Q' as double points, and the harmonic ranges P, P'', P', Q' and Q'', Q, P', Q' are related; the latter, and, therefore, also the former, is related to the range Q, Q'', Q', P' (Vol. I, p. 25, Ex. 1). This shews that (P, Q), (P'', Q''), (P', Q') are pairs of an involution.

If the points P, Q correspond to the roots of $ax^2 + 2hx + b = 0$, or, say, $F = 0$, being given by $O + x_1U$, $O + x_2U$, where x_1, x_2 are the roots of this equation, and, similarly, with the same points of reference O, U, the points P', Q' correspond to the roots of $a'x^2 + 2h'x + b' = 0$, or, say, $F' = 0$, it may be shewn that P'', Q'' correspond, similarly, to the roots of the equation

$$(a'b' - h'^2)F - (ab' + a'b - 2hh')F' = 0.$$

Ex. 4. If A, A'; B, B'; ... be pairs of points of a line, which are in involution, and we take the harmonic conjugate of every one of these in regard to two points, U and V, of the line, so obtaining the pairs P, P'; Q, Q'; ..., then these are also pairs in involution.

For any range P, Q ... is then related to the corresponding range A, B ...; this in turn is related to the range A', B' ...; and this to P', Q' ....

Ex. 5. Given any two pairs of points of a line A, B and A', B', let the pair of points which are harmonic both in regard to A, B and in regard to A', B', be denoted by $(AB, A'B')$; and, therefore, if A'' and B'' be two other points of the line, let $\{(AB, A'B'), A''B''\}$ denote the pair harmonic both in regard to the pair $(AB, A'B')$ and in regard to the pair A'', B''. Shew that the three pairs of points

$$\{(AB, A'B'), A''B''\}, \quad \{(A'B', A''B''), AB\}, \quad \{(A''B'', AB), A'B'\}$$

are in involution. If A, B be given by $f=0$, where

$$f = ax^2 + 2hxy + by^2,$$

and A', B' be given by $f'=0$, where $f' = a'x^2 + 2h'xy + b'y^2$, shew that $(AB, A'B')$ are given by

$$\begin{vmatrix} y^2, & -yx, & x^2 \\ a, & h, & b \\ a', & h', & b' \end{vmatrix} = 0,$$

and $\{(AB, A'B'), A''B''\}$ are given by $Hf - H'f' = 0$, where, if $A''B''$ be similarly given by $f''=0$, the function H is $a'b'' - 2h'h'' + b'a''$, while $H' = ab'' - 2hh'' + ba''$.

A general abbreviated argument for relating two ranges. Consider two lines, which may coincide, or, more generally, may lie in space of any number of dimensions. Let O, U be two points of the former line, and O', U' be two points of the latter line; if the lines coincide O' and U' will each be in syzygy with O and U, the symbols of O' and U' being each expressible by O and U; if the lines intersect there will be one syzygy connecting the four points. Now, suppose that we have a geometrical construction whereby there is determined a definite point P', of the second line, corresponding to every point P of the first line, and a construction whereby we may conversely pass back from P' to the same point P. The construction may be such as gives, when we start from P, other points $A', B', \ldots$, of the second line, beside P', provided these remain the same for every position of P; and similarly for the construction by which we pass back from P' to P.

For greater definiteness we must also add that the construction must be analogous to those considered in the Third Section of Chap. I of Vol. I (p. 74); it must be such that, if the point P have the symbol $O + xU$, and the point P' the symbol $O' + x'U'$, then x' is determined from x by those laws of combination of the symbols which do not involve the solution of any equation of the second or higher order, the solution of such an equation not being without ambiguity; and x must be determined from x' in a similar way. There is therefore a single algebraic equation, connecting x and x', of the form $\Sigma a x'^m x^n = 0$, containing only a finite number of terms, in which every coefficient a is quite definite, m and n being positive integers. Then, as, to every value of x, there belongs only one value of x', other than those independent of x, the equation may be expected to be such that the highest value of the exponent m is 1; and, similarly, such that the highest value of n is also 1. (Cf. Chap. IV, below.) The relation would then be of the form

$$ax'x + bx' + cx + d = 0.$$

When we have such a determinate construction we shall, sometimes, assume, for the sake of brevity, that it is possible to find a third range with which both the given ranges are in perspective, from appropriate centres; so that the given ranges are related.

Of the distinction between the so-called real and imaginary points. In the general discussion introductory to Chap. III of Vol. I (p. 141), and in some other cases, we have spoken of the distinction between real and imaginary points in a way which, if definite when we approach the matter from the point of view of the Real Geometry, is not so clear from the point of view to which we desire to reach. It might be proper then to enter now into more detail. But we do in fact regard the distinction as arising in connexion with an arbitrary limitation of the possibilities of the points which can exist in the space considered; for this reason we postpone this discussion until (in Chap. IV, below) we definitely agree to make this limitation. This limitation is represented by a restriction in the system of symbols appropriate to the geometrical results obtained. While we wish to leave the logical possibilities as open as we can, we desire to expound a system of geometry in harmony with what is commonly accepted. For this purpose we have suggested, in Vol. I, that we may take as a geometrical postulate the possibility of what we have called Steiner's construction (Vol. I, pp. 155 ff.). In a similar way we shall in the first three chapters of the present volume adopt as a postulate the theorem that *two* curves in a plane which are *conics*, in the sense to be immediately explained, *have four common points, of which two, or more, may coincide.* It will be seen below (in Chap. IV) how this would be proved when the limitation referred to is adopted. Cf. pp. 19, 157 below.

CHAPTER I

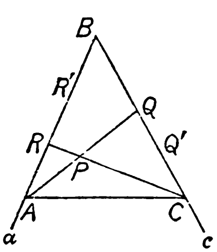
GENERAL PROPERTIES OF CONICS

Definition of a Conic. Consider two pencils of lines, in the same plane, of centres A and C, and suppose these are related to one another, in the sense explained in Vol. I; to any line, AP, of one pencil, there corresponds, then, a definite line, CP, of the other, and, conversely, to any line, CP, there corresponds one line, AP. The curve which is the locus of the intersection, P, of such corresponding rays AP, CP, is called a conic section, or, briefly, a conic. Conversely, it will be seen that any conic can be so obtained, from any two points, A, C, of itself.

By its definition the curve contains one point, P, beside A, upon any line drawn through A; though, when the line drawn through A is that which corresponds to the line CA drawn through C, the point P coincides with A. Similarly for a line drawn through C. Consider however any line not passing through A nor C. This line contains two points of the conic. For the related pencils, of centres A and C, determine upon this line two related ranges. These have two common corresponding points. If these be P_1 and P_2, the ray AP_1, of the one pencil, corresponds to the ray CP_1, of the other, and P_1 is on the locus; and it is the same for P_2.

There is however one case, which we regard as exceptional, to which reference should be made: It may be that, to the ray AC of the pencil (A), there corresponds the ray CA of the pencil (C). When this is so, the locus consists of a line of the plane, together with the line AC itself. For if P_1 and P_2 be, then, any two points of the locus, not lying on the line AC, and the line P_1P_2 meet the line AC in B, the two related pencils (A), (C) determine, on the line P_1P_2, two related ranges having three common corresponding points, namely P_1, P_2 and B. These two ranges thus coincide, and every point of the line P_1P_2 is a point of the locus. If there were any point, P, of the plane, not lying on the line P_1P_2 or the line AC, which was upon the locus, then the join of P to any point of P_1P_2, would, by what has been said, be a line of which every point was a point of the locus; and in that case every point of the plane would be a point of the locus. The complete locus thus consists of the line P_1P_2, and of the line AC, of which every point evidently satisfies the definition. Conversely, any two lines of the plane may be regarded as constituting a degenerate conic, determined by related pencils whose centres are any two points of one of the lines. Such a degenerate conic may be spoken of as a line pair. In Vol. I (p. 58), we have seen that two related ranges on two intersecting lines, which are such that the intersection of the lines is a common corresponding point, are in perspective. The aggregate of the lines joining corresponding points of the two ranges consists then of a pencil of lines, together with every line through the common point of the ranges. This is the result dually corresponding to that here remarked.

In what follows we shall, in general, suppose that, to the ray, AC, of the pencil (A), there corresponds a ray, CB, of the pencil (C), which does not coincide with CA. To the ray CA, of the pencil (C), will then correspond a ray, AB, of the pencil (A), meeting the former, say, in B. As the rays AC, CB meet in C, and the rays CA, AB meet in A, the locus contains the points A and C.

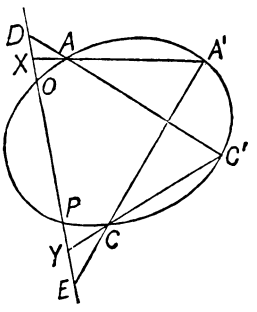


The lines CB, AB, say, respectively, c and a, are determined when the related pencils are given. Conversely, if these lines be given, and, upon them, respectively, the points C and A, and, also, a point, P, of the locus, be given, then the related pencils are determined; for, the three rays AC, AB, AP, of the one, then correspond, respectively, to the three rays CB, CA, CP, of the other. These lines c, a contain no other point of the locus beside, respectively, C and A. For, if AP, CP meet c and a, respectively, in Q and R, there are two related ranges on c and a, in which the points C, B, Q, of the one, correspond, respectively, to the points B, A, R, of the other; if then the point, P, of the locus, lie on c, the point R will be at B, and, therefore, Q, and hence also P, will be at C. Moreover if, for a moment, we limit ourselves to only real points, and take a further point, P', of the locus, for which the corresponding Q, say Q', is separated from B by Q and C, then the corresponding R, say R', will be separated from A by R and B. We therefore speak of the locus as having two *coincident* points at C; similarly, it has two coincident points at A. The lines c and a are called *tangents* of the conic, respectively at C and A. It will appear that, through every point of the conic, a line can be drawn containing only this point of the locus; this line will be called the tangent at the point.

We have remarked that, if the points A, C, and the tangents a, c at these points, and also a point, P, of the locus, be given, the related pencils, and, therefore, also, the conic, are determined. More generally, if the points A, C, and three points P_1, P_2, P_3 (of which we suppose at most one, but, in general, none, to lie on the line AC)

be given, the conic is determined; for we have only to make the rays CP_1, CP_2, CP_3, of the pencil (C), correspond, respectively, to the rays AP_1, AP_2, AP_3, of the pencil (A), whereby the pencils are related. Thus a conic can be described through five points of the plane, of general position; when three of these are in line, the conic becomes a line pair; when four of them are in line the conic is not determined.

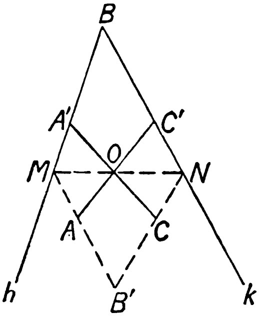
It has been stated that the points A, C, in the definition of the conic, may be replaced by any other two points of the locus, say A' and C'. This is easy to prove. Let O be any point of the conic, and let any line, drawn through O, meet the conic again in a point P. Let the lines AA', CC' meet the line OP, respectively, in X and Y, and the lines AC', $A'C$ meet this line, respectively, in D and E. Then, the pencil, of centre A, formed with lines joining this point to A', C', O, P, is, by hypothesis, related to the pencil, of centre C, formed with lines joining this point to the same four points. Wherefore, the range X, D, O, P is related to the range E, Y, O, P, and, therefore, also to the range Y, E, P, O. Thus (Preliminary, above, p. 3), the three pairs of points X, Y; D, E; O, P are in involution. To prove, now, that the conic defined with related pencils of centres A' and C' to pass through the points A, C, O, also passes through P, whatever point of the original conic P may be, we require only to shew that the pencil of lines joining A' to A, C, O, P is related to the pencil of lines joining C' to these same points, respectively. This will be so if the range X, E, O, P is related to the range D, Y, O, P; which will be so if the range X, E, O, P is related to the range Y, D, P, O. The condition for this, however, is the same as before, that the pairs of points X, Y; D, E; O, P should be in involution.



The result is therefore established. Thereby, there is also defined, at every point of the curve, a line, called the tangent, meeting the curve only at this point.

Involution on a line by conics having four common points. Incidentally there appears from the preceding proof a theorem which is of great importance: If four points (A, C, A', C') be taken on a conic, and two pairs of lines (AC', $A'C$ and AA', CC') of which each pair contains the four points, then an arbitrary line is met by these line pairs, and by any conic passing through the four points, in three pairs of points belonging to the same involution. We have seen that a conic can be drawn through five general points, so that an infinite number of conics can be drawn through four general points; we have also seen (Preliminary, above, p. 3) that an involution is determined by two of its pairs. Hence we have the result that, the pairs of points in which the conics, drawn through four general points, cut an arbitrary line, are pairs of the same involution. Any one of the three line pairs which can be drawn through these four points is a particular degenerate conic of this description.

Maclaurin's definition of a conic. Pascal's theorem. It has been shewn in Vol. I (pp. 21 ff.) that two related ranges, on different lines, a and c, are both in perspective with another range, on a line o, say, from proper centres, say H and K, respectively. The dually corresponding result is that, two related pencils, with different centres, A and C, must consist of lines joining A and C to the points, respectively, of two related ranges on different lines, say h and k, these ranges being in perspective with one another from some centre, say O.



Thus the definition of a conic which has been given is the same as, the locus of a point, B', which is the intersection of two lines MB', NB', passing, respectively, through two fixed points, A and C, where M and N are any two points on two given lines, h and k, such that MN passes through a third fixed point, O. Conversely, the ranges (M), (N) being in perspective, the pencils $A(B')$ and $C(B')$ are clearly related, so that the present definition leads back to the former.

If B be the intersection of the lines h and k, and OA, OC meet the lines k and h, respectively, in C' and A', the conic contains the points B, A', C'. For, first, when M and N coincide at B, the lines MA, NC intersect in B; and, next, when M is at A', and, therefore, N is at the point where OC meets k, the line NC contains A', which is then the intersection of NC and MA; similarly, when N is at C', so also is B'. As was remarked above, the locus contains also the points A and C. We have thus, at once, a construction, with lines only, for finding any number of points of a conic passing through five arbitrary given points B, A, C, A', C'; as was seen, such five points determine the conic. And, from the symmetry which was shewn to hold among the fundamental points, we can now infer that, if A, B', C, A', B, C' be any six points of a conic, the three points of intersection of the pairs of lines, BC', $B'C$; CA', $C'A$; AB', $A'B$, are in line. This result is the celebrated one known as Pascal's Theorem. From six points, we can form two sets of three in ten ways, and either of these sets can be arranged, relatively to the other, in six ways; thus, from six given points of a conic can be deduced sixty different lines, each containing three such points of intersection as those here remarked. When the conic consists of two lines, one containing the points A, B, C, the other the points A', B', C', Pascal's Theorem becomes that which, in Vol. I, we have called Pappus' theorem.

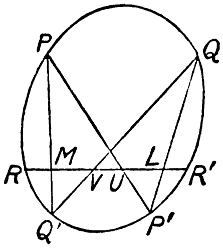
The construction at once gives the tangent of the conic at the point A: If the line AC meet the line k in N_0, and the line N_0O meet the line h in T, then AT is the tangent at A. So, if AC meet h in M_0, and M_0O meet k in U, then CU is the tangent at C. The tangent at A thus appears as the position of the line AB' when B' is at A, or, equally, as the ray of the pencil of centre A which corresponds to the ray CA of the pencil of centre C; and similarly for the tangent at C. To find the points, B', of the conic, which lie on an arbitrary line, it is necessary to solve the problem considered in Vol. I, pp. 155 ff., of finding lines through three given points whose intersections lie on three given lines.

Ranges of points on a conic. Since the pencils of four lines which join any four given points of a conic to other points of the conic are all related, the definition of a conic ascribes a definite character to four points of the curve in relation to any other four points: two such sets of four points of the locus may be said to be related to one another when the pencil of four lines, joining the first set of four to any point of the conic, is related to the pencil of four lines joining the second set of four points to any point of the conic. Thus, given any two triads of points of the conic, say A, B, C and A', B', C', we can, to any point, D, of the conic, determine a point, D', of the curve, such that, in the sense explained, the range A', B', C', D', of points of the conic, shall be related to the range A, B, C, D. There exists, therefore, a theory of related ranges of points of the conic precisely like that of related ranges of points of a line.

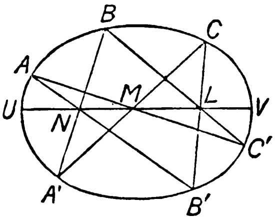
Involution of pairs of points of a conic. In particular, there is a theory of pairs of points of the conic which are in involution, one form of the condition that three pairs of points of the conic, P, P'; Q, Q'; R, R', be in involution, being, as in the case of points of a line (Preliminary, above, p. 3), that the range P, Q, R, R' should be related to the range P', Q', R', R. This condition, however, is capable of very simple geometrical interpretation: The necessary and sufficient condition that the three pairs of points of the conic, P, P'; Q, Q'; R, R', should be in involution, is that the lines PP', QQ', RR' should meet in a point.

This fact is easy to prove from what we have seen above. Take any three pairs of points of the conic, P, P'; Q, Q' and R, R'; let the line RR' meet the line PP' in U, and meet the line QQ' in V;

further, let the lines $P'Q$ and PQ' meet the line RR' in L and M. By what we have seen, on the line RR' the pairs of points R, R'; U, V and L, M are in involution; therefore, the range U, L, R, R' is related to the range V, M, R', R. The former range, U, L, R, R', is, however, the section, by the line RR', of the pencil of lines joining to P' the points P, Q, R, R' of the conic. The condition that the pairs of points of the conic, P, P'; Q, Q' and R, R', should be in involution, is that the pencil joining P, Q, R, R' to any point of the conic should be related to the pencil joining P', Q', R', R to any point of the conic. The lines joining, to P, these last four points, meet the line RR' in, respectively, U, M, R', R. The condition is, then, that the range U, M, R', R should be related to the range U, L, R, R'; this, however, we have remarked, is related to the range V, M, R', R. The condition, therefore, is, that the ranges, U, M, R', R and V, M, R', R, should be related, or that V should coincide with U. This is the condition that the lines, PP', QQ', RR', should meet in one point, as was stated.



Pascal's theorem and related ranges of points upon a conic. From the existence of related ranges upon a conic, we can at once deduce Pascal's theorem. And another proof of the preceding theorem, in regard to involutions of points upon the conic, offers itself immediately.



Let A, B, C, A', B', C' be any six points upon the conic; let L be the intersection of the lines BC', $B'C$, and, similarly, M the point $(CA', C'A)$ and N the point $(AB', A'B)$. We can, we have seen, determine two related ranges of points upon the conic by the condition that the points A', B', C', of one of these, correspond, respectively, to the points A, B, C of the other. These ranges will have two common corresponding points; let these be U and V, which, for the present, we suppose not to coincide. Then the pencil of lines joining the points U, V, A, B to any point of the conic is, by hypothesis, related to the pencil joining, respectively, U, V, A', B' to any point of the curve. If the former point be taken to be A', and the latter to be A, and we consider the sections of these pencils by the line UV, so obtaining two sets of four points of which three are the same in both, we infer at once that the point N is on the line UV. Similarly M, and L, lie on this line; thus L, M, N are in line. This is Pascal's theorem.

The condition that the ranges U, V, A, B and U, V, A', B' should be related is the same as that U, V, A, B and V, U, B', A' should be related. This, however, is the same as that the pairs U, V; A, B' and A', B, of points of the conic, should be in involution; for this, then, the lines UV, AB' and $A'B$, must meet in a point. Conversely, Pascal's theorem is equivalent to saying that, if A, B, C, A', B', C' be any six points of the conic, the three involutions determined, respectively, by the two pairs B, C' and B', C; by the two pairs C, A' and C', A; and by the two pairs A, B' and A', B, have a pair common to all three involutions (the pair U, V).

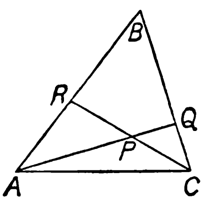
If H, K be any two points of the range $A, B, C, \ldots$, of points of the conic, and H', K' be the respectively corresponding points of the related range $A', B', C', \ldots$, the lines HK', $H'K$ can similarly be shewn to meet on the line UV. This line may be called the *axis of relation* of these two ranges, or the axis of homography; cf. Vol. I, p. 53.

Pascal's theorem remains equally true when the points U, V coincide. The line UV is then replaced by the tangent of the conic at U.

Converse of Pascal's theorem. It is easy to prove from the direct theorem that, if A, B, C, A', B', C' be such six points of the plane that the three intersections $(BC', B'C)$; $(CA', C'A)$ and $(AB', A'B)$ are in line, then the six points all lie on a conic.

Introduction of the algebraic symbols. We have thus obtained many of the fundamental theorems for a conic immediately from the definition. It is our purpose to make the geometrical theory complete in itself. But it may be interesting, at the same time, to consider the application of the algebraic symbols.

Returning to the definition, the point, P, of the locus, being the intersection of the corresponding rays AP, CP of two related pencils, of centres A and C, let AP meet in Q the tangent CB at the point C, and CP meet in R the tangent AB at the point A. Then Q, R describe related ranges on the lines CB, AB, of which the points C, B, of the former, correspond, respectively, to the points B, A, of the latter.



If then we represent the point Q by the symbol $C + \theta B$, where θ is an algebraic symbol, we can, absorbing a proper multiplier in the symbol A, represent R by the symbol $B + \theta A$. Thence the point P is given by the symbol

$$P = \theta^2 A + \theta B + C,$$

and all points of the conic are given by this, for different symbols θ. In particular, the points A and C arise, respectively, for $\theta^{-1} = 0$ and $\theta = 0$. We might equally, however, have represented the point Q by $C + m\theta B$, where m is an arbitrary algebraic symbol; to fix the symbol θ for every point of the conic, it is necessary to fix it for one point beside A and C; say, by specifying the point of the curve for which $\theta = 1$.

That a locus, of which every point is given by a symbol such as that here representing P, contains two points of an arbitrary line, is clear, by remarking that the point

$$x_1A + y_1B + z_1C + \lambda\,(x_2A + y_2B + z_2C),$$

of the line joining the given points $x_1A + y_1B + z_1C$, $x_2A + y_2B + z_2C$, will be a point of the conic if, and only if,

$$x_1 + \lambda x_2 = \theta\,(y_1 + \lambda y_2) = \theta^2\,(z_1 + \lambda z_2);$$

by elimination of λ from these two equations we obtain a quadratic equation for θ.

The result that the conics through four points, A, C, A', C', meet an arbitrary line in pairs of points in involution, which was proved in order to shew that the two points A, C, used in the definition of the conic, may be replaced by any other two points A', C', of the conic, may be obtained thus: there is, as was proved, one conic through the four points A, C, A', C' and an arbitrary point, P, of the line. This conic will meet the line in another point, say P'. Thus, to any position of P on the line, there corresponds one and only one position of P' on the line. Conversely, the conic through A, C, A', C' and P' meets the line in P. The determination of P' from P, or of P from P', is, beside, by a rational algebraic equation. Thus (see the remarks above, Preliminary, p. 8), (*a*) the ranges (P), (P'), on the line, are related, (*b*) when P assumes the position P', then P' assumes the position P. Hence the pairs P, P' belong to an involution.

The existence of related ranges of points on the conic follows from the expression of the points of the conic by means of the parameter θ. In fact, the line joining the arbitrary fixed point, H, of the conic, for which the symbol is $\alpha^2A + \alpha B + C$, to the point, P, of symbol $\theta^2A + \theta B + C$, contains the point $(\alpha\theta^2 - \theta\alpha^2)B + (\theta^2 - \alpha^2)\,C$, that is the point $\alpha\theta B + (\theta + \alpha)\,C$, of the line CB. Putting $M = B + \alpha^{-1}C$, for the symbol of a definite fixed point on the line CB, the point in question is $\theta M + C$. Similarly the line joining the fixed point, K, of symbol $\beta^2A + \beta B + C$, to the point P, meets the line CB in the point $\theta N + C$, where $N = B + \beta^{-1}C$, is the symbol of another fixed point of the line CB. The pencil of lines joining H to four points, P, is thus related to the pencil of four lines joining K to these same four points. Further, a range of various positions of points P of the conic, expressed by various values of the parameter θ, is related to a range of positions, Q, expressed by values of ϕ, when there is a condition of the form

$$a\theta\phi + b\theta + c\phi + d = 0,$$

in which a, b, c, d are independent of θ and ϕ. The pairs of corresponding positions, P, Q, then belong to an involution when, in this condition, $c=b$. In other words, points P, Q, of respective parameters θ, ϕ, form a pair of an involution of points on the conic, when θ, ϕ are connected by an equation

$$a\theta\phi+b(\theta+\phi)+d=0.$$

When this is so, we at once see that

$$(\phi a+b)(\theta^2A+\theta B+C)-(\theta a+b)(\phi^2A+\phi B+C)$$

is equal to $$(\phi-\theta)(dA-bB+aC),$$

so that the line PQ passes through the fixed point $dA-bB+aC$.

But the fact, that the lines drawn through an arbitrary point, O, of the plane, meet the conic in pairs of points, P, Q, of an involution, is clear, also, by remarking, (a), that, when P is given, Q is determined without ambiguity, by the line OP, which meets the conic again in Q; and that P is similarly determined when Q is given, the determination being by a rational algebraic equation connecting the parameters of P and Q; and (b) that when P takes the position Q, then Q takes the position P. The converse result, that, if P, P'; Q, Q' and R, R' be pairs of points of the conic which are in involution, the lines PP', QQ', RR' meet in a point, follows from this if we recall that an involution is determined by two of its pairs.

Pascal's theorem can also be proved at once with the symbols. For let A, B, C, A', B', C' be six points of the conic; and let U, V be the common corresponding points, on the conic, of the two related ranges A, B, C,... and A', B', C',.... In the first instance suppose U and V not to coincide. Let the tangents at U and V meet in W; the points of the conic can then be represented, as above, in terms of a parameter θ, by a formula $\theta^2U+\theta W+V$. Let $\alpha, \beta, \gamma, \alpha', \beta', \gamma'$ be the parameters for A, B, C, A', B', C' respectively. For corresponding points, with parameters θ, θ', of the two related ranges, there will be a condition of the form

$$p\theta\theta'+\theta'-q\theta+r=0,$$

where p, q, r are to be determined by the fact that this equation is satisfied by $\theta=\alpha$, $\theta'=\alpha'$; by $\theta=\beta$, $\theta'=\beta'$; and by $\theta=\gamma$, $\theta'=\gamma'$. By hypothesis, however, the equation

$$p\phi^2+(1-q)\phi+r=0,$$

which gives the common corresponding points of the ranges, is satisfied by $\phi=0$ (at the point V), and by $\phi^{-1}=0$ (at the point U). Thus $p=0$ and $r=0$. Therefore, for a proper value of q, we have

$$\alpha'=q\alpha,\ \beta'=q\beta,\ \gamma'=q\gamma.$$

These relations shew that the lines AB' and $A'B$ meet on the line

UV, namely in the point whose symbol is $q\alpha\beta U - V$. For this is $\alpha\beta' U - V$, or

$$[\alpha-\beta']^{-1}[\beta'(\alpha^2U+\alpha W+V)-\alpha(\beta'^2U+\beta' W+V)],$$

and this point, therefore, lies on the line AB'; and it similarly lies on $A'B$. By the same argument the lines BC', $B'C$ meet on the line UV, as do the lines CA', $C'A$. This establishes Pascal's theorem.

If the common corresponding points of the two related ranges, $A, B, C, \ldots$ and $A', B', C', \ldots$, on the conic, be coincident, say in U, we may take an arbitrary point, V, of the curve, and, as before, represent any point of the curve by a symbol $\theta^2U+\theta W+V$. The equation, $p\phi^2+(1-q)\phi+r=0$, for the common corresponding points of the two related ranges is, now, to be satisfied by $\phi^{-1}=0$ (at the point U), *twice over*; thus $p=0$ and $q=1$. The relation for the corresponding points of the two ranges is, therefore, $\theta'=\theta-r$, so that $\alpha'=\alpha-r$, $\beta'=\beta-r$, $\gamma'=\gamma-r$. The line AB' now contains the point, of the line UW, given by

$$\alpha^2U+\alpha W+V-(\beta'^2\,U+\beta' W+V);$$

this is the point given by $(\alpha+\beta')\,U+W$, or $(\alpha+\beta-r)\,U+W$. By the symmetry of this form, the line $A'B$ also passes through this point. Similarly the intersection of the lines BC', $B'C$, and the intersection of the lines CA', $C'A$, lie on this line UW, which is the tangent of the conic at U.

We have stated, in the Preliminary (above, p. 9), that, in the first three chapters of this volume, we propose to assume that two conics in the same plane have four common points. It may be desirable to remark on the representation of this fact in terms of the symbols. The expression for a point of a conic, $\theta^2A+\theta B+C$, is in terms of two points A, C, lying on the conic, and the intersection, B, of the tangents of the conic at these two points. If U, V, W be three arbitrary points of the plane, the points A, B, C will be expressible in terms of these by formulae $A=a_1U+a_2V+a_3W$, $B=b_1U+b_2V+b_3W$, $C=c_1U+c_2V+c_3W$ (Vol. I, p. 71). Thus in terms of U, V, W, a point of the conic will have a representation

$$(a_1\theta^2+b_1\theta+c_1)\,U+(a_2\theta^2+b_2\theta+c_2)\,V+(a_3\theta^2+b_3\theta+c_3)\,W.$$

If now there be another conic, the points of this may, similarly, be represented in terms of U, V, W, the expression being of the form

$$(l_1\phi^2+m_1\phi+n_1)\,U+(l_2\phi^2+m_2\phi+n_2)\,V+(l_3\phi^2+m_3\phi+n_3)\,W,$$

where ϕ is the parameter. At a point common to the two conics, the three functions

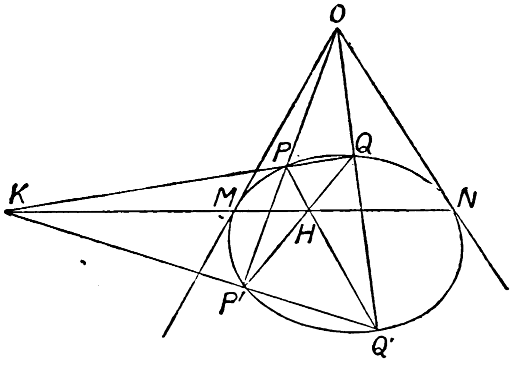
$$(a_r\theta^2+b_r\theta+c_r)/(l_r\phi^2+m_r\phi+n_r),$$

for $r=1, 2, 3$, must be equal to one another. From the two equations which express this fact we may eliminate ϕ; the result is at once seen to be a quartic equation to be satisfied by θ. The assumption to be made is then equivalent to the assumption that this equation has four roots. From any one of these, the corresponding value of ϕ can be found without ambiguity.

With these indications, we now leave the use of the symbols. They will be employed again in Chapter III.

Geometrical theory resumed. Polar lines. We saw that any line of the plane contains two points of the conic. We now shew that through any point, O, of the plane, not lying on the curve, two tangents of the curve pass. Let lines be drawn through O, each meeting the curve in a pair of points, say P and P'. The pairs P, P' have been shewn to belong to an involution on the curve; let M and N be the points of the curve which are the double points of this involution. The line OM will then meet the curve only at M, in two coincident points, and will be the tangent of the curve at M. So the line ON is the tangent at N. And there is no other tangent passing through O, since the involution has only two double points.

Moreover, an involution is, by definition, formed by the aggregate of two related ranges of points which are such that two corresponding points, one from each range, are interchangeable. Thus if, through the point O, be drawn various lines OPP', OQQ', ORR', ..., meeting the conic, respectively, in P and P', in Q and Q', in R and R', ..., the ranges, $P, Q, R, \ldots$ and $P', Q', R', \ldots$, are related, and M, N are the common corresponding points of these two ranges. Thus, by what has been proved, in particular by Pascal's theorem, the



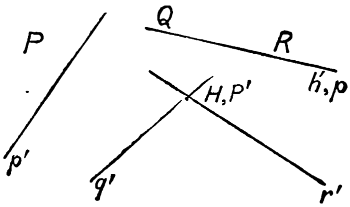
lines PQ', $P'Q$ meet on the line MN, say, in H, as do the lines PQ, $P'Q'$, say, in K. It follows that the line MN can be constructed when the four points P, P', Q, Q' are given; it also follows that the line PP' is met by MN in a point which is the harmonic conjugate of O in regard to P and P'. The line QQ' is similarly met by MN in a point which is the harmonic conjugate of O in regard to Q and

Q'; with a similar statement in regard to every one of the lines ORR', ... Thus, if lines be drawn from a point, O, not lying on the conic, and upon each be taken the harmonic conjugate of O in regard to the two points in which this meets the conic, the locus of this fourth harmonic point is a line. This line is called the *polar line*, or simply the *polar*, of O. From this there follows at once a property which is often applied, that, if the polar of one point O pass through a point O', then the polar of O' passes through O. And, therefore, if two points of the line MN be given, then O is determinate, namely, as the intersection of the polar lines of these two points.

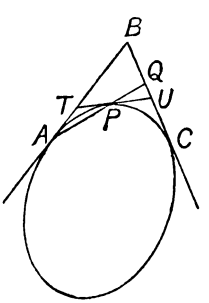
When O is on the conic, the harmonic conjugates of this in regard to the pairs P, P' and Q, Q', of which, say, P and Q coincide with O, also coincide with O. In this case we speak of the tangent of the curve at the point O as being the polar of O. Conversely, it may be shewn to follow from the character of the harmonic relation of four points that the polar of O can only pass through O when O is a point of the conic.

We may speak of the point O as the pole of the line MN; and in particular of a point of the conic as the pole of the tangent line of the conic at this point.

Duality in regard to a conic. From what we have just said, a conic, given in a plane, determines a particular duality therein. Any point, P, of the plane, regarded as belonging to one figure, determines a particular line, p', which we may regard as belonging to a derived figure, this line p' being here, the polar of P in regard to the given conic. Any line, p, of the first figure, joining two points, Q and R, of the first figure, gives rise to a point, P', of the derived figure, this being the intersection of the polars, respectively q' and r', of Q and R. To a point H, of the first figure, which coincides with P', corresponds the line, h', of the second figure, which is the polar line of P'; but, as P' lies on the polars of Q and R, these points, Q, R, lie on the polar of P', which is the line h'. Thus, the lines h' and p are the same. The correspondence is, therefore, of an involutory, or reciprocal, character, the line which arises from any point being the same whether the point is regarded as belonging to the first, or to the derived, figure; the point which arises from any line is therefore, also, capable of both derivations. The necessary and sufficient condition for a line to contain the point to which it corresponds is, that the point lie on the conic, and that the line be a tangent of the conic. We may, therefore, speak of the conic as the *curve*, or *envelope*, *of incidence*, of the two figures.

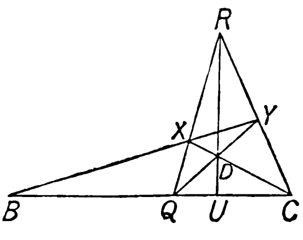


Dual definition of a conic. When one figure is the dual of another, it follows from the original definition of related ranges, by means of incidences, as developed in Vol. I, and the fact that Pappus' theorem involves the dual proposition which corresponds to it (Vol. I, chap. I, and p. 55), that related ranges give rise to related pencils, and related pencils give rise to related ranges. Hence, as we defined the conic as a locus of points, by the intersection of corresponding rays of two related pencils, so, equally well, we could have defined the aggregate of the tangents of the conic as the joins of corresponding points of two related ranges. In other words, if the tangent at any point, *P*, of the conic, meet the two tangents at the points *A* and *C*, respectively, in *T* and *U*, the range of points, *T*, upon *AB*, is related to the range of points, *U*, upon *BC*, the point *U* being at *B* when *T* is at *A*, and at *C* when *T* is at *B*.



In fact, the range of points, *U*, where the tangent, *CB*, at a fixed point, *C*, of the curve, is met by the tangent at a variable point *P*, is related to the pencil of lines joining the points *P* to any fixed point of the curve. To prove this, if *AP* meet the tangent *CB* in *Q*, the point *A* being any fixed point of the curve, it is sufficient to prove that the range of points *U* is related to the range of points *Q*.

That this is so follows by the abbreviated argument referred to above (Preliminary, p. 8). For when *U* is given, *P* is determined, without ambiguity, as the point of contact of the tangent, other than *UC*, which can be drawn from *U* to the conic; and when *P* is given, *Q* is found by the line *AP*. Conversely when *Q* is given, *P* is found, and, thence, *U* follows. As, however, this argument, as we have stated it, involves a tacit reference to the symbols, we may give an alternative one. In fact, the points *Q*, *C* are harmonic conjugates of one another in regard to *B* and *U*; that is, by perspective from *P*, if the point of intersection of *TU* and *AC* be *L*, the line *BP* meets *AC* in a point which is the harmonic conjugate of *L* in regard to *A* and *C*; in other words *BP* is the polar line of *L*; for as *L* lies on the tangent at *P*, and on the polar of *B*, the polar of *L* passes through *P*, and through *B*. We have then to shew that, if *Q*, *U* be variable points of the line joining two fixed points *B* and *C*, such that *B*, *U* are harmonic conjugates of one another in regard to *Q* and *C*, then the ranges (*Q*), (*U*) are related. For this, take an arbitrary

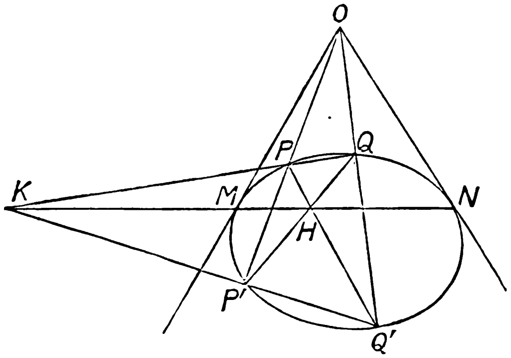


fixed point, R, and an arbitrary line, BXY, passing through B and meeting RC, RQ, respectively, in Y and X; thus Y is a fixed point; if then QY, CX meet in D, the line RD passes through U, and the line BD is a fixed line, meeting YC in the harmonic conjugate of R in regard to Y and C. The range (Q), by perspective from Y, is then related to the range (D) on this fixed line BD, and the range (D), by perspective from R, is related to the range (U). This makes the result clear.

Having proved that the range of points, U, on the tangent CB of the conic, is related to the pencil of lines joining A to the points, P, of the conic; and, then, similarly, that this pencil is related to the range of points, T, on the tangent AB, it follows that these ranges (U), (T) are related. Therein, to the point B, regarded as a point of AB, corresponds the point of contact, C, of the conic with BC, and to B, regarded as a point of BC, corresponds the point of contact, A, of the conic with BA. This is exactly the dual of what was the case when the points of the conic were determined by related pencils.

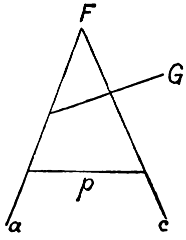
Examples of the application of the foregoing theorems. We may now regard ourselves as having given the indispensable fundamental propositions of a theory of conics. We proceed to make applications of these, in various directions.

Ex. 1. *The self-polar triad of points for conics through four points; the self-polar triad of lines for conics touching four lines.* It has appeared that if P, P', Q, Q', be four points of a conic, and the three pairs of lines which contain these points intersect respectively in the points O, H and K, then the line HK is the polar



of O; similarly the line OH is the polar of K; and, therefore, the line OK, containing the poles of HK and HO, is the polar of H. For this reason the triad O, H, K is called a self-polar triad, in regard to the conic. The same triad clearly arises for all conics which contain the four points P, P', Q, Q'. We saw that the conics through these four points meet an arbitrary line in pairs of points in involution; this involution has two double points. The conic through the four points and one of these, will not intersect the line again; this line will, therefore, be the tangent of the conic at this point. In other words, two conics can be drawn through four points to have a given line as tangent.

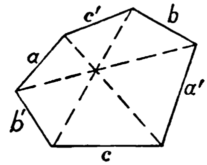
It was remarked that a tangent of the conic meets the curve in two coincident points. It will be found independently that, if this is understood, theorems in regard to four points of the curve continue to hold when these are not all distinct. For instance, if C, A, B be three points of the curve, and a line meet CA, CB respectively in L and M; meet the tangent at C, and the line AB, respectively in T and R; and meet the curve in X and Y, then it can be proved that the pairs L, M; T, R; X, Y belong to an involution. Or again, if A and C be two points of the curve, and a line meet AC in O; meet the tangents at A and C respectively in T and R; and meet the curve in X and Y; then O is one of the double points of the involution determined by the pairs T, R; X, Y. The other double point, U, is the harmonic conjugate of O in regard to T and R, or X and Y. In this latter case, only one conic can be drawn to pass through A and C and have at these points, for tangents, the given lines AT, CR, which shall touch the given line OU. It touches this at U. A degenerate conic having two coincident points at A, and at C, which also has two coincident points on OU, consists of the line OCA taken twice over.

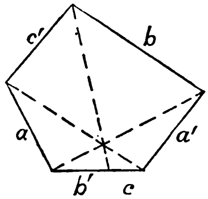


Dually, the aggregate of the tangents of a conic consists of lines, p, whose intersections with two given lines, a, c, form two related ranges thereon. The lines a, c are tangents of this conic. If the ranges have the point of intersection, F, of the lines a, c, for a self-corresponding point, they are in perspective, say, from a centre G. In this case we may regard the envelope as consisting of all lines through G, together with all lines through F; it is sometimes said to degenerate into a point pair, F and G. All this has been remarked above (p. 11). In the general case, such a conic envelope can be found having five arbitrary lines, of general position, for tangents. Let four tangents of such an envelope be p, p', q, q'; corresponding to the three ways of dividing these into two pairs, we have three pairs of points of intersection of the four lines. Let o, h, k be the joins of these pairs. Then, as the result dually corresponding to that above, any two of the lines o, h, k intersect in the pole of the remaining line, and form what we may call a self-polar triad of lines in regard to the envelope. There is an infinite number of conic envelopes touching the four lines p, p', q, q'; among these there are three point pairs, the pairs referred to above. The pairs of tangents that can be drawn, from an arbitrary point of the plane, one pair to each conic touching the four lines p, p', q, q', form a pencil in involution; of these pairs, three are those which join the arbitrary point to one of the point pairs referred to, namely, the pairs of points (p, p') and (q, q'); (p, q) and (p', q'); (p, q') and (p', q). This pencil in involution has two double rays; there are thus two conics which can be drawn, to touch the four lines p, p', q, q' and pass through an arbitrary point of the plane; the tangents of these conics at this point are the two double rays of the pencil in involution referred to.

In particular only one proper conic can be drawn to pass through an arbitrary point, O, and touch each of two given lines, which intersect in B, at given points, A, C. The tangent of this conic at O meets the line AC in the harmonic conjugate, with respect to A and C, of the point where the line BO meets AC. A degenerate conic with the definition given, consists of the point B taken twice over, that is of the aggregate of all lines through this point, taken twice over.

Ex. 2. *Dual of Pascal's theorem.* To Pascal's theorem there is a dually corresponding one, known as Brianchon's theorem. This may be stated by saying that, if a, b, c, a', b', c' be any six tangents of a conic, the three lines joining, the point (b, c') to the point (b', c), the point (c, a') to the point (c', a), and the point (a, b') to the point (a', b), are three lines which meet in a point. Taking the six lines in the order a, b', c, a', b, c', we may speak of the lines which are stated to meet in a point, as those joining opposite angular points of a hexagon, or as diagonals of this.





We saw that a tangent of a conic, regarded as a locus of points, may be regarded as meeting the conic in two coincident points. Dually, for a conic envelope, the point of contact of any tangent may be regarded as the intersection of two coincident tangents. Suppose then that, in the general figure for Brianchon's theorem, the two tangents b' and c coincide. We then infer that if a', b, c', a and b' or c, be five tangents of a conic, the point of contact of the last line lies on the line joining the point of intersection (b, c') to the point where the join of the points (a, b'), (a', b) meets the join of the points (a, c'), (a', c). We have given above, in connexion with Pascal's theorem, a construction for the tangent at any one of the five points by which a conic is determined; it may be seen that the present construction, for the point of contact, follows from this by the principle of duality. A particular case, when b and c' coincide, suggests the result that, if AB, BC, CD, DA be four tangents of a conic, the join of the points of contact with AB and CD passes through the intersection of AC and BD.

We remarked the existence, given six points of a conic, of sixty Pascal lines. There are similarly, given six tangents, sixty Brianchon points. The properties of the Pascal lines, which are extremely curious, have been much studied. It will be seen below, in Note II, pp. 219 ff., that these properties can be summarised and grasped most easily by regarding the figure as obtained by projection from a figure in space of three, or, better still, of four, dimensions.

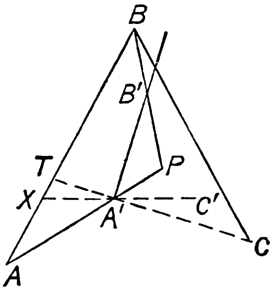
Ex. 3. *The director conic of a given conic in respect of two arbitrary points.* Let S be a given conic, and P, Q be two given points, not lying on the conic, in general. Let any line, l, be drawn through P, and, then, the line, m, be drawn through Q which contains the pole of the line l in regard to S. Thus the line l also contains the pole of m; and the lines l, m are a pair of lines, respectively through P and Q, each of which contains the pole of the other; two such lines are generally spoken of as *conjugate* to one another, in regard to the conic. We prove that the lines l, m intersect in a point which describes another conic; this conic contains P, and contains the points of contact of the two tangents which can be drawn from P to touch the given conic S; it also contains Q, and the two points of contact of the tangents from Q to the given conic. Further, the tangents at P and Q, of this conic, meet in the point, H, which is the pole of the line PQ in regard to the given conic. For reasons which will appear, this new conic may be called the *director* conic of the given conic, in regard to P and Q.

In fact, the poles, in regard to the conic S, of all lines drawn through P, lie upon a line, the polar line of P in regard to S; and they constitute a range upon this line which is related to the pencil of lines, spoken of, drawn through P. This fact is, at once, to be proved directly, by remarking that the pole of any line, l, through P lies on the polar of P, in regard to S, and that the harmonic conjugate of this pole, in regard to the two points where the polar of P cuts the conic S, lies on the line l; or the fact follows from what was remarked above, that, in two dually corresponding figures, a range of points, of one figure, is related to the corresponding pencil of lines, of the other figure. Therefore the lines m, through the point Q, each drawn to the pole of a line l, form a pencil related to the pencil of lines l; and thus the point of intersection of corresponding lines of these pencils describes a conic containing the points P and Q. Either of the tangents drawn to the conic S from the point P, is a particular line l, whose pole is its point of contact with S; thus the corresponding line m contains this point of contact, which is therefore on the conic described. Similarly for the other three points of contact of which we have spoken. If H be the pole of the line PQ, in regard to S, the pole of the line PH is on the line PQ; this line is then the line through Q which corresponds to the line PH through P; thus, by what was seen above, PH is the tangent of the new conic at the point P. So QH is the tangent at Q.

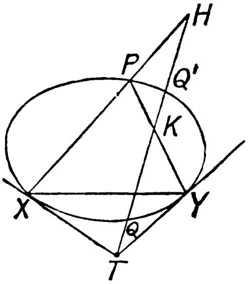
It is easy to see that if the line PQ touches the conic S, the director conic breaks up into PQ and another line.

Ex. 4. *The polars of three points determine a triad of points in perspective with the original triad.* As an application of the ideas involved in the definition of a conic, we may prove that, if A, B, C be three arbitrary points, whose polars, in regard to a conic are the lines a, b, c, respectively, and the points of intersection (b, c), (c, a), (a, b) be, respectively, called A', B', C', then the lines AA', BB', CC' meet in a point. The points A', B', C' are, respectively, the poles of the lines BC, CA, AB, and the figure may start from these.

Take the points B, C, A', C'; these fix the line BA, the polar of C', and fix the line $A'B'$, the polar of C. On the line BA, take various positions of A, to which correspond various positions of $C'B'$, the polar of A, and, hence, various positions of B', the pole of CA. Let BB' and AA' meet in P. The pencil formed by the various lines joining A' to P, or, say, the pencil $A'(P)$, is then related to the range (A); this range, determined by the pencil $C(A)$, of lines which are polars of the various positions of B', is related to the range (B'), on the fixed line $A'B'$. For in two dually corresponding figures, a range of points is related to the corresponding pencil of lines, as has been remarked. And the range (B') is determined by the pencil $B(P)$. The pencils $A'(P)$ and $B(P)$ are thus related, and the point P describes a conic. But, when A is at B, the point B' is at A', so that the ray $A'B$ of the former pencil corresponds to the ray BA' of the latter. The conic which is the locus of P, thus breaks up into the line $A'B$ and another line. If, however, the lines $C'A'$ and CA' meet AB in X and T, respectively, it is at once seen that, when A is at X, the point P is at C', and, when A is at T, the point P is at C. Thus P, C', C are in line. And it is this which it was desired to prove. Another proof of this result is given below, Ex. 10. [Add.]

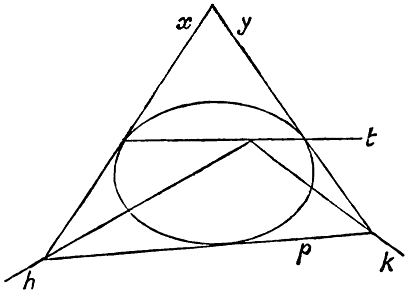


Ex. 5. *A construction for two points conjugate in regard to a conic.* Two points which are such that the polar of either contains the other are said to be conjugate in regard to the conic. The following simple property seems to deserve remark: If P, X, Y be three points of a conic, the lines PX, PY are met by any line drawn through the pole of the line XY in points which are conjugate in regard to the conic.



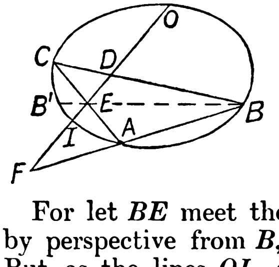
Let T be the intersection of the tangents of the conic at X and Y, the pole of XY; let any line drawn through T meet the conic in Q and Q', and meet PX, PY, respectively, in H and K. The pair of points Q, Q', on a line through T, is a pair of an involution of points of the conic, of which X and Y are the double points. Thus, in the pencil formed by lines joining the point P, of the conic, to X, Y, Q, Q', the rays PX, PY are harmonic conjugates in regard to the rays PQ, PQ'. Therefore on the line TH, the points H, K are harmonic conjugates in regard to Q and Q'. Wherefore the polar of H contains K, or H and K are conjugate points in regard to the conic.

The dually corresponding theorem is that, if x, y, p be three tangents of a conic, and any point of the line, t, which joins the points of contact of x and y, be joined, by lines h and k, to the points where p meets x and y, respectively, then the lines h, k are conjugate to one another in regard to the conic.



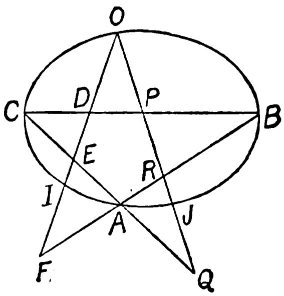
The result was remarked by von Staudt and, previously, by Seydewitz.

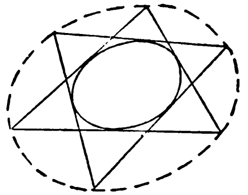
Ex. 6. *Range determined by a conic, and by the joins of three points of the conic, upon any line drawn through a fixed point of the conic.* Let A, B, C, O be four fixed points of a conic. Let any line drawn through O meet BC, CA, AB, respectively, in D, E and F, and meet the conic again in I. Then the range D, E, F, I is related to the pencil which the points A, B, C, O subtend at any point of the conic.



For let BE meet the conic again in B'. The range D, E, F, I, by perspective from B, gives the range C, B', A, I on the conic. But, as the lines OI, AC, BB' meet in E, the pairs of points OI, AC, BB' belong to an involution of points on the conic; therefore the range C, B', A, I, of points of the conic, is related to the range of points A, B, C, O, respectively paired with the former in this involution. Wherefore, the range D, E, F, I is related to the pencil of lines joining any point of the conic to the points A, B, C, O; as stated.

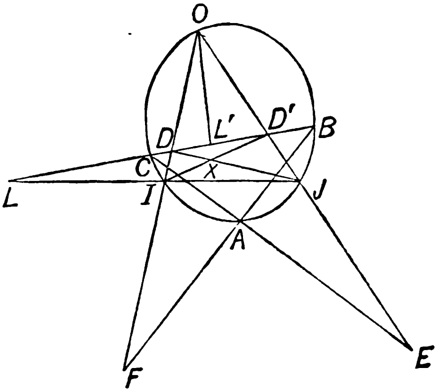
Ex. 7. *The six joins, of two triads of points of a conic, touch another conic.* Let O, I, J and A, B, C be any two triads of points of a conic; then the six joins consisting of BC, CA, AB and OI, OJ, IJ all touch another conic. For, as in the preceding example, let OI meet BC, CA, AB, respectively, in D, E, F; and, let OJ meet BC, CA, AB, respectively, in P, Q, R. The two ranges, D, E, F, I and P, Q, R, J, being, by the preceding example, both related to the points A, B, C, O of the conic, are related to one another. The two lines OI, OJ are thus met in related ranges by the four lines BC, CA, AB, IJ. Therefore, by the definition of a conic, in dual form, these six lines all touch a conic. (See also p. 142, Ex. 24.)





Dually we have the theorem that, if two triads of lines are tangents of a conic, and we take the three intersections in pairs of the lines of a triad, the six points so obtained lie on another conic. [Add.]

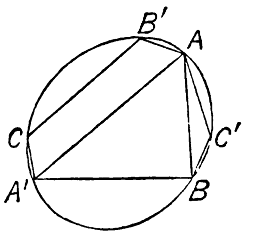
Ex. 8. *The pedal line of three points of a conic in regard to three other points of the conic, taken in a particular order.* The following result, though somewhat involved, may be proved here, because it depends on the same figure as that just employed. It is of interest later. Let A, B, C and O, I, J be two triads of points of a conic; let IJ meet BC, CA, AB, respectively, in L, M and N. From O are drawn three lines which are the harmonic conjugates, respectively, of OL, OM and ON, in each case in regard to OI and OJ. If these lines be, respectively, OL', OM', ON', then the pairs OL, OL'; OM, OM', and ON, ON' are in involution, of which the double



rays are OI, OJ. Supposing L', M', N' taken, respectively, upon BC, CA, AB, the theorem to be proved is, that L', M', N' are in line.

Let OI meet BC, CA, AB, respectively, in D, E, F, and OJ meet these, respectively, in D', E', F'. By what was seen in Ex. 6, the ranges D, E, F, I and D', E', F', J are related. Wherefore, the three points of intersection (ID', JD), (IE', JE), (IF', JF) are in line (Vol. I, p. 53); let these points be named, respectively, X, Y and Z. Of these, the point X is evidently on the line OL', being the harmonic conjugate of O, in regard to the point L' and the point where OL' meets IJ. Similarly, Y and Z are, respectively, on OM' and ON', and there is a corresponding harmonic relation. If then the line XYZ meet IJ in T, the points L', M', N' lie on a line through T, this being the harmonic conjugate of the line TIJ in regard to the lines TO and $TXYZ$. [Add.]

Ex. 9. *The Hessian line of three points of a conic. The Hessian point of three tangents of a conic.* If the tangents at the points A, B, C, of a conic, meet BC, CA, AB respectively in P, Q, R, then these points are in line.



By Pascal's theorem, if A, B', C, A', B, C' be six points of a conic, the three points of intersection $(AB', A'B)$, $(BC', B'C)$, $(CA', C'A)$ are in line. Suppose now that B' coincides with A, and A' with C, and C' with B. Then, instead of the lines AB', BC', CA', there will be the tangents of the conic at A, B and C, respectively; and, instead of the lines $A'B$, $B'C$, $C'A$, there will be the lines BC, CA, AB, respectively. The theorem in question thus expresses the fact that Pascal's theorem continues to hold when these coincidences occur. We can, in fact, prove it directly in the same way as Pascal's theorem. For, going back to the original definition of a tangent, we see that the theorem expresses that if two ranges of points of the conic be related to one another by the condition that the points A, B, C, of the one, correspond, respectively, to the points C, A, B, of the other, then the common corresponding points of these ranges are on a line containing the points, P, Q, R, where the tangents at A, B, C meet, respectively, the opposite joins (cf. Vol. I, p. 174, Ex. 5). We shall speak of the line PQR as the Hessian line of the triad A, B, C in regard to the conic.

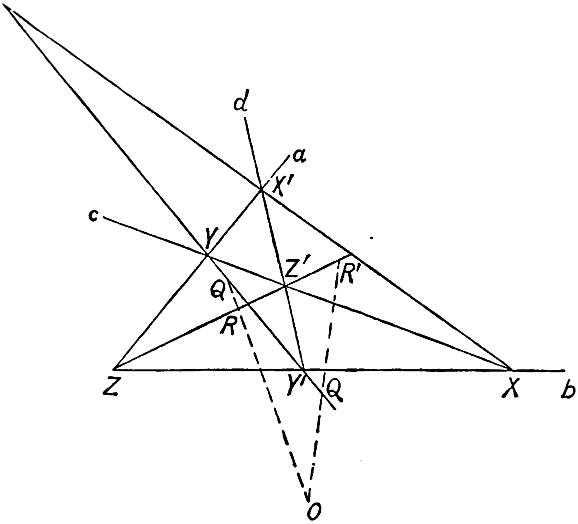
If the tangents of the conic at B, C meet in A', the line AA' is the polar of P. The three lines such as AA' thus meet in a point, which is the pole of the line PQR.

Dually, we have the result that, if a conic touch the joins VW, WU, UV, of any three points, U, V, W, respectively, in A, B, C, then the lines AU, BV, CW meet in a point. We shall call this the Hessian point of the three tangents in regard to the conic.

If BC meet VW in D, then D is the pole of UA. Thus the three points such as D are in line.

Ex. 10. *Polar triads in regard to a conic. Hesse's theorem.* The preceding result is a particular case of another, of which a proof has already been given (Ex. 4, above), which we may state as follows: The polar lines, in regard to a conic, of any three points A, B, C, meet the joins BC, CA, AB, respectively, in three points which are in line. If the polars of B and C meet in A', the polars of C and A meet in B', and the polars of A and B meet in C', the result will follow, by Desargues' theorem of perspective triads, if we prove that the lines AA', BB', CC' meet in a point. But if BB' and CC' meet in D, and we notice that B' is the pole of CA and C' the pole of AB, this is the same as saying that, if A, B, C, D be any four points such that one pair of joins of these, AC and BD, be conjugate lines in regard to a conic, and also another pair of joins of these, AB and CD, be conjugate lines in regard to this conic, then also the third pair of joins of these, BC and AD, are conjugate lines in regard to this conic. This result may be called Hesse's theorem; it is of importance in the sequel.

In dual form, this theorem is that, if any four lines a, b, c, d be divided into pairs in each of the three possible ways, and the points, Y, Y', obtained by the intersection of the pair a, c, and by the intersection of the pair b, d, be conjugate points in regard to a



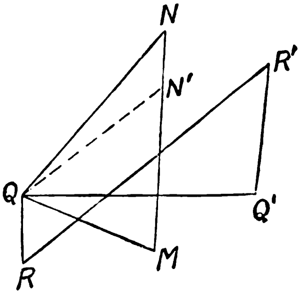
conic; and the same be true of the points, Z, Z', obtained by the intersection of the pair a, b, and by the intersection of the pair c, d: then the points, X, X', the intersections, respectively, of b and c, and of a and d, are also conjugate points in regard to the conic. We prove this by shewing that the points in which the conic meets the line XX' are harmonic conjugates of one another in regard to X and X'.

Let the conic meet the line YY' in Q and Q'; since the polar of Y passes through Y', the points Q, Q' are harmonic conjugates of one another in regard to Y and Y'. The points, R and R', in which the conic meets the line ZZ' are, similarly, harmonic conjugates of one another in regard to Z and Z'. Let QR and $Q'R'$ meet in O. As the conics through the four points Q, R, Q', R' meet the line XX' in pairs of points belonging to an involution, the given conic will be shewn to meet XX' in points harmonic in regard to X and X', if there be found two other conics, through the four points Q, R, Q', R', having this property; the points X, X' will then be the double points of the involution. By the original definition of the harmonic relation, the line pair QQ', RR', or YY' and ZZ', is one such conic. In fact the line pair OQR, $OQ'R'$ is another such conic. For the three line pairs joining O to the point pairs Y, Y'; Z, Z' and X, X' are in involution (p. 4, above), and the lines OQR, $OQ'R'$ are harmonic in regard to OY, OY', and also in regard to OZ, OZ', as we have seen; they are, therefore, the double rays of this pencil in involution of centre O, and are, thus, harmonic in regard to OX and OX'. Thus OQR, $OQ'R'$ are, as stated, a second conic through the four points Q, R, Q', R' which cuts XX' in points harmonic in regard to X and X'; the result required. [Add.]

We have seen, in Ex. 1, above, that the tangent pairs, from the point O, to conics which touch the four lines a, b, c, d, are a pencil in involution, of which OY, OY' are a pair of rays, as are OZ, OZ'; the lines OQR, $OQ'R'$ being, as we have just remarked, the double rays of this pencil, are then harmonic in regard to the tangents from O to any such conic. Now, two points, which are harmonic in regard to the two points in which their join meets a conic, are conjugate points in regard to the conic; and, dually, two lines, which are harmonic in regard to the tangents drawn to a conic from their intersection, are conjugate lines in regard to the conic. Thus, the lines OQR, $OQ'R'$ are conjugate lines in regard to any conic touching the four lines a, b, c, d. The lines YY' and ZZ' have also been seen (Ex. 1, above) to be conjugate to one another in regard to any such conic. The line pairs OQR, $OQ'R'$ and YY', ZZ' (or QQ', RR') are two of the three line pairs containing the points Q, R, Q', R'; by the dual of the theorem proved in this example, it follows, since two of these line pairs are conjugate lines in regard to any particular conic, Σ, touching a, b, c, d, that the third line pair, QR', $Q'R$, containing these points, are also conjugate in regard to Σ. We have thus proved a theorem which may be stated thus: Let a, b, c, d be any four tangents of a conic, Σ; let two (and, therefore, the third) of the point pairs of intersection of these tangents (Y, Y' and Z, Z') be conjugate points in regard to another conic, S. There is then a set of four points of the conic S (namely Q, R, Q', R') such that each line pair, containing these, is a pair of conjugate lines in regard to Σ.

Ex. 11. *Outpolar conics.* Let Q, R, Q', R' be four points of a conic, S, which are such that two (and, therefore, the third) of the line pairs containing these, say QR, $Q'R'$ and QQ', RR', are pairs of conjugate lines in regard to another conic, Σ. Such a figure is not possible for any two conics S, Σ, arbitrarily given. When it is possible, we shall speak of the conic S as being *outpolar* to Σ. Dually, when there are four tangents of Σ whose three point pairs of intersection are pairs of conjugate points in regard to S, we shall speak of Σ as being *inpolar* to S. The result obtained at the conclusion of the preceding example may then be stated by saying that when Σ is inpolar to S, then S is outpolar to Σ. By dual reasoning it follows that, when S is outpolar to Σ, then Σ is inpolar to S.

Proceeding now with the hypothesis made at the beginning of this example, that the line pairs QR, $Q'R'$ and QQ', RR', are conjugate lines in regard to Σ, take the polar line of Q, in regard to Σ, and let this meet the conic, S, containing the points Q, R, Q', R', in the points M and N. On MN take the pole, N', of QM, also in regard to Σ, so that M is the pole of QN'. The lines QM, $R'N'$ are then conjugate in regard to the conic Σ; and the lines QN', $R'M$ are also conjugate in regard to Σ. Now, when any lines are drawn through Q, their poles, in regard to Σ, lie on the polar line MN of Q in regard to Σ; and the lines joining R' to these poles form a pencil related to the range of these poles, and therefore related to the pencil of lines drawn through Q. Thus the pencil $Q(M, N', Q', R)$ is related to the pencil $R'(N', M, R, Q')$, and, hence, to the pencil $R'(M, N', Q', R)$, for the lines QQ', $R'R$ were given to be conjugate lines in regard to Σ, as were QR and $R'Q'$. It follows that the six points Q, Q', R, R', M, N' lie on a conic; this is, therefore, the same as the conic, S; and the point N', not coinciding with M in general, coincides with N. The points Q, M, N' were constructed to form a

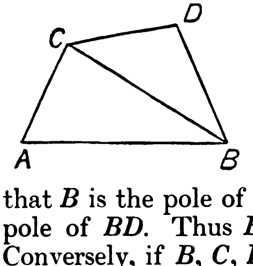


self-polar triad in regard to Σ; the points Q, M, N thus form such a triad. We have, therefore, shewn that when the conic S is outpolar to Σ, as containing four points whose line pairs of joins are conjugate pairs in regard to Σ, then a triad of points can be found on S which are a self-polar triad in regard to Σ. And one point of this triad is any one of the four given points of S. [Add.]

Conversely, let a triad of points of S, say Q, M, N, form a self-polar triad in regard to Σ; take, upon S, two other quite arbitrary points, R and R'; draw, also, the line QQ' through Q which is conjugate to the line RR' in regard to Σ, and draw the line $R'Q'$ through R' which is conjugate to QR in regard to Σ; let these lines meet in Q'. It can then be proved, as above, that the point Q' lies on the conic S. There are then four points, Q, R, Q', R', of the conic S, such that the lines QR, $Q'R'$ are conjugate in regard to Σ, as also are the lines QQ' and RR' (and, therefore, also QR' and $Q'R$). The conic S is thus outpolar to Σ. Therefore, by what was proved above, if the polar of R in regard to Σ be taken, this will meet S in two points which, with R, form a triad of points of S which is self-polar in regard to Σ. The point R was an arbitrary point of S; such triads exist, therefore, in infinite number, of which one point is arbitrary.

Hence, if two conics S, Σ be so related that there is one triad of points of S which are a self-polar triad in regard to Σ, there is an infinite number of such triads, one of the three points being arbitrary. There is then also an infinite number of sets of four points of S, which are such that each of the line pairs containing them is a pair of conjugate lines in regard to Σ; of such a set, three of the points may be taken arbitrarily upon S.

If two of such a set of four points upon S be conjugate to one another in regard to Σ, then the set consists of a triad which is self-polar in regard to Σ (consisting of these two points and another), together with a fourth point. For let A, B, C, D be such a set, the lines AB, CD being conjugate in regard to Σ, as also AC, BD, while B and C are conjugate in regard to Σ; and suppose A, B, C are not a self-polar triad in regard to Σ. Then the pole of AB is some point of CD, say C_1, and C_1 is not at C. The polar of C_1 being AB, and the polar of C passing through B, it follows that B is the pole of the line CC_1, or CD. In a similar way C is the pole of BD. Thus B, C, D are a self-polar triad in regard to Σ. Conversely, if B, C, D be points of S forming a self-polar triad in regard to Σ, and A be any other point of S, the four points A, B, C, D have the property that every line pair containing them consists of conjugate lines in regard to Σ.

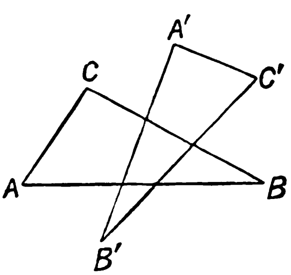


By what has been said, it follows, also, that if there are three points of S forming a self-polar triad in regard to Σ, then, the conic Σ being inpolar to S, there are sets of three tangents of Σ forming a self-polar triad of lines in regard to S.

An important consequence of what has been said is, that if S and S' be two conics which are both outpolar to a conic Σ, then the four common points of S and S' are such a set of four points as has been spoken of: every line pair which contains these four points consists of lines which are conjugate to one another in regard to Σ. And, thus, every conic through the four common points of S and S' is also outpolar to Σ.

For, let A, B, C be three points common to S and S'; if these form a self-polar triad in regard to Σ, then these, with the fourth intersection of S and S', form such a set of four points; and, every conic through A, B, C is outpolar to Σ. When A, B, C do not form such a self-polar triad, by drawing, from B, the line BD, conjugate to AC, in regard to Σ, and drawing, from C, the line CD, conjugate to AB, in regard to Σ, we determine a point D. By what has been proved above, this point D lies both on S and S'. There is a dually corresponding theorem in regard to the four common tangents of two conics Σ, Σ' which are both inpolar to a conic S.

Ex. 12. *Two self-polar triads of one conic are six points of another conic.* One incidental consequence of the theory of the preceding example is, that if two triads, A, B, C and A', B', C', be both self-polar in regard to a conic, Σ, then the six points A, B, C, A', B', C' lie on another conic. For the conic, S, which is drawn to contain A, B, C and A', B', is outpolar to Σ, as containing A, B and C. Therefore, by what has been shewn, the polar line of A', in regard to Σ, meets S in two points which, with A', are a self-polar triad in regard to Σ. One of these points is B'; the other is on $B'C'$, and is the pole of $A'B'$ in regard to Σ; it is therefore C'.



The direct proof, which is equivalent to a repetition, may be given. The lines AB, AC, AB', AC' are evidently conjugate, in regard to Σ, respectively, to $A'C$, $A'B$, $A'C'$, $A'B'$. Thus the pencil $A(B, C, B', C')$ is related to the pencil $A'(C, B, C', B')$, and hence, also, to the pencil $A'(B, C, B', C')$. Thus the six points lie on a conic.

By the dually corresponding proof, we can shew that the six lines BC, CA, AB, $B'C'$, $C'A'$, $A'B'$ all touch the same conic.

We shall (Ex. 21) prove, conversely, that, if A, B, C, A', B', C'

be any six points of a conic, there exists another conic in regard to which both A, B, C and A', B', C' are self-polar triads. By combining this with the theorem here, we shall thus have another proof of a theorem given above (Ex. 7), that if A, B, C and A', B', C' be points of a conic, there is another conic which touches all of BC, CA, AB and $B'C'$, $C'A'$, $A'B'$.

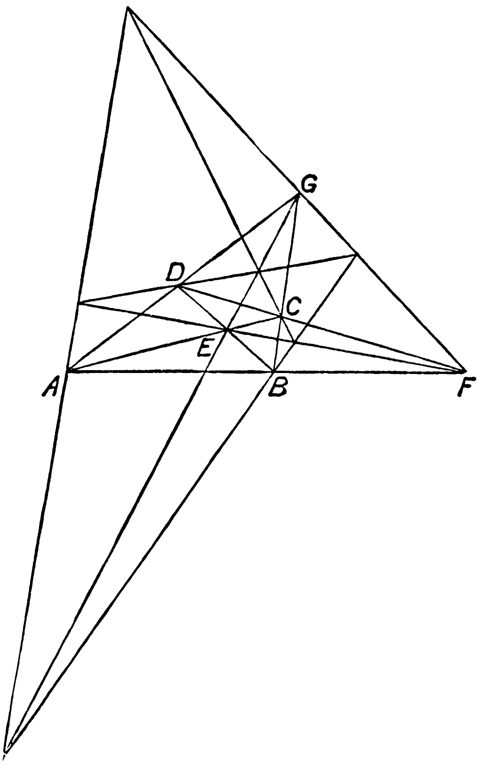
Ex. 13. *Particular cases of outpolar, or of inpolar, conics.* A particular case of a conic, S, outpolar to a proper conic, Σ, is a pair of lines which are conjugate in regard to Σ. A particular case of a conic, Σ, inpolar to a proper conic, S, is a pair of points which are conjugate in regard to S. In the general case, while the conic S is regarded as the locus of its points, the conic Σ is regarded as the envelope of its tangents; thus, a better statement of the latter case is, that the degenerate conic, Σ, consists of all lines through one of the two points conjugate in regard to S. A line pair may also be spoken of as inpolar to a conic, S, when the lines intersect at a point lying on S. But this point is to be regarded as a point pair of which the points coincide; the conic Σ consists then of all lines through this point. Similarly a line, taken twice over, may be spoken of as outpolar to a conic Σ when the line touches Σ.

These statements may be verified geometrically. Further confirmation will arise below when the matter is treated with the help of the algebraic symbols (Chap. III, Ex. 24).

Ex. 14. *The joins of four points of a conic and the intersections of the tangents at these points. The common points, and the common tangents, of two conics.* We have seen (Ex. 1) that the intersections of the three line pairs, which contain four points of a conic, form a self-polar triad in regard to the conic. Dually, the lines which join the three point pairs, through which four tangents of the conic pass, are a self-polar triad of lines in regard to the conic. When the four points are the points of contact of the four tangents considered, the triad of lines consists of the joins of the triad of points. In other words, the tangents at four points of a conic meet in pairs on the joins of the three points which form the common self-polar triad of all conics passing through the four points. We have seen, in Ex. 2, that, effectively, the result follows directly from Brianchon's theorem.

Let the line pairs containing the points A, B, C, D of a conic intersect, respectively, in E, F and G. The tangents of the conic at A and B meet in the pole of the line AB; as AB passes through one of the points E, F, G, say, through F, the pole of AB lies on the polar of F, that is, on the line EG. In the same way, the point of intersection of the tangents at any two of the points A, B, C, D is on one of the lines FG, GE, EF.

We have seen that, if we have two conics, the intersections of the line pairs passing through their intersections, form a self-polar triad of points for both conics. Dually, the joins of the point pairs, through which the common tangents of the two conics pass, form a self-polar triad of lines for the two conics (Ex. 1, above). These lines are in fact the joins of the points spoken of. In other words, through a point of intersection of two complementary chords common to two conics, there pass two lines each containing the intersection of two common tangents of the conics, and also the intersection of the other two common tangents; this line passes through the intersection of another pair of complementary chords common to the two conics.



To see that this is so, let us speak of two points P, P' as being harmonic images of one another in regard to a given point F, and a given line EG, when they are harmonic conjugates of one another, in regard to F, and the point where FP meets EG. Then either of P, P' determines the other; and if Q' be the harmonic image of another point Q, the lines $PQ, P'Q'$ intersect on EG. We may then regard a conic, for which E, G, F is a self-polar triad, as consisting of pairs of points, P, P', which are harmonic images of one another in regard to F and EG, the tangents of the conic at P and P' intersecting on EG. And, if E, G, F be the intersections of the line pairs through the common points of two conics, the harmonic image of a common tangent of the two conics is another common tangent of these conics, meeting the former on the line EG.

Ex. 15. *The polar lines of any point in regard to the conics through four given points all pass through another point.* For if the polars of a point, P, taken in regard to two of these conics, meet in a point P', the points P, P' are harmonic conjugates of one another in regard to the two points in which the line PP' meets either of these conics; they are, therefore, the double points of the involution determined on this line by the two pairs of intersections of this line with these two conics. As all the conics meet this line in pairs of points belonging to this involution, the points P, P', being harmonic conjugates in regard to any pair of the involution, are conjugate points in regard to any one of the conics. Thus the polar of P in regard to any one of the conics passes through P'.

In particular, if E be the intersection of one of the line pairs through the four points, the lines EP', EP are harmonic conjugates of one another in regard to this pair of lines. Thus, if F be the intersection of another of the line pairs through the four points, the point P' may be constructed from P by joining P to E and drawing a fourth harmonic line through E, and joining P to F and drawing another such fourth harmonic line through F. The point P' is the intersection of these. It lies on the similar fourth harmonic line which can be drawn through the intersection of the remaining line pair containing the four points.

Dually, the poles of any line in regard to all conics touching four given lines, lie on another line. This can be constructed by joining points determined as fourth harmonic points, on the lines containing the point pairs through which the four given lines pass.

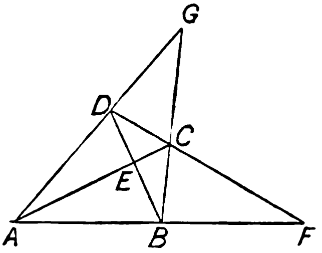
Ex. 16. *A point to point correspondence in regard to four given points.* Of the two points P, P' of the preceding example, either determines the other without ambiguity, when the four points A, B, C, D are given; and the relation is reciprocal or involutory, in the sense that, if P take the position of P', then P' takes the position of P. To this statement, however, there is an exception: Let E, F, G be the intersections of the line pairs containing A, B, C, D. Then when P is on the line FG, the point P' is at E; thus, to the position E, for P', the corresponding position of P is undetermined, being anywhere on the line FG. Similarly when P' is at F or G.

It can be shewn that, if P describes any line, then P' describes a conic passing through E, F, G; and, conversely, if P' describes any conic passing through E, F, G, then P describes a line. Evidently, conics passing through three fixed points E, F, G, are in some sense analogous to lines; in that any two such conics have one point of intersection, beside E, F, G, while such a conic can be drawn through two arbitrary points, other than E, F, G. The relation now in question enables us to pass from theorems relating to lines to theorems relating to such conics, or conversely.

To prove the statement made: when P describes any line, the pencils of lines joining E and F to P, or say $E(P)$ and $F(P)$, are related. As, however, the lines EP, EP' are harmonic in regard to the line pair intersecting in E, the pencils $E(P')$, $E(P)$ are related. Similarly, so are the pencils $F(P')$, $F(P)$. Thus the pencils $E(P')$, $F(P')$ are related. Thus, P' describes a conic containing the points E and F. This conic contains G; for this is the position of P' when P is on the line EF, at the point where this is met by the line on which P lies.

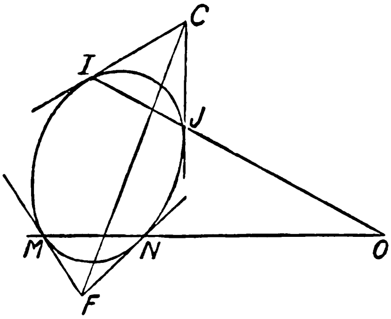
Now suppose that any points E, F, G are given, and also any other two points I, J. We shew that points A, B, C, D can be found so that, (*a*), the points E, F, G are the intersections of the line pairs containing A, B, C, D, (*b*), the points I, J are points corresponding to one another, in regard to A, B, C, D, in the sense just considered. The correspondence in question can then be regarded as determined by an arbitrary triad of points, E, F, G, and one given pair of corresponding points.

In fact two lines, FBA, FCD, are determined by the conditions that, they shall be harmonic conjugates of one another in regard to the given lines FE, FG, and shall also be harmonic conjugates of one another in regard to the given lines FI, FJ. And two lines, GDA, GCB, are determined by the conditions that, they shall be harmonic in regard to GE, GF, and also harmonic in regard to GI, GJ. These lines determine four points A, B, C, D. We have to shew that AC, BD meet in E, and are harmonic in regard to EI, EJ. In fact, AC and BD must meet on the line through G, which is the harmonic conjugate of GF in regard to the lines GCB and GDA; and they must, likewise, meet on the line through F which is the harmonic conjugate of FG in regard to the lines FBA and FCD; therefore AC, BD meet in E. And then it follows, by what was said above, that EC, EB are harmonic in regard to EI and EJ.



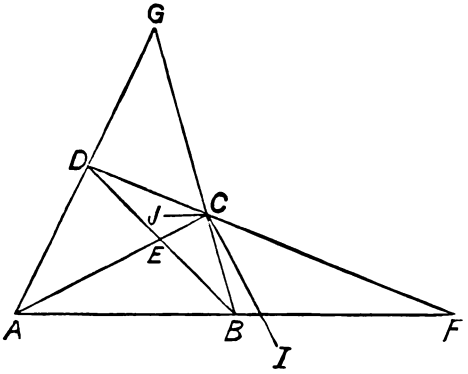
Ex. 17. *Four conics can be drawn through two given points to touch three given lines.* We have proved above that two conics can be drawn through a given point to touch four given lines. We consider now the conics that can be drawn through two given points to touch three given lines.

For this, notice, first, that, if FM, FN be the tangents drawn, from a point F, to a conic, of which I, J are two points, and C be the pole of the line IJ, then the involution determined by the two pairs of rays, FM, FN and FI, FJ, has FC for one double ray. In fact, if MN and IJ meet in O, this is the pole of the line FC, and its harmonic conjugates, both in regard to the pair I, J, and in regard to the pair M, N, lie on FC. Thus the lines FO, FC are harmonic, both in regard to FM, FN, and in regard to FI, FJ.



Take now the figure of the preceding example. We desire to find conics passing through I and J which shall touch the lines EF, FG, GE.

One conic can be drawn through I and J, to have CI, CJ as the tangents at these points, which shall touch FG. (Another degenerate conic which contains two coincident points of CI at I, two coincident points of CJ at J, and two coincident points of FG, consists of the line IJ, taken twice over. See Ex. 1, above.) This conic does, in fact, touch FE and GE, and is therefore such a conic as is desired. To prove that this conic, which touches FG, also touches FE, we use the remark made above, shewing that the involution which is determined by the pair of lines FI, FJ, and the double ray FC, contains the lines FE, FG as a pair. For this we have only to notice that FC, FB are harmonic in regard to FE, FG, and also harmonic in regard to FI, FJ (by the property of I, J in regard to A, B, C, D); the lines FC, FB are thus the double rays of an involution of which FI, FJ and FE, FG are pairs. This is then the involution spoken of. By a similar argument the conic described touches GE.

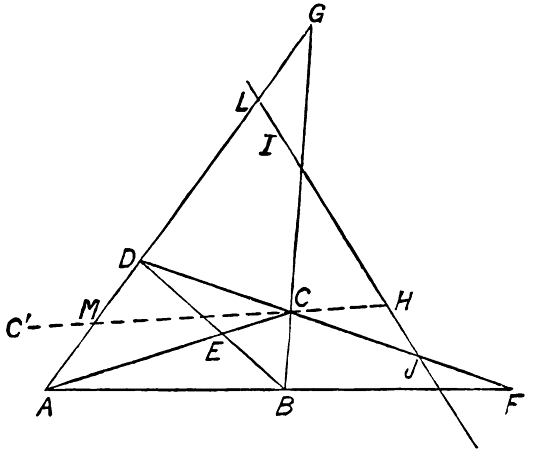


Another conic through I, J touching EF, FG, GE, is that described to touch DI, DJ, respectively, at I, J, and to touch FG. A third touches AI, AJ at I and J; and a fourth touches BI, BJ at I and J.

No other conics can be drawn through I, J to touch EF, FG, GE. For, by the remark made above, if FE, FG be the tangents from F to a conic which contains I and J, one of the double rays of the pencil in involution determined by the pairs, FI, FJ and FE, FG, must contain the pole of IJ in regard to this conic. The pole of IJ must then lie either on the line FAB or the line FCD. It must, similarly, lie either on GCB or on GDA. It must therefore be at one of A, B, C, D.

The dual of this proposition is that four conics can be drawn through three given points to touch both of two given lines. Of this a proof, which then also proves the direct proposition, follows at once from the correspondence explained in the preceding example (Ex. 16). This correspondence transformed conics passing through three given points into lines, and lines into conics passing through these three points. It therefore changes a conic which touches a line into a line touching a conic, the two common points of these being coincident in both cases. Thus a conic passing through the three given points and touching two given lines, becomes a line touching two conics which pass through the three given points. The result to be proved is, therefore, that, two conics have four common tangents. This we know, as the dual of the result assumed (Preliminary, above, p. 9) that two conics have four common points.

Ex. 18. *The poles of a line, in regard to conics with four common points, lie on a conic.* We have remarked that the poles of a line in regard to conics with four common tangents lie on a line. We may, however, consider the poles of a line in regard to conics with four common points. These lie on another conic, which is of importance. Of this conic eleven points can be specified at once, from the figure; it is therefore sometimes called the eleven-point conic.



Let A, B, C, D be the four common points of the conics considered. These determine, on the given line, an involution of pairs of points; let I, J be the double points of this involution. Let E, F, G be the intersections of the line pairs containing the four given points. A conic can be drawn through the five points E, F, *G*, *I*, *J*; we shew that this contains the pole of the given line in regard to every conic through the four given points.

For, *I*, *J* are harmonic conjugates in regard to the points in which any particular conic, *S*, through *A*, *B*, *C*, *D*, meets the line *IJ*; the polars of *I* and *J*, in regard to this particular conic *S*, thus pass, respectively, through *J* and *I*. Therefore, if these polars meet in *T*, the points *T*, *I*, *J* are a self-polar triad in regard to *S*. We have shewn that *E*, *F*, *G* are a self-polar triad in regard to any conic *S* (Ex. 1). We have also shewn that any two triads of points, which are both self-polar in regard to a conic, lie on another conic (Ex. 12). Thus *T* lies on the conic containing *I*, *J*, *E*, *F*, *G*. But *T* is the pole *IJ* in regard to the conic *S*. This proves the statement made.

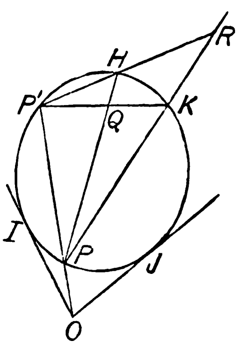
Now, let the line *IJ* meet *AD* in *L*; and let *M* be the harmonic conjugate of *L* in regard to *A* and *D*. Further, let *MC* meet the line *IJ* in *H*, and let *C′* be the harmonic conjugate of *C* in regard to *M* and *H*. If then we consider the particular conic through *A*, *B*, *C*, *D* which contains the point *C′*, the polar of *M* in regard to this conic contains both the point *L* and the point *H*. Thus *M* is the pole of the line *IJ* in regard to this particular conic. Wherefore *M* is on the conic obtained above, which is the locus of the poles of the line *IJ* in regard to all conics through *A*, *B*, *C*, *D*. By considering the intersections of the line *IJ* with the joins of every pair of the four points *A*, *B*, *C*, *D*, as we have just considered the intersection *L* with the join *AD*, and taking on each join the fourth harmonic in regard to the two points, as we have taken *M* on *AD*, we find in all six points of the conic in question. And we found that it contained the five points *E*, *F*, *G*, *I*, *J*.

Dually, the polars of a point, in regard to all conics touching four given lines, touch another conic, which will also be found to be of importance (p. 90, below).

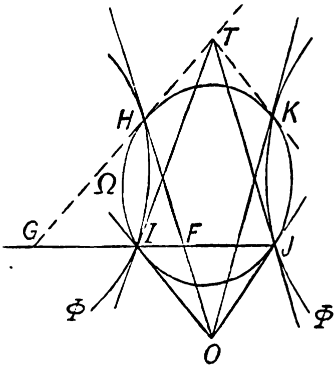
Ex. 19. *Two conics of which the tangents at their common points meet, in fours, at two points.* Suppose that the four points common to two conics are *I*, *J* and *H*, *K*; and that the tangent of one conic, at the point *H*, passes through the intersection of the tangents of the other conic at the points *I* and *J*. For distinctness, let the first conic be called Φ, and the second be called Ω, and let the tangents of Ω at *I* and *J* meet in *O*. It can then be shewn that the tangent of the first conic, Φ, at the point *K*, also passes through *O*, which is then a point through which four of the tangents of the conics pass; and that the tangents of the second conic, Ω, at the points *H*, *K*, as well as the tangents of the first conic, Φ, at *I* and *J*, all pass through another point.

Evidently, when the conic Ω is given, and the points *I*, *J*, *H*, *K* thereon, the conic Φ may be defined as that passing through the points I, J, H, K and having HO for its tangent at H. We obtain it somewhat differently.

Let Ω be any given conic, I, J, H, K any points thereon, the tangents at I, J meeting in O. Draw through O any line meeting Ω in P and P'; let PH, $P'K$ meet in Q, and PK, $P'H$ meet in R. We consider the locus of the point Q; which will be found to contain the point R. The pairs of points P, P' of the conic forming an involution thereon, the pencils of lines, $H\,(P)$, $K\,(P')$, with centres at H and K, are related. This shews that the locus of Q is a conic, say Φ, passing through H and K; and, as P, P' are interchangeable, this conic Φ contains R. When P' is at H, the line HP becomes the line HO, and the line KP' becomes KH; thus, HO is the tangent of the conic Φ at H. When P is at K, the line HP becomes the line HK, and the line KP' becomes the line KO, which is thus the tangent of the conic Φ at K. When P' is at I, so also is Q. The conic Φ thus passes through I; and, similarly, it passes through J.

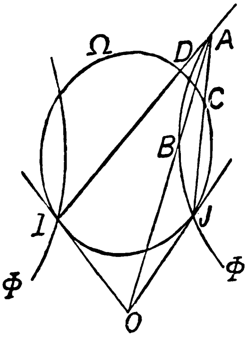


Now let T be the intersection of the tangents of the conic Φ at I and J. We shew that the tangents of Ω at H and K pass through T. Let HO meet IJ in F, and TH meet IJ in G. The point F is on the polar of T in regard to Φ, so that its polar contains T; the polar of F also passes through H, since the tangent of Φ at H passes through F. Thus the line THG is the polar of F in regard to Φ; and G is the harmonic conjugate of F in regard to I and J. If, however, the tangent of Ω at H meet IJ in G', the polar of G', in regard to Ω, passes through H, and passes through O, which is the pole of IJ in regard to Ω. Thus HO is the polar of G' in regard to Ω. Wherefore G and G' are the same, and TH is the tangent of Ω at H. So TK is the tangent of Ω at K.



It appears, thus, that the relation of the conics Φ, Ω is mutual, and either may be defined from the other. And the conic Φ may, equally, be defined by drawing variable lines through the point T to meet the conic Ω, say, in X and X', and, then, finding the locus of the intersection of the lines IX and JX'.

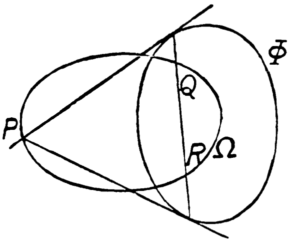
In the definition of the conic Φ, from Ω, the points Q, R of Φ are conjugate to one another in regard to all conics through the points P, P', H, K (Ex. 1, above), and the line QR, which is the polar of the intersection of the lines PP' and KH, contains the intersection, T, of the tangents of the conic Ω at H and K. The two conics, Ω, Φ, are, therefore, such that any line drawn through T meets one of the conics, say Φ, in two points which are harmonically conjugate in regard to the two points in which the line meets the other conic Ω. The same is therefore true of any line drawn through the point O.



If Ω be given, and, on any line drawn through the intersection, O, of the tangents of Ω, at any two points, I, J, of this, there be taken two points, A, B, conjugate to one another in regard to Ω, then any conic, Φ, through the four points I, J, A, B, is related to Ω as in the above. In fact, IB, JB pass through the further intersections, C, D, of Ω with AJ, AI, respectively, and CD passes through the intersection of the tangents of Φ at I and J. Or an independent proof may be given.

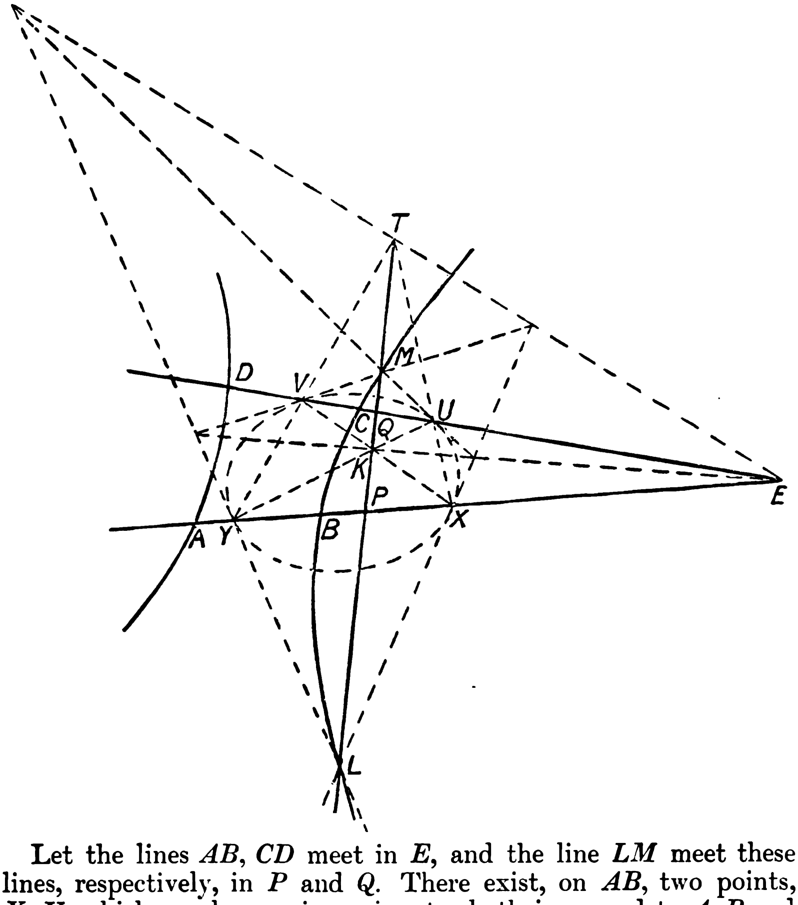
Ex. 20. *A conic derived from two given conics.* In connexion with the last example, the following remarks, though an anticipation of results given below (in Chap. III, p. 125), may be made.

Given any two conics Ω, Φ, we may consider all lines of the plane whose intersections with one of the conics are harmonic conjugates in regard to the intersections of the line with the other conic. Of such lines, two can be drawn through any point, P, of one of the conics, say Ω; those, namely, joining P to the points, Q, R, in which this conic, Ω, is met by the polar of P in regard to Φ. It may, therefore, be expected that the lines in question touch a conic; as will be found to be the case (pp. 125, 135, below). If this be assumed, it is at once clear that this third conic touches the eight lines which are the tangents of the given conics, Ω, Φ, at their four intersections. The two particular conics, Ω, Φ, considered in the preceding example, are so related that this third conic, regarded as an envelope, degenerates into a point pair, consisting of the points O and T. It can be shewn, further, that the points of contact of these particular conics Ω, Φ with their four common tangents, lie on two lines, four on each; and that the tangents, from any point of either of these lines, drawn to Φ, are harmonic conjugates in



regard to those drawn to Ω. In general, a point of a plane from which the tangents to two general conics form such a harmonic pencil, describes a conic passing through the eight points of contact of these given conics with their four common tangents. [Add.]

Ex. 21. *To construct a conic in regard to which two triads of points of a given conic shall both be self-polar.* Let A, B, L and C, D, M be any two triads of points lying on a conic.



Let the lines AB, CD meet in E, and the line LM meet these lines, respectively, in P and Q. There exist, on AB, two points, X, Y, which are harmonic conjugates both in regard to A, B and in regard to P, E. Any conic for which L, A, B is a self-polar triad must necessarily meet AB in points which are harmonic conjugates in regard to A and B; for any conic for which L, A, B and M, C, D are self-polar triads, the intersection, E, of AB and CD, must be the pole of LM; any such conic must, therefore, meet AB

in points which are harmonic conjugates in regard to P and E. The conic we seek to construct must then, if it exist, pass through X and Y. Two other points through which such a conic must pass are the points, U, V on CD, which are harmonic conjugates both in regard to C, D and in regard to Q, E. It follows from the fundamental properties of the harmonic relation that the lines XU, YV meet on the line LM, say, at T; and, also, that the lines XV, YU meet on LM, say, at K. Considering any four lines, we have seen (Ex. 10, above) that if, of the three point pairs through which all the four lines pass, two pairs consist each of points which are conjugate to one another in regard to a conic, so does the third pair. In the present case, for the four lines TUX, TVY, UKY, VKX, the three point pairs through which all the lines pass are X, Y; U, V and T, K; of these, the two former consist of conjugate points in regard to the given conic containing the two triads L, A, B; M, C, D; wherefore K and T are conjugate in regard to this conic. Thus T and K are harmonic conjugates in regard to L and M. The harmonic conjugate of T in regard to the points U and X is, however, the point in which UX is met by EK. Thus it follows that the lines MU, LX meet on EK; as do, for a similar reason, MV, LY. In the same way, the lines VM, LX meet on ET, as do UM and LY. Whence we see that a conic can be described through X, Y, U, V having MU, MV and LX, LY as tangents (Ex. 14, above).

For this conic, L, A, B and M, C, D are self-polar triads. It is therefore such a conic as we desired to construct. And there can be no other; for we have seen that such a conic must pass through X, Y, U, V; and, that L may be the pole of AB in regard to the conic, its tangents at X, Y must meet in L; its tangents at U, V must likewise meet in M.

Ex. 22. *To construct a conic for which a given triad of points shall be a self-polar triad, and a given point and line shall be pole and polar.* Let L, A, B be the triad, M the point and CD the line. Draw any conic through L, A, B, M; let it cut the line in points C, D. Construct, by the foregoing example, the conic having L, A, B and M, C, D as self-polar triads. This is such a conic as is desired. It is, in fact, the only one; for, though C, D may vary, they are pairs of the involution determined on the line CD by all conics through L, A, B, M; and the points U, V, of the conic described, are unique, being the double points of this involution.

Ex. 23. *To construct a conic for which a given triad of points shall be self-polar, to pass through two given points.* Let A, B, C be the triad, and I, J the two other points. There exists a point, D, such that the lines BC, AD, the lines CA, BD, and the lines AB, CD, meet the line IJ in three pairs of points of an involution of which

I, J are the double points. This is the particular case of Hesse's theorem (Ex. 10, above), which arises when the conic, there referred to, becomes a point pair; it is obvious at once, by finding D, so that BD and CA meet IJ in points harmonic in regard to I, J, and that CD and AB meet IJ in such points; then I, J are the double points of the involution determined on the line IJ by the joins of the points A, B, C, D, so that AD and BC meet IJ in points harmonic in regard to I and J.

There is then, by the preceding example, one conic having A, B, C for a self-polar triad, and having the point D and the line IJ as pole and polar of one another. For this conic the points A and D are the poles, respectively, of BC and IJ, and the line AD is the polar of the point where BC meets IJ. Thus the conic meets the line IJ in points which are harmonic conjugates in regard to the points where IJ is met by BC and AD. There is a similar statement for CA and BD, and for AB and CD. The conic, therefore, passes through I and J, and is the conic we desired to construct. The tangents at I and J are the lines DI and DJ. The reader will compare this work with that of Ex. 17.

Ex. 24. *The polar reciprocal of one conic in regard to another. A particular case.* It follows from what has been said above in regard to duality with respect to a conic, and the dual definition of a conic (p. 22), that if we have two conics, S and Ω, and take the polars, in regard to Ω, of all the points of S, these polars touch another conic, say S'. Any two points of S thus give two tangents of S', and the polars, in regard to Ω, of the points of their join, become the lines passing through the point of intersection of these two corresponding tangents of S'. In particular the pole, in regard to Ω, of any tangent of S, is a point of S'. Thus S can be obtained from S' by the same rule as was S' from S. Two such conics S, S' are called polar reciprocals in regard to Ω. Conversely, it will be seen below, in Chap. III, that, given two arbitrary conics S, S', there are, in general, four conics Ω, in regard to which S and S' are polar reciprocals.

Now consider two conics, S and S', which are such that there is a triad of points of S, say A, B and C, for which the joins BC, CA, AB are tangents of S'. If then we draw from any point, P, of S, the two tangents to S', and these meet S again in Q and R, the six lines BC, CA, AB, PQ, PR and QR all touch a conic (above, Ex. 7); and this is the conic S', because S' touches five of these lines. In other words, an infinite number of triads of points P, Q, R can be found on S, for which the joins QR, RP, PQ touch S'. Take now one of these triads, P, Q, R. By what is proved above, in Ex. 21, there is a conic, say Ω, for which both A, B, C and P, Q, R are self-polar triads. Consider the conic which is the polar reciprocal of S

in regard to Ω. This touches the six lines BC, CA, AB, QR, RP, PQ (which are the polars in regard to Ω, of the points of the triads); it is therefore the conic S'. It follows from this that, if P', Q', R' be another triad of points of S for which $Q'R'$, $R'P'$, $P'Q'$ touch S', then P', Q', R' must be a self-polar triad in regard to Ω.

To prove this, let the polar of P', in regard to Ω, meet S in Q_1 and R_1; then, if the polar of Q_1, in regard to Ω (which polar passes through P'), meet Q_1R_1 in R_2, a conic contains A, B, C, P', Q_1, R_2 (Ex. 12, above), which is therefore S; thus R_2 coincides with R_1, and P', Q_1, R_1 is a self-polar triad in regard to Ω. Therefore, as P', Q_1, R_1 are points of S, the lines $P'Q_1$, $P'R_1$, Q_1R_1 are tangents of the polar reciprocal, S'. Hence Q_1, R_1 are the same as Q', R'. We have therefore an infinite number of triads of points of S, of which the joins touch S', which are self-polar in regard to Ω.

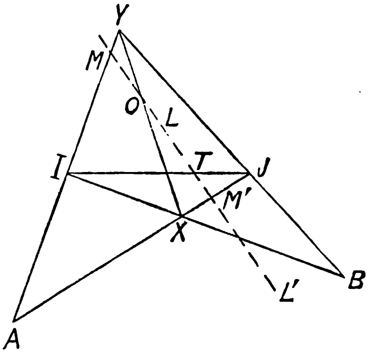
There are, in fact, as has been remarked, three other conics beside Ω for which S and S' are polar reciprocals. These have not the same property in regard to the triads P, Q, R. And, in general, when S and S' are polar reciprocals in regard to a conic Ω, it is not the case that triads of points of S are self-polar in regard to Ω. The matter arises again for consideration in Chap. III (Ex. 24).

A conic S which contains triads of points A, B, C for which the joins BC, CA, AB all touch another conic Σ, may be spoken of as triangularly circumscribed to Σ. Let S_1, S_2, ... be a set of conics all triangularly circumscribed to Σ. Let Ω_1 be the conic by which S_1 is the polar reciprocal of Σ, the triads spoken of being self-polar in regard to Ω_1; let Ω_2 similarly arise from S_2 and Σ, and so on. The set of conics Ω_1, Ω_2, ... are then all outpolar to Σ.

Similarly, if we have a set of conics Σ_1, Σ_2, ..., all triangularly inscribed to a conic S, we can find a set of conics Ω_1, Ω_2, ... all inpolar to S.

Ex. 25. *Gaskin's theorem for conics through two fixed points outpolar to a given conic.* Let Ω be a given conic, and I, J be two given points. We have defined (Ex. 3, above) the director conic of Ω in regard to I and J. We have considered two conics such that the tangents at their four common points intersect, in fours, in two points (Ex. 19, above). We have defined a conic as outpolar to Ω when there are triads of points of the conic which are self-polar in regard to Ω (Ex. 11). We now prove that all conics outpolar to Ω passing through the points I, J, are in the special relation with the director conic which was considered in Ex. 19. Such an outpolar conic is obtained by taking any triad which is self-polar in regard to Ω, and drawing the conic through I, J which contains the points of this triad. We have proved (Ex. 11) that any conic through the common points of two conics which are both outpolar to Ω is also outpolar to Ω; in particular any one of the line pairs through these common points consists of two lines conjugate to one another in regard to Ω. Thus, if any two conics outpolar to Ω be described through the points I, J, and X, Y be the remaining intersections of these, then the line XY passes through the pole of IJ in regard to Ω; this pole we denote by O. We denote, also, by A, the intersection of the lines IY and JX; as these lines are conjugate in regard to Ω, the point A is on the director conic of Ω in regard to I and J. Similarly, the point B, in which the lines IX, JY intersect, is on the director conic. This director conic passes through I and J, and, as we have remarked (Ex. 3), the tangents at I, J, of this conic, meet in the pole, O, of the line IJ taken in regard to the conic Ω.

Now draw any line through O, and consider the involution of pairs of points determined thereon by all conics through the four points I, J, X, Y. We prove that the double points of this involution are the points, say L and L', in which this line meets the director conic. One pair of this involution consists of the point O and the point, T, in which the line meets IJ. As O is the pole of IJ in regard to the director conic, the points O and T are harmonic conjugates in regard to L and L'. Let the line, drawn through O, meet the lines IY and JX, respectively, in M and M'. As these lines join the point A, of the director conic, to the points I, J of this, and O is the pole of IJ in regard to this conic, it follows (Ex. 5, above) that M, M' are conjugate points in regard to the director conic, and are, therefore, harmonic conjugates in regard to L and L'. The points M, M' are, however, another pair of points determined, on the line OLL', by a conic through the four points I, J, X, Y; this pair, together with O and T, determine the involution. It is, therefore, shewn that L and L' are the double points of this involution.



Hence, the conic drawn through I, J, X, Y to contain L has, for its tangent at L, the line OLL'; as this passes through the pole, O, of IJ in regard to the director conic, the conic $IJXYL$ is related to the director conic as were the conics in Ex. 19. The conic $IJXYL$ was obtained as passing through the intersections of any two conics through I, J which are outpolar to Ω, and through any point L of the director conic. It is, therefore, in effect, any conic through I, J outpolar to Ω. And thus we have proved the result. [Add.]

The result was given by Gaskin (*Geometrical construction of a conic section subject to five conditions*, Cambridge, 1852, p. 33, Prop. 15).

Ex. 26. *Two related ranges upon a conic obtained by composition of two involutions.* Referring for a moment to the symbolic representation, in order to explain the meaning of the result to which we now pass, we have remarked (Preliminary, above, Ex. 2), that two related ranges of points, $O+xU$, $O+yU$, are given by one of the two relations

$$\frac{y-\beta}{y-\alpha}=\sigma\frac{x-\beta}{x-\alpha},\qquad \frac{1}{y-\alpha}=\frac{1}{x-\alpha}+\frac{1}{\lambda}.$$

Considering the former, if we take μ arbitrary, and take z so that

$$\frac{x-\beta}{x-\alpha}\cdot\frac{z-\beta}{z-\alpha}=\mu,$$

then we have

$$\frac{y-\beta}{y-\alpha}\cdot\frac{z-\beta}{z-\alpha}=\sigma\mu.$$

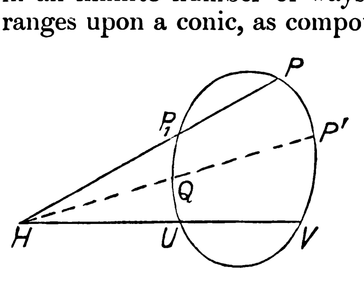
The first of these expresses that the points, $O+xU$, $O+zU$, are a pair of a certain involution; the second expresses that $O+zU$, $O+yU$ are a pair of another involution.

Similarly the latter equation is obtained by the composition of the two,

$$\frac{1}{x-\alpha}+\frac{1}{z-\alpha}=\frac{1}{\nu},\qquad \frac{1}{y-\alpha}+\frac{1}{z-\alpha}=\frac{1}{\nu}+\frac{1}{\lambda},$$

wherein ν is arbitrary; and each of these connects a pair of points belonging to an involution.

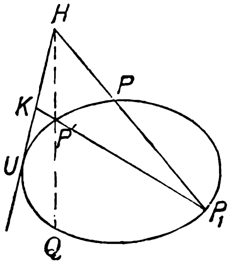
Now consider two related ranges upon a conic, the general point of one range being P, the point of the other range corresponding to this being P'. Suppose that the pairs, P, P', do not belong to an involution; and, in the first instance, that the common corresponding points of the two ranges are not coincident. It is to be shewn that we can, in an infinite number of ways, find a range of points P_1, upon the conic, such that the pairs, P, P_1, form an involution, and the pairs P_1, P' also form an involution. Thus we may, in an infinite number of ways, regard a correspondence of related ranges upon a conic, as compounded of two involutions.



Let U, V be the common corresponding points of the two related ranges, and, on the line UV, take an arbitrary point, H. Let the lines joining H to any two corresponding points, P and P', of the two ranges, meet the conic again, respectively, in P_1 and Q. Then, as P varies, since the lines P_1P, QP', UV meet in a point, the pairs P_1, P; Q, P'; U, V belong to an involution. Therefore, the range P, Q, U, V is related to the range P_1, P', V, U, and is, hence, related to the range P', P_1, U, V. Wherefore, in the two original related ranges, to the position Q of the point P, corresponds the position P_1 of the point P'.

The ranges (P_1), (P') are related; for, as P_1, P are pairs of an involution, the range (P_1) is related to (P); and this, by the original hypothesis, is related to (P'). And, when P_1 is at P', the point P, by the construction, is at Q. To this position of P, however, we have shewn, corresponds the position P_1 for P'. Namely, in the two related ranges (P_1), (P'), when P_1 is at P', the point P' is at P_1. Thus (Preliminary, above, p. 2), the two related ranges (P_1), (P'), together, form an involution. Therefore, the line P_1P' passes through a fixed point, say, K. This point is on UV; for when P is at V, then P_1 is at U and P' is at V.

We can, therefore, pass from the range (P) to the range (P'), by first passing to (P_1), where P, P_1 are pairs of an involution, the lines P_1P meeting UV in a fixed point, H, which is arbitrary on this line, and, then, passing from (P_1) to (P'), the pairs P_1P' forming another involution, the lines P_1P' meeting UV in another fixed point, K, whose position depends upon that taken for H. Clearly K may be taken arbitrarily on UV, if preferred, and H determined accordingly.



The theorem, and the proof, are, essentially, unchanged when the points U, V coincide. The line UV is then replaced by the tangent at U.

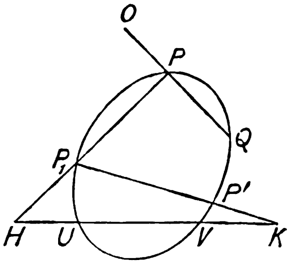
The proposition will be of use, later, in discussing the composition of two general screw motions. For this, and other purposes, it is desirable to state it in terms only of points which lie on the conic, without H and K. If L and L' be the points of contact with the conic of the two tangents which can be drawn from H, then, thinking first of U and V as distinct, the points L and L', as points of the conic, are harmonic conjugates in regard to U and V; for the lines joining L to H and L' are harmonic conjugates in regard to the lines LU, LV Similarly, L and L', are harmonic conjugates in regard to P_1 and P. Thus, in place of taking H arbitrarily on UV, we may take any two points L, L', of the conic, which are harmonically conjugate, on the conic, in regard to U and V. Then P_1 will be obtained from P by the fact that, as points of the conic, P_1 and P are harmonic conjugates in regard to L and L'. There will then be two other fixed points of the conic, say, M and M', also harmonic conjugates in regard to U and V, in regard to which P_1 and P' are harmonic conjugates. The points M, M' are the points of contact of the tangents from K. When U and V coincide, in U, we are, similarly, to take a quite arbitrary point, L, of the conic, and determine P_1 as the harmonic conjugate of P in regard to U and L; there will then be another fixed point, M, of the conic, such that P_1 and P' are harmonic conjugates in regard to U and M.

Ex. 27. *Three triads of points of a conic are all in perspective with another triad of points of the conic.* If A, B, C; A', B', C', and A'', B'', C'', be any three triads of points of a conic, we can find another triad of points of the conic, A_1, B_1, C_1, which is in perspective with each of the three given triads, from three properly chosen centres. For if we regard A, B, C and A', B', C' as determining two related ranges upon the conic, wherein the points A, B, C, of the first range, correspond, respectively, to the points A', B', C', of the second, these ranges will have two common corresponding points on the conic, whose joining line is the axis of relation of the two ranges, containing all such cross intersections as that of AB' and $A'B$, of BC' and $B'C$, etc. By taking the three triads in pairs, we have, thus, three such axes of relation, whose intersections are three in number. These intersections are the centres of perspective spoken of. This follows from Ex. 26; the range (A, B, C) is related to the range (A', B', C') by means of two involutions, one of these, with the pairs A, A_1; B, B_1; C, C_1, with the use of one of the centres of perspective, the other, with the pairs A_1, A'; B_1, B'; C_1, C', with the use of another of the centres of perspective. And so on.

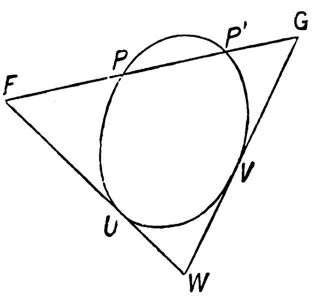
Though out of logical order, it may be as well to remark that this result is connected with one that, in the language of metrical geometry, which we consider later (Chap. v, below), is expressed by saying that three congruent figures in a plane may be regarded as images, by reflexion, of the same figure, in three suitably taken mirrors.

Ex. 28. *The envelope of the line joining two corresponding points of two related ranges on a conic.* We have seen that the joins of pairs of points of an involution on a conic, all pass through a point. Also, that the joins of corresponding points, of two related ranges of points, on two lines, are tangents of a conic. In generalisation of these we now prove that the joins of two corresponding points, of two related ranges of points on a conic, are tangents of another conic, which touches the original, at the two (generally distinct) points which are the common corresponding points of the two ranges.

Let the corresponding points be P, P'; let O be an arbitrary point of the plane. There are two of the lines PP' which pass through O. For, let the relation between the ranges (P), (P') be given, as in Ex. 26, by means of lines, PP_1, passing through a fixed point, H, and lines, P_1P', passing through a fixed point, K. Let OP meet the conic again in Q. The pairs (Q, P), (P, P_1), (P_1, P') are then pairs of three involutions; from this it can be shewn that the ranges (Q), (P') are related. These two related ranges will have two common corresponding points, in general distinct; but when Q coincides with P, there is a line PP' passing through O.

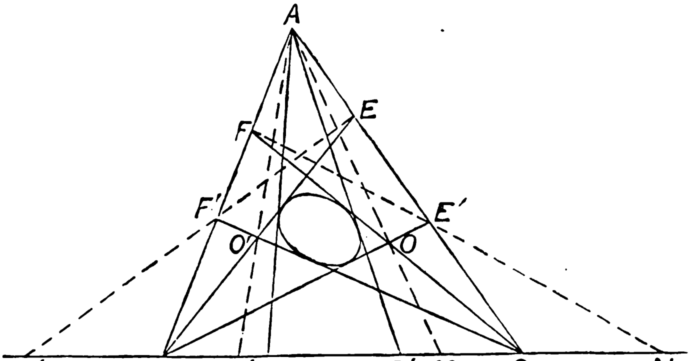


Assuming this result, let U, V be the common corresponding points of the ranges (P), (P'); and let F be any point of the tangent at U. There will then pass through F two lines PP', of which, however, FU is one. The other will meet the tangent at V in a definite point, G. Similarly, to an arbitrary position of G, on the tangent at V, there corresponds a single definite position of F, on the tangent at U. Hence, by an abbreviated argument, spoken of in the Preliminary remarks (above, p. 8), we infer that the ranges (F), (G) are related; and hence, that the lines PP' touch a conic; this conic touches the tangent at U at the point where F lies when G is at the intersection, W, of the tangents at U, V, that is at U. It similarly touches VW at V.



It is easy to state the corresponding result when U and V coincide.

Ex. 29. *The tangents from three points, A, B, C, to a conic, meet BC, CA, AB in six points of a conic.* Let the tangents from three points, A, B, C to an arbitrary conic Ω, meet BC, CA, AB, respec-



tively in D, D', in E, E', and in F, F'. These six points then lie on another conic.

Let BE', CF meet in O, and AO meet BC in M; let BE, CF' meet in O', and AO' meet BC in M'. Let $E'F$ meet BC in N, and EF' meet BC in N'.

We have shewn that the tangents from an arbitrary point to the conics touching four lines are a pencil in involution; and of such conics there are three point pairs, through each of which the four lines pass. For the four lines constituted by the tangents to the conic Ω from B and C, two of these point pairs are B, C and O, O'. Hence we see that the pairs D, D'; M, M'; B, C, lying on tangents from A, are in involution.

The point N is, however, the harmonic conjugate of M in regard to B and C, and the point N' is the harmonic conjugate of M', in respect of the same. Thus (see Preliminary, above, Ex. 3), the points N, N' also belong to the involution spoken of.

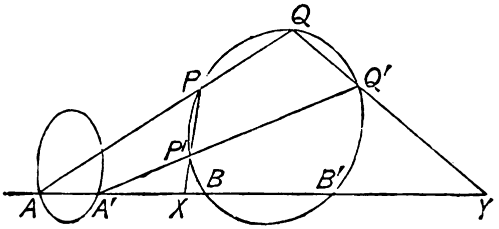
Now the conics drawn through the four points E, E', F, F' meet the line BC in pairs of points belonging to an involution; of this involution, however, B, C and N, N' are two pairs; so that this is the same involution as the former.

Wherefore, the conic through E, E', F, F' which is drawn through D, equally contains D'. And this is what we desired to prove.

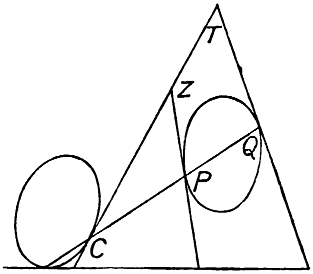
If this conic be called Σ, the reader may proceed to prove that there is a conic, through the intersections of Ω and Σ, which touches BC, CA, AB.

A particular case of the result proved, arises when the conic Ω is a point pair. Of this again a particular case is that, if AD, BE, CF meet in a point, then a conic exists touching BC, CA, AB, respectively, at D, E, F. And the theorems lead, by duality, to other theorems worth notice. (See also Chap. III, Ex. 14.)

Ex. 30. *Two tangents of one conic meet two tangents of another in four points lying on a conic through the common points of the two conics, if the four points of contact are in line.* Let a line joining two points, A and A', of one conic, Φ, meet another conic, Ω, in B and B'. Let any line through A meet Ω in P, Q, and any line through A' meet Ω in P', Q'. Let PP', QQ' meet the line AA', respectively, in X and Y.



The pairs of points A, A'; B, B'; X, Y then belong to the involution determined on the line AA' by all conics through the four points P, Q, P', Q'. And as this involution is determined by the first two pairs, it is the same as the involution determined on the line AA' by all conics through the common points of the conics Φ, Ω. To this latter involution, therefore, the pair X, Y belong.



By supposing A' to coincide with A, and P' with P, and Q' with Q, we reach the result that, if any line, drawn through a point, A, of the conic Φ, meet the conic Ω in P and Q, and the tangents at P, Q meet the tangent at A in X and Y, then these last are a pair of the involution determined, on the tangent at A, by the conics which pass through the four common points of Φ and Ω.

Now let the line APQ meet the conic Φ again in C, and let the tangents at P and Q meet the tangent at C in Z and T. Then, by parity of reasoning, taking P on Ω instead of A on Φ, and A, C on Φ instead of P, Q on Ω, we infer that the conic drawn through the intersections of Φ and Ω to contain X also contains Z; from what was said, this conic contains Y. By a similar argument, the same conic contains T.

This is the result enunciated, the points A, C, P, Q being in line.

Dually, if from an arbitrary point the two pairs of tangents be drawn to two conics, the four joins, of the points of contact on one conic, to the points of contact on the other conic, are all tangents of a conic which touches the four common tangents of the two conics.

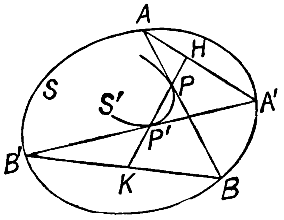
From the combination of these theorems many interesting results can be deduced. It will be proved in Chap. III, that, if the tangents of the conics Φ, Ω, respectively at A and P, meet in X, and the conic, through the common points of Φ, Ω, which contains X, be S, while that, touching the common tangents of Φ and Ω, which touches AP, be Σ, then, to another position of X on S, there corresponds, by the same construction, another tangent, such as AP, of Σ.

Ex. 31. *Poncelet's theorem, for sets of points A, B, C, ... of one conic, of which the joins AB, BC, ... separately touch other fixed conics, all the conics having four points in common.*

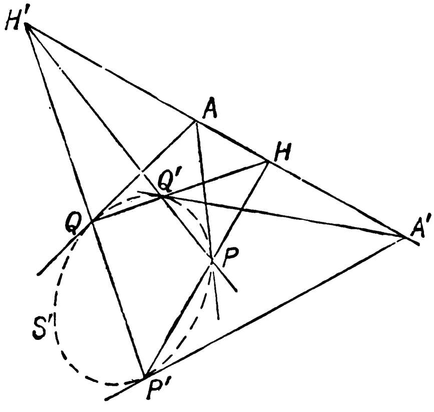
The reference is to Poncelet's *Propriétés Projectives*, Paris, 1865, t. I, p. 316.

Let A, A', B, B' be four points of a conic, S, such that the lines AB, $A'B'$ touch another conic, S', respectively, in P and P'. Let PP' meet AA', BB', respectively, in H and K. We shew, first, that a conic can be drawn, through the common points of S and S', to touch AA' in H, and BB' in K.

For consider the four points consisting of P repeated and P' repeated; and the involution determined on AA' by the conics through these four points. Three pairs of this are (1), the points A, A', on the conic S, (2), the points in which the conic S' meets AA', (3), the point H repeated. The pairs (1), (2) shew that this is the same involution as that determined on AA' by the conics through the common points of S and S'. Of this involution, then, H is a double point, and is, thus, a point of contact with AA' of a conic, say, T, through the common points of S and S'. We prove, now, that this conic, T, touches BB' at K. This we do by shewing, from the preceding example, that, if T meet HK again in K_1, the tangent of it, at K_1, passes through B and B'. By that example, the conics S', T being met by a line in P, P' and H, K_1, the tangents at P, P' must meet the tangents at H, K_1, in four points lying on a conic passing through the common points of S' and T, which are the common points of S and S'. These four points are A, A', and the points where the tangent at K_1 meets AB and $A'B'$; the two former points identify the conic through them as S. This proves that the tangent at K_1 passes through B, B'; so that K_1 is K.



It follows, of course, in the same way, that if PP' meet AB' and $A'B$ in L and M, a conic through the common points of S and S' touches these lines in L and M.



If the other tangent from A to S' touch this in Q, and the other tangent from A' to S' touch this in Q', it follows, similarly, that PQ' meets AA' in a point, H', which is also a point of contact with AA' of a conic through the common points of S and S'. Thus, H' is the other double point of the involution spoken of, and is the harmonic conjugate of H in regard to A and A'. But, then, by the same argument, $Q'Q$ meets AA' in the harmonic conjugate of H', that is, in H; and, so, $P'Q$ passes through H'.

Now take a further conic, S'', passing through the common points of S and S', or, say, for brevity, a conic of the system (S, S'). Let either one of the tangents drawn from B to S'' meet S again in C, touching S'' in R. It follows, then, from what has just been said, that it is possible to pair with this such an one of the two tangents from B' to S'', touching S'' in R', that the line RR' shall pass through K; this point, K, is one of the two points of possible contact, with BB', of conics of the system (S, S'). If the appropriate tangent meet S again in C', the line RR' will meet CC' in a point, J, in which the conic (S, S'), which touches BB' at K, touches CC'.

There are now two pairs of points of S, the pairs A, A' and C, C', such that the lines AA' and CC' both touch the same conic of the system (S, S'), respectively at H and J. Call this conic Σ. By applying to the lines AA', CC', and the conics S and Σ, the argument we originally applied to the lines AB, $A'B'$, and the conics S and S', we can then infer that the lines AC, $A'C'$ are both touched by a further conic, S''', of the system (S, S'), the points of contact being on the line JH.

It is thus possible to have an infinite number of triads A, B, C; A', B', C'; ... of points of S, for which the joins $BC, B'C', \ldots$; $CA, C'A', \ldots$; $AB, A'B', \ldots$; touch, respectively, three fixed conics S', S'', S''', of the system (S, S'). The argument can clearly be extended to the case when the points of a set are not triads, but of any greater number.

A particular case of the foregoing arises when, with four points, A, A', B, B', of the conic S, of which AB, $A'B'$ meet in a point O, we have, instead of the proper conic S', a pair of lines which intersect in O. There are then no distinct points of contact, P, P', with which to determine the points H, K of AA' and BB'. But, a point H can be determined on AA', as one of the two which are harmonic, both in regard to A, A', and in regard to the two points in which AA' is met by the lines of the line pair, S'. The line HO then meets BB' in a point, K, which is one of the two, which are harmonic conjugates, both in regard to BB', and in regard to the two points in which BB' is met by the lines of the line pair, S'. A conic of the system (S, S') can then be drawn to touch AA' at H, and to touch BB' at K.

If, in the preceding theory, we start with two proper conics, S and S', a line pair, of the system (S, S'), can intersect only in a point, O, which is one of the three points of the common self-polar triad of the system. Such a line pair can then replace S'' or S'''.

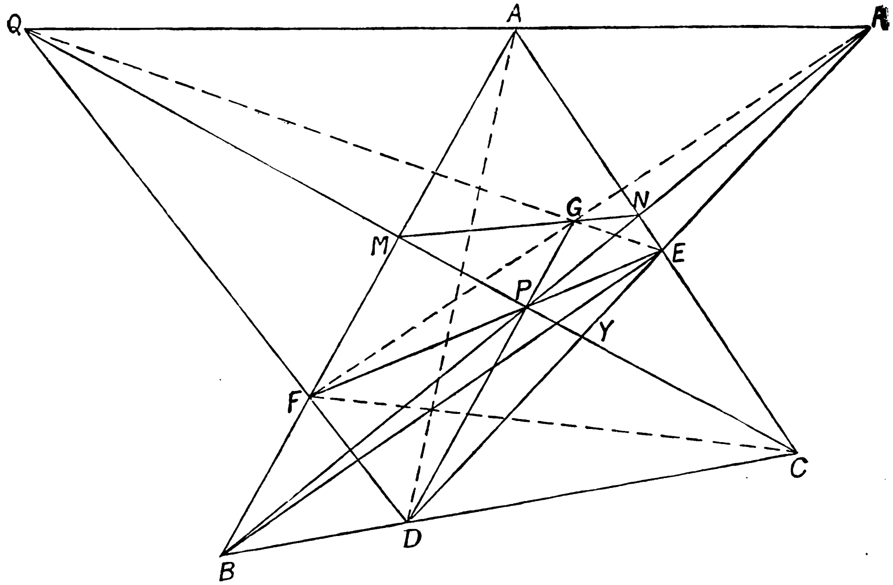
In particular, we may have triads, A, B, C, of points of S, such that AB, BC touch two proper conics, S', S'' of the system (S, S'), respectively in P and Q, say, while CA passes through one of the three points, O, of the self-polar triad of (S, S'). It will appear (in Chap. III) that, in this case, the line PQ is a tangent of a fixed conic, which touches the common tangent lines of S' and S''; and that the line pair of (S, S') which meet in O are harmonic conjugates in regard to the lines OP, OQ.

A very particular case is the intersecting simple result that triads A, B, C exist on a conic, of which the joins BC, CA, AB pass, respectively, each through one of the points of any given triad which is self-polar in regard to the conic. (Cf. Ex. 5, p. 28.)

Ex. 32. *Construction of a fourth tangent, with its point of contact, of a conic touching three lines at given points.*

The present example, which, in effect, collects various results already given, is introduced in view of the following example.

Respectively on the joins BC, CA, AB, of three points A, B, C, let D, E, F be points such that the lines AD, BE, CF meet in a point. Let the lines DE, DF, respectively, meet any line, drawn through A, in R and Q. Let CQ, BR meet AB, AC, respectively, in M and N, the lines CQ, BR intersecting in P. We prove that the lines QR, MN, BC meet in a point; and that the lines MN, DP, EQ, FR, meet in a point; while P is on EF. Also that MN is a tangent of the conic which can be drawn to touch BC, CA, AB, respectively, at D, E, F, whose point of contact is on DP, as well as on EQ and FR.



In fact FE meets BC in the point harmonic to D with respect to B and C; thus F, E are harmonic with respect to the points in which FE is met by DA and BC. Therefore, Q, R are harmonic with respect to A, and the point where QR is met by BC. This shews that QB, RC meet on AP, so that the triads QMB, RNC are in perspective, the lines QR, MN, BC meeting in a point. That P lies on FE is a direct application of Pappus' theorem for the two triads Q, A, R and B, D, C. That QE, FR meet on MN is, then, also a consequence of Pappus' theorem, applied to the two triads Q, A, R and F, P, E. To shew that DP passes through the point, say, G, where MN is met by EQ or FR, it is necessary to prove that E, F are harmonic in regard to P, and the point where QR meets EF; or, that AP, AR are harmonic in regard to AE, AF, which follows because QB, RC meet on AP. Finally, that the conic which (Ex. 29) can be drawn to touch BC, CA, AB at D, E, F, respectively, touches MN, on DP, follows from Ex. 14, above; or can be deduced, independently, by considering, with fixed points D, E, F, various lines QAR, giving rise to related ranges (M), (N), on AB, AC. In regard to this conic, P, Q, R will be a self-polar triad.

It is clear that B and N are harmonic conjugates in regard to P and R; and, further, if QP meet DE in Y, that D and E are harmonic conjugates in regard to Y and R.

Ex. 33. *Hamilton's extension of Feuerbach's theorem.* (See, also, p. 117.)

With the results of the previous example in mind, consider two conics. One of these, Ω, is to be any conic having P, Q, R for a self-polar triad. The other, Σ, is to be the conic through D, E, F which meets the line MN in the points in which it is met by Ω. We prove that these conics meet further on the line, which we call l, which contains the three intersections (BC, EF), (CA, FD), (AB, DE). This is the line which, for the conic touching BC, CA, AB at D, E, F, we have called the Hessian line of D, E, F (Ex. 9). In fact, the conic Ω meets the line DR in points harmonic in regard to Y and R; the conic Σ also meets this line in points, D and E, harmonic in regard to Y and R. Wherefore the common chord MN, of Ω and Σ, and the line joining the other two common points of these conics, meet DR in points harmonic in regard to Y and R. The point harmonic to the intersection of MN with DR, with respect to Y and R, is, however, we have seen, the point where MB meets DR. This is a point of the line, l, spoken of. Another point of the common chord of Ω and Σ, other than MN, is proved, similarly, to be on l, by considering the line DQ, in place of DR.

This is a slight extension of a result ascribed to Sir W. R. Hamilton (Salmon's *Conics*, 1879, p. 313). For what follows we take for Ω any conic touching BC, CA, AB and touching MN, say, at K; this will have P, Q, R for a self-polar triad; then Σ will be the conic through D, E, F which touches MN at K. The result is that the join, of the two remaining intersections of these two conics, is the line l.

Conversely, let A, B, C be any points, and l any line. Let D, on BC, be the harmonic, in regard to B and C, of the point where l meets BC; and make a similar construction for E and F. Let Ω be any conic touching BC, CA, AB. Let its intersections with l be I and J. Then the conic Σ, defined as that containing D, E, F, I, J, touches Ω. This is the theorem desired.

The point of contact of Σ with Ω may be defined as the point of contact with Ω of the fourth common tangent of Ω with the conic which touches BC, CA, AB at D, E, F, respectively. But it may be defined without this conic. For, if Ω touch BC, CA, AB respectively at D', E', F', the point P (one of the three points of the common self-polar triad of Ω and the conic which touches BC, CA, AB at D, E, F) is the intersection of $E'F'$ and EF, by what we have seen. Hence the points M, N can be constructed, as in the preceding example, by the lines CP, BP (as also the points Q and R). The point, K, required, is then the intersection of $D'P$ with MN (which also lies on $E'Q$ and $F'R$). Incidentally, given the points of contact of two conics with BC, CA, AB, we thus construct their remaining common tangent, and its points of contact with the two conics.

When the points A, B, C, I, J are given, we can (Ex. 10, above) find a point, T, such that each of the line pairs, AT, BC; BT, CA; CT, AB, meet the line IJ in points which are harmonic in regard to I and J. The conic Σ will then be (Ex. 18) the locus of the poles of the line IJ in regard to all conics through A, B, C, T. Let then A, B, C, T be four arbitrary points, and let I, J be any two points conjugate to one another in regard to all conics through A, B, C, T. Four conics, such as Ω, can (Ex. 17) be constructed, to pass through I, J, and touch the joins of three of the four points A, B, C, T. All the sixteen conics so obtained are touched by the conic which is the locus of the poles of IJ in regard to the conics through A, B, C, T.

Feuerbach's theorem in its original form will be referred to in the next Chapters. (See pp. 75, 89, 113, 122.)

Ex. 34. *Theorem in regard to the remaining common tangents of three conics which touch three given lines.*

If three conics, S_1, S_2, S_3, all touch the lines BC, CA, AB, the points of contact being, in the case of S_1, respectively D_1, E_1, F_1, with a similar notation for the others, and, if the remaining common tangent of S_2 and S_3 meet BC in T_1, with a similar notation for the other pairs, then the pairs T_1, D_1; T_2, D_2; T_3, D_3 are in involution.

For, by what has been said, in the two preceding examples, the remaining common tangent of S_2 and S_3 meets AB, AC, respectively, in M_1 and N_1, where N_1 and M_1 are, respectively, on the lines joining B and C to the point, P_1, in which F_2E_2 intersects F_3E_3.

Thus the point T_1, where M_1N_1 meets BC, is the harmonic conjugate, in regard to B and C, of the point in which AP_1 meets BC. The point D_1 is also the harmonic conjugate in regard to B and C, of the point where F_1E_1 meets BC. This line F_1E_1 is the same as the line P_2P_3. It is a fundamental property of the joins of four points, that the joins of A, P_1, P_2, P_3 meet BC in pairs of points in involution. As these points are the harmonic conjugates, in regard to B and C, of the pairs T_1, D_1; T_2, D_2; T_3, D_3, it follows that these are also in involution. (Preliminary, above, p. 7, Ex. 4.)

The dual theorem is that, if three conics be drawn through three points A, B, C, and we draw the three lines from A to the remaining intersections of the pairs of these conics, and pair these, properly, with the tangents at A of the three conics, there is obtained a pencil in involution.

A more general proposition is that, if any four conics be drawn through the three points A, B, C, say S_1, S_2, S_3, S_4, then the three pairs of lines through A constituted by (1) the common chords through A of S_2, S_3 and of S_1, S_4; (2) the common chords through A of S_3, S_1 and of S_2, S_4; (3) the common chords through A of S_1, S_2 and of S_3, S_4, are in involution. This may be proved as above, or also, by the transformation of Ex. 16 preceding. It depends on the fact that the pairs of lines from an arbitrary point, to the opposite pairs of intersections of four lines in a plane, belong to an involution. (Preliminary, p. 4, above.) When the fourth conic breaks up into two lines, of which one passes through A, we obtain the theorem referred to in regard to three conics through A, B, C.

Ex. 35. *The four conics, through two points, of which each contains three of four other given points.*

If the two given points be O, Q, and the four given points be denoted by 1, 2, 3, 4, and the conic which contains O, Q, 2, 3, 4 be called S_1, its tangent at O being called t_1, with a similar notation for three other conics, then the four pairs of lines $(O1, t_1)$, $(O2, t_2)$, $(O3, t_3)$, $(O4, t_4)$ are in involution. For the conics S_1, S_2, S_3 have in common the three points O, Q, 4, while S_2, S_3 have also the point 1 in common, S_3 and S_1 the point 2, and S_1, S_2 the point 3. The pairs of lines $(O1, t_1)$, $(O2, t_2)$, $(O3, t_3)$ are, thence, in involution, by the preceding example. Again the conics S_2, S_3, S_4 have in common the points O, Q, 1; the residual intersections of the pairs of these are, for S_3, S_4, the point 2; for S_4, S_2, the point 3; and, for S_2, S_3, the point 4. Wherefore $(O2, t_2)$, $(O3, t_3)$, $(O4, t_4)$ are in involution; this is, therefore, the same involution as before.

Ex. 36. *The polars of any point in regard to the six conics which can be drawn through the sets of five, from six arbitrary points of a plane, touch a conic.*

This result was suggested by Mr H. M. Taylor, Trinity College, Cambridge. (See W. W. Taylor, *Messenger of Mathematics*, XXXVI, 1907, p. 113; and particularly, E. J. Nanson, *Mess. of Math.* XLVI, 1917, p. 183.)

Let the six given points be denoted by 1, 2, ..., 5, 6, the other point being O, the conic containing the five points 2, 3, 4, 5, 6 be S_1, etc., the polar of O in regard to S_1 being p_1, etc. Any two of the conics have four points in common, and a further, auxiliary, conic can be drawn through O and these four points. As the polars of O, in regard to conics through four points, meet in a point (Ex. 15, above), the polars of O in regard to the two conics meet on the tangent, at O, of the auxiliary conic spoken of.

Consider then the intersections of p_5 with p_1, p_2, p_3, p_4. These lie, by what has been said, on the tangents, at O, respectively of the four conics containing the points

$$O, 2, 3, 4, 6; \quad O, 1, 3, 4, 6; \quad O, 1, 2, 4, 6; \quad O, 1, 2, 3, 6.$$

These however are conics, through the points O and 6, containing, respectively, the various sets of three points which can be chosen from the four 1, 2, 3, 4. By the result of the preceding example, it follows that the range of four points in which p_5 is met by p_1, p_2, p_3, p_4 (these points lying on the tangents at O of the four conics just named) is related to the pencil of lines joining O to the points 1, 2, 3, 4. The range in which p_6 is met by p_1, p_2, p_3, p_4 is, similarly, related to this pencil. Whence the six polar lines touch a conic.

The above interesting proof of Taylor's theorem is derived from that given by Mr S. G. Soal, of the East London College, in J. L. S. Hatton's *Principles of Projective Geometry*, Cambridge, 1913, p. 299.

From this demonstration we can state the theorem: *Given six arbitrary points of a plane, there exists, corresponding to any further arbitrary point, O, of the plane, a conic, and, upon this conic, six points subtending, at any point of the conic, a pencil which is related to that of the lines which join O to the six given arbitrary points.* For the points of contact of p_1, p_2, p_3 p_4 with the conic are, as a range on the conic, related to the range determined by these tangents on the tangent p_5.

If seven points be taken, and each in turn omitted, the seven conics obtained have three common tangents.

Ex. 37. Let A, B, C, A', B', C', D be seven given points, and p a given line through D. Any conic through A, B, C, D meets p in a further point, M, and there is a second conic through A', B', C', D, M. The chord of these two conics, other than p, passes through a fixed point.

CHAPTER II

PROPERTIES RELATIVE TO TWO POINTS OF REFERENCE

Introductory. The multiplicity of metrical results often found in books on Geometry are in fact relations of the figure which is considered, either to two points of reference, regarded as given, or, more generally, to a conic of reference, regarded as given. This is one of the striking discoveries, essentially due to Poncelet, of the early part of the nineteenth century. The fact is generally proved by beginning, on the basis of Euclid's geometry, with the metrical relations, and gradually shewing how these can be summarised under more general points of view. We adopt the converse procedure. Without assuming the metrical basis, and as consequences of the foundations which have been explained, we obtain a number of results which are easily recognised as containing those usually developed as consequences of the notion of distance. Finally, from this and Chapter v, it should emerge quite clearly that distance is only a special way of using the algebraic symbols; and that it is an arbitrary limitation to regard it as fundamental.

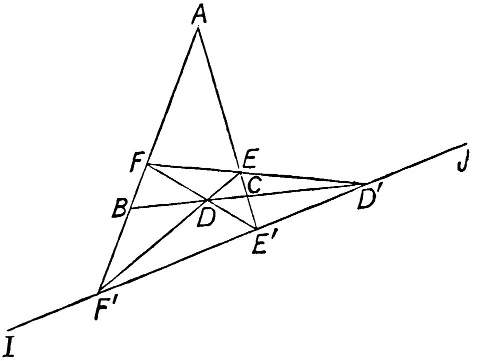
For the sake of clearness we shall employ the terms, such as *perpendicular*, *circle*, *rectangular hyperbola*, and so on, which are current in metrical geometry. They have here, however, a more general meaning, depending on the choice of the absolute points of reference.

Middle points, Perpendicular lines, Centroid, Orthocentre. Suppose that two points of reference are given; they may be called the Absolute points, and will often be denoted by I and J.

If any line, AB, meet the line IJ in K, the point, say C, which is the harmonic conjugate of K in regard to A and B, may be called the *middle point* of AB, in regard to I and J. Any two lines whose intersection is on the line IJ may be said to be *parallel* to one another, in regard to I and J. Any two lines which meet the line IJ in two points which are harmonic conjugates of one another, in regard to I and J, may be said to be *at right angles*, or, to be *perpendicular*, in regard to I and J. With these definitions, all the theorems of incidence involving these terms remain true. Thus, for instance, two lines, which are both parallel to a third line, are parallel to one another; all lines which are at right angles to a line are parallel to one another; if a series of parallel lines be drawn, meeting any two lines, say a and b, the former in A and the latter in B, the middle point of AB lies on a definite line through the intersection of a and b.

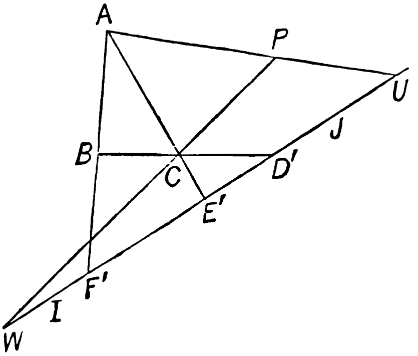
Or, passing to somewhat less obvious results, the ordinary constructions for the centroid, and for the orthocentre, of three given points A, B, C, can be carried out, these words being defined as we now explain.

For the *centroid*, this is defined as the intersection of the lines joining A, B, C, respectively, to the middle points of BC, CA, AB. If the line IJ be met by BC, CA, AB, respectively, in D', E', F', and D be the harmonic conjugate of D' in regard to B, C, while E is similarly defined from E' by means of C and A, and F from F' by A and B, we have only to shew that AD, BE, CF meet in a point. In fact, it is clear, from the construction, that E, F, D' are in line; as, likewise, are F, D, E' and D, E, F'; and, hence, that the line, joining A to the intersection of BE and CF, passes through D.



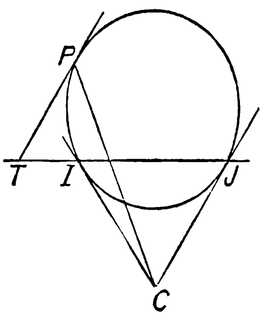
For the *orthocentre*, we are to shew that the lines, drawn through A, B, C, respectively perpendicular to BC, CA, AB, meet in a point. As before, let D', E', F' be the points in which IJ is met by BC, CA, AB, respectively; and let U, V, W be the harmonic conjugates, in regard to I and J, respectively of D', E', F'. We are to shew that AU, BV, CW meet in a point.

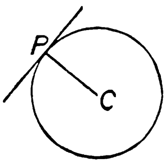
If AU, CW meet in P, the involution determined on the line IJ by the joins of A, B, C, P (Preliminary, above, p. 4), is determined by the two pairs D', U and F', W. In regard to these pairs, I, J are harmonic conjugates; these are then the double points of the involution, and thus AC, BP meet the line IJ in points harmonic in regard thereto. Thus BV passes through P. Each of A, B, C, P is then the orthocentre of the other three in regard to I and J.



Considering I, J as a degenerate conic, regarded as an envelope (above, p. 24), the theorem of the orthocentre is evidently a particular case of the theorem (above, p. 31) that, if, of the line pairs containing four points, two pairs consist of lines which are conjugate in regard to a conic, so does the third pair. [Add.]

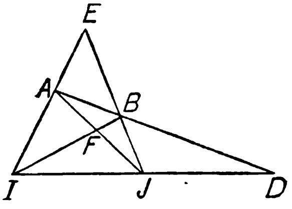
Circles. Any conic which passes through the two absolute points of reference, I, J, will be spoken of as a circle in regard to I and J, or, simply, as a circle. By the *centre* of the circle will be meant the pole, in regard thereto, of the line IJ. As a conic is determined by five points, a circle is determined by three points, beside I and J.

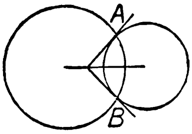




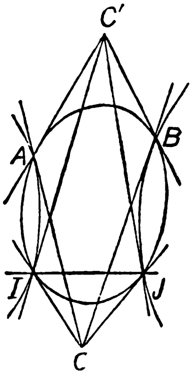
If the tangent, at a point P, of a circle, whose centre is C, meet the line IJ in T, this point, T, lying on the polar of C, and on the tangent at P, is the pole of the line PC. Thus PT, PC meet IJ in points which are harmonic in regard to I and J. In other words, the tangent at any point of a circle is at right angles to the line joining this point to the centre of the circle.

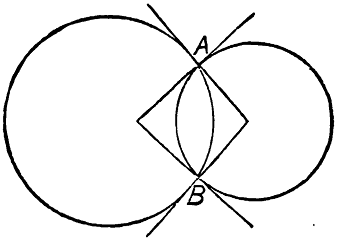
Two circles will have two points of intersection, beside I and J. The tangents of one of the circles, at these two points, meet on the line joining the centres of the circles. For, if these two points be denoted by A and B, and D, E, F be the intersections, respectively, of IJ, AB, of IA, JB, and of IB, JA, the polar, in regard to either circle, of the point D, is the line EF (above, p. 23), and this line contains the intersection, both of the tangents at A, B, and of the tangents at I, J. This line, EF, is thus the line joining the centres of the two circles.





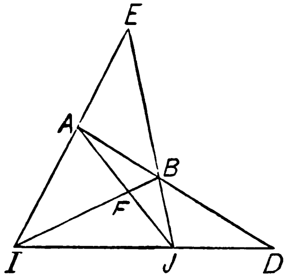
Suppose that, at one of the common points, A, of two circles, the tangents of the circles are at right angles to one another, in regard to I and J. As the tangent of a circle at any point is at right angles to the line joining this point to the centre, it follows that the tangent, at A, of either circle, passes through the centre of the other. Thence, as the tangents of either circle, at the points A, B, meet on the line joining the centres of the circles, it follows that the tangent at B, of either circle, passes through the centre of the other circle. Wherefore the tangents at *B*, of the two circles, are at right angles. Two such circles are said to *cut at right angles*, or *orthogonally*; they are such a pair of associated conics as were considered before (Chap. I, Ex. 19, above, p. 42). It follows from what was then said that, any line, drawn through the centre of either of two circles which cut at right angles, meets the two circles, respectively, in two pairs of points which are harmonic in regard to one another; and, conversely, that if, on any line drawn through the centre of a circle, there be taken two points which are harmonic conjugates of one another in regard to the points in which the line cuts the circle, then any circle drawn through these two points cuts the given circle at right angles. It follows, also, that two points, which are such that every circle, passing through them, cuts a given circle at right angles, must be conjugate points in regard to this circle, and lie on a line through its centre.

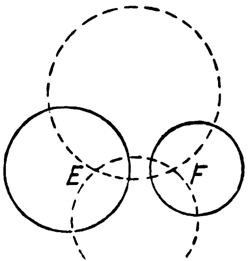




Coaxial circles. The common chord, *AB*, of two circles, other than *IJ*, may be called the *radical axis* of the two circles. Circles passing through *A* and *B*, that is, conics through *A*, *B*, *I*, *J*, may be said to be *coaxial.*

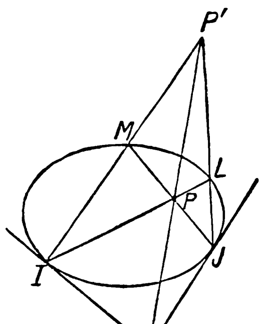
Of such conics, beside the lines *IJ*, *BA*, there are two which are line pairs, the pair *IA*, *JB*, meeting, say, in *E*, and the pair *IB*, *JA*, meeting, say, in *F*. The points *E*, *F* may be called the *limiting points* of the coaxial circles through *A* and *B*. The line *EF* contains the centres of all the coaxial circles; and *E*, *F* are conjugate points in regard to any one of these circles. The triad of points self-conjugate in regard to all the coaxial circles consists of the limiting points *E*, *F*, together with the point, *D*, where the radical axis intersects the line *IJ*. Thus, by what we have said above, all circles through the limiting points, *E*, *F*, cut every circle of the coaxial system at right angles; these circles form a second coaxial system, of which *A* and *B* are the limiting points, their centres being on the radical axis, AB, of the first system. Conversely, a circle whose centre is at any point on the radical axis, AB, of the first system of circles, can be drawn, to cut all the circles of this system at right angles; it passes through the limiting points.





Inversion in regard to a circle. There is a process, which has been much employed, by which, when we are given a circle in a plane, we can pass from any point of the plane to another point. It will subsequently be found, in dealing with the relations of geometry in two and in three dimensions, that the process can be regarded from a very simple point of view. It can also be shewn that, in its effect, the process does not differ from the transformation explained in Chap. I, Ex. 16 (above, p. 38). We give, however, some provisional results obtained from the present point of view.

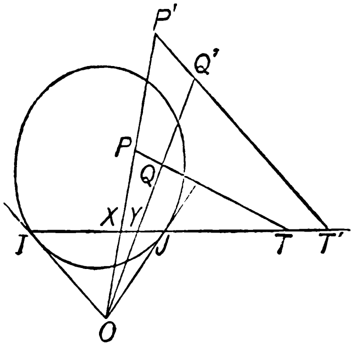
Two points, P and P', are said to be inverses of one another in regard to a given circle when, (*a*) they are conjugate in regard to the circle, and, (*b*) their join passes through the centre of the circle. When this is so, it follows, by what has already been remarked in the preceding chapter (Ex. 5, above, p. 28), that the lines IP, JP' meet in a point, say, L, lying on the circle, and the lines IP', JP also meet in a point of the circle, say, M. The relation of the points P, P' is evidently reciprocal. The definition can be held to include the inverse of a point in regard to a line, which, taken with the line IJ, may be regarded as a degenerate circle; the inverse of P in regard to the line, say, P', will be such that PP' is at right angles to the line, and the mid-point of PP' is on the line.



When P describes any locus, P' will describe a corresponding locus. The most important case is that, when P describes any circle, then P' also describes a circle. Of this a particular case arises when P describes a circle which passes through the centre, O, of the given circle by which we define the inversion; then the circle described by P' degenerates into a line, taken with the line IJ. Conversely, we may say that the inverse of a line is a circle passing through the centre of the fixed circle of inversion. These statements are easy to prove: When P describes any conic passing through I and J, the pencils $I(P)$, $J(P)$ are related; these, however, give, respectively, the ranges (L), (M), of the given fundamental conic, which are, therefore, also related. Thus P', the intersection of JL and IM, describes another conic passing through I and J, that is, a circle. While, if P, on its locus, can take the position O, the points L, M, take, then, respectively, the positions I and J; then the ray IJ, of the pencil $I(P')$, corresponds to the ray JI, of the pencil $J(P')$, and the locus of P' degenerates (above, p. 10) into the line IJ and another line. Conversely, if P' describes a line, the pencils, $I(P')$, $J(P')$, are related; so then, also, are the pencils $I(P)$, $J(P)$; thus P describes a conic passing through I and J. But, in particular, to the point P' which is on IJ, correspond positions, of L and M, respectively at I and J; the corresponding position of P is then at O. The locus of P is, thus, a circle passing through the centre, O, of the circle of inversion.

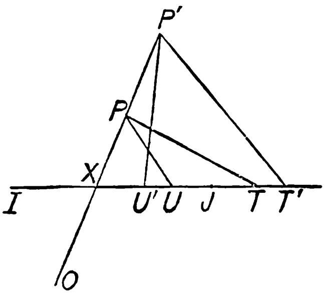
Examples of inversion in regard to a given circle.

Ex. 1. Let the point P, of one circle, invert into the point P', of the inverse circle; and let the tangents of these circles, respectively at P and P', meet the line IJ, in T and T'; let the line OPP' meet IJ in X. Then X is a double point of the involution determined by the pairs I, J and T, T'. Consider, first, two points, P and Q; and their inverses, respectively P' and Q'. Let PP' and QQ' meet IJ, respectively, in X and Y, while PQ and $P'Q'$ meet IJ in T and T'. Then, by what has been said above, the conic drawn through I, J, P, Q, P' also contains Q'; or, the points P, Q, P', Q' lie on a circle, cutting the circle of inversion at right angles. Thus, the pairs X, Y; T, T'; I, J belong to the involution, of points on IJ, determined by conics through P, Q, P', Q'. When Q coincides with P, and Q' with P', this leads to the result stated.



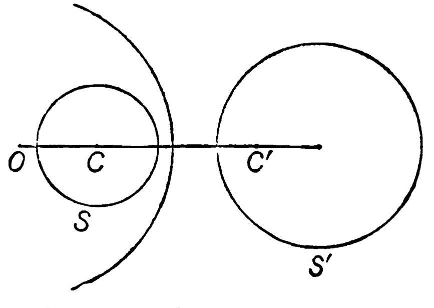
Ex. 2. The circles which are the inverses of two circles which cut at right angles are two circles which also cut at right angles.

Let the tangents of two circles, which meet at P, and cut at right angles, intersect the line IJ, respectively, in T and U; let the tangents of the, respectively, inverse circles, at the inverse point P', meet IJ in T' and U'. Consider the involution determined by the two pairs of points, I, J and T, T'. The point, U, which is the harmonic conjugate of T in regard to I and J, and the point, V, which we may take, which is the harmonic conjugate of T' in regard to I and J, form a pair also belonging to this involution (above, p. 7). If the line $P'PO$ meet IJ in X, we have seen in the preceding example that the involution determined by I, J with X as a double point, contains the pairs T, T' and U, U'. By what we have now said, this same involution, as determined by I, J and T, T', contains the pair U, V. Thus V coincides with U', and the points T', U' are harmonic conjugates in regard to I, J. Therefore, the inverse circles cut at right angles at P'. It is easy to prove, also, that the inverses of two circles which touch one another are two circles, which also touch one another.



Ex. 3. Suppose we are given a circle and two points which are inverse to one another in regard to this circle, that is, these points are conjugate to one another in regard to this circle, and lie on a line passing through the centre of this circle. If we invert this system in regard to a circle, we obtain another circle and two points. The new points are inverse to one another in regard to the new circle.

For, every circle through the two original inverse points cuts at right angles the circle in regard to which they are inverse, as we have proved. Wherefore, by Ex. 2 above, every circle through the two new points cuts the new circle at right angles. This shews, by what we have said, that the two new points are inverse points in regard to the new circle.

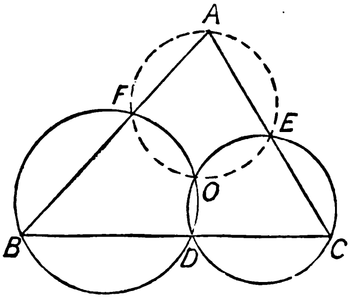


Ex. 4. It follows, from Ex. 3, that, when a circle, say S, of centre C, inverts into a circle, S', the point C' which is the inverse of C (in regard to the circle of inversion), is the inverse of the centre, O, of the circle of inversion, taken in regard to S'. For, if K be any point of the line IJ, the points C

and K are inverses of one another in regard to S. The inverse of K (in regard to the circle of inversion) is, however, O. Thus O, C' are inverse points in regard to S'. In particular, when S' is a line, it passes through the middle point of OC' and is at right angles to this.

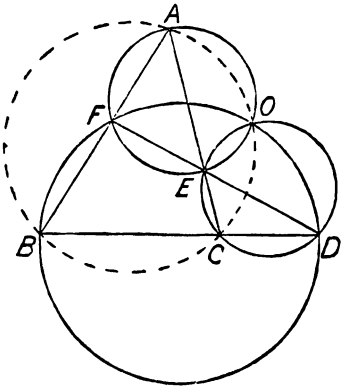
Examples in regard to circles. *Ex.* 1. If any three circles be taken, and the common chord, other than IJ, of each of the three pairs of these circles, these three common chords meet in a point. Let the circles be S, U, V; consider the common points of S with U, and, also, of S with V; let the former be P, P', and the latter be Q, Q', and let the chords PP', QQ' meet in T. By what has been seen, a circle can be described with T as centre, to cut the circle S at right angles; it is the conic touching TI and TJ, respectively at I and J, which passes through one (and therefore the other) of the points of contact of the tangents drawn from T to S. The points P, P', being on S, are inverse in regard to this circle, as also are Q, Q'. This circle, therefore, cuts U and V, also, at right angles. Its centre T is, therefore, on the common chord of U and V. For, if H be one of the common points of U and V, and TH meet U and V again, respectively, in L and M, it follows that L and M are both inverses of H, in regard to the circle of centre T, and, therefore, coincide.

Ex. 2. Let A, B, C be any three points; and D, E, F be any three points lying respectively on BC, on CA and on AB. Through the three points F, B, D (beside I, J) a circle can be drawn; through the three points E, C, D another circle. These, beside D (and I, J), will have common a further point O. This point lies on the circle passing through A, E, F. (Miquel, *Liouv. J.*, iii, 1838.)



Denote the points in which the line IJ is met by BC, CA, AB, respectively, by A', B', C'; and the points in which the lines OD, OE, OF, respectively, meet IJ, by D', E', F'. Then the pairs of points I, J; A', F'; C', D' are in involution, that determined on IJ by the conics through the four points F, B, D, O; so that the range C', F', J, I is related to the range D', A', I, J. Again, by conics through E, C, D, O, the pairs I, J; A', E'; B', D' are in involution, and, therefore, the range D', A', I, J is related to the range B', E', J, I, and is, hence, related to the range E', B', I, J. But, then, the ranges, C', F', J, I and E', B', I, J, being related, the pairs I, J; B', F'; C', E' are in involution. This shews that a circle passes through the points A, E, F, O. [Add.]

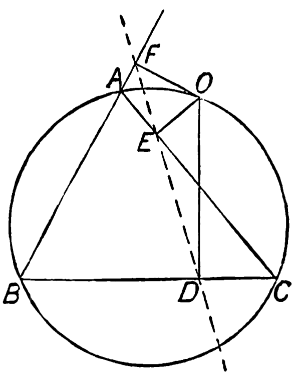
Ex. 3. Wherefore, by supposing the points D, E, F to be in line, we infer that, if four lines be taken in a plane, and, from every three of these lines, by intersections of pairs, a triad of points be defined, then the three circles determined by three of these triads have a common point. Therefore, by symmetry of reasoning, the four circles determined by the four triads have a point in common.



Conversely, let points, D, E, F, lying, respectively, on the three joins BC, CA, AB, be such that the circle ABC contains the point of concurrence, O, of the three circles AEF, BFD, CDE, whose existence is proved in Ex. 2. Then the points D, E, F are in line. For, let the line EF meet BC in P. The point O is determined by the intersection of the circles AEF and ABC, and the circle EPC passes through O. But this circle has, with the circle CDE, the points E, O, C, I, J in common, and thus coincides with it. Hence P coincides with D.

The circle ABC may thus be regarded as the locus of the point of intersection of the circles AEF, BFD, CDE, when D, E, F are determined by a varying line.

Ex. 4. A particular corollary from this is the fact (already proved, Chap. I, Ex. 8) that, if, from a point, O, of the circle ABC, lines be drawn at right angles to BC, CA, AB, meeting these, respectively, in D, E and F, then these points D, E, F are in line. For, the pencil of lines $E(I, J, O, A)$, being harmonic, is related to the pencil $F(I, J, O, A)$. Thus a circle can be drawn through O, E, F, A, I, J. Similarly, circles can be drawn through O, F, B, D and O, D, C, E.



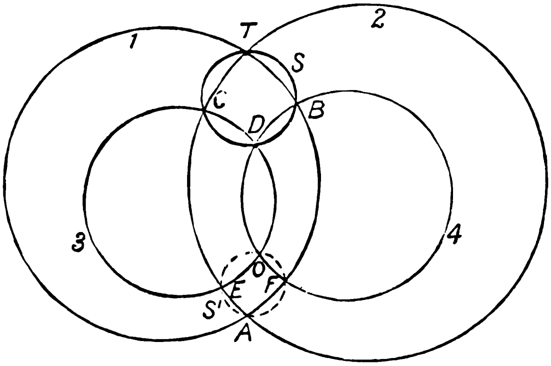
If the lines OD, OE, OF meet the line IJ, respectively, in D', E', F'; and L be the harmonic conjugate, on the line OD, of the point O in regard to D and D', so that D is the middle point of OL; and, similarly, M, N be taken, on OE, OF, respectively, such that E is the middle point of OM, and F the middle point of ON, it follows that L, M, N are in line.

Ex. 5. If, in the preceding example, there be four lines, instead of only the three BC, CA, AB, and O be the point of concurrence of the four circles, determined, as in Ex. 3, by every three of these, there will be obtained four points, L, M, N, P, lying in line. The rule for these is, that the middle point of OL lies on one of the four given lines, the line OL being at right angles to this line.

Now apply the theory of inversion, explained above, to this figure, the circle of inversion being any circle of which O is the centre. The four given lines then invert into circles passing through O; the centres of these circles will (Ex. 4, above, in regard to inversion) be the points obtained by inversion of L, M, N, P. These centres will then lie on a circle passing through O. In the original figure, the point O was obtained as a point of concurrence of four circles; of these, every two have an intersection beside O, which is also an intersection of two of the given lines. These circles will invert into four lines, say a', b', c', d'. The original figure can, then, be obtained, by inversion, from four arbitrary lines a', b', c', d', and an arbitrary point, O.

We thus infer a further property of the four circles considered in Ex. 3 above (given, with other properties, by Steiner, *Ges. Werke*, i, p. 223)—namely, that their centres lie on a circle which passes through O. This result may, also, be regarded as built up from the theorem, similarly obtainable from Ex. 4, by inversion, that, if three circles with a common point be such that the other three points of intersection of the pairs of these lie in line, then the centres of the three circles lie on a circle passing through their point of concurrence.

Ex. 6. In the figure of Ex. 3, we have four lines, and four circles which meet in O. This arose from the figure of Ex. 2, in which there



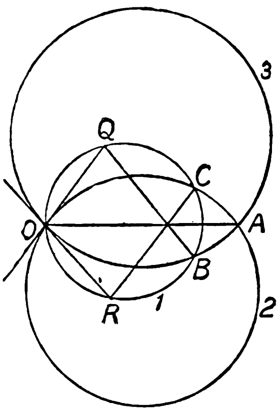
were three lines, and three concurrent circles. There is a generalisation, of importance, in which the lines are replaced by circles.

Let any four circles, which we suppose considered in a definite order, be denoted, respectively, by 1, 2, 3, 4. Let the pairs of intersections (other than I, J), of the successive pairs of these circles, be denoted, respectively, as follows:

for 1, 2 by T, A; for 2, 3 by C, E; for 3, 4 by D, O; for 4, 1 by B, F.

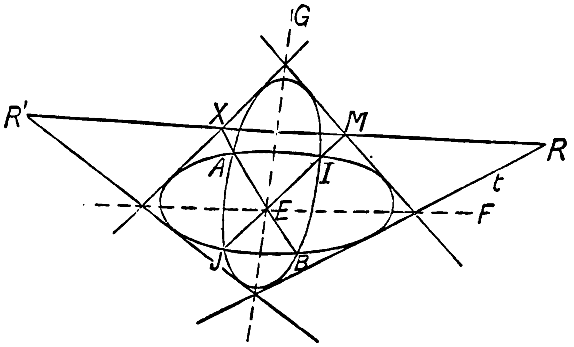
Then it can be shewn that, if the four points T, C, D, B lie on a circle, say S, the four remaining points, A, E, O, F, also lie on a circle, say S'.

This result is obtainable by inversion in regard to any circle of centre T, whereby we are led back to Miquel's theorem of Ex. 2. But, as will be seen below, in dealing with the relations of geometry in two and three dimensions, this is not the simplest way of regarding the theorem.



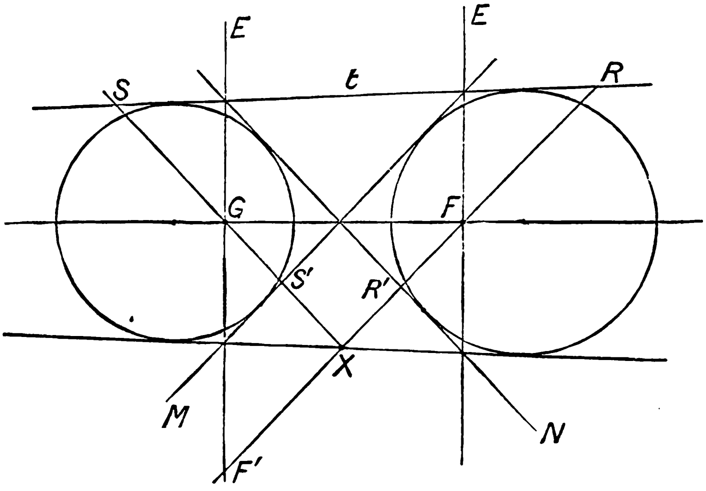
Ex. 7. Three circles, 1, 2, 3, meet in a point O. The tangents at O, respectively of the circles 2 and 3, meet the circle 1 in Q and R; the points of intersection of the circles are A or (2, 3), B or (3, 1), C or (1, 2). Prove that OA, QB, RC meet in a point. (Chap. I, Ex. 34.)

Ex. 8. If a pair of common chords of two conics, which meet in E, meet two common tangents of the conics, respectively, in X and M, the line XM passes through one of the two points, F, which, with E and another point G, form the common self-polar triad of the two conics. The points X, M belong to the involution determined on the line XM by the two conics, the double points of this involution being the point F, and the point of XM which lies on EG; the points, R, R', in which the line XM meets the other two tangents common to the conics, also belong to this involution.



The result follows at once from the fact remarked (Chap. I, Ex. 14), that the figure consists of pairs of points which are harmonic images of one another in regard to the line EG and the point F.

Ex. 9. In the case of two circles, the common self-polar triad consists of the two limiting points, F, G, and the point, E, in which the common chord, AB, meets the line IJ. Let one of the four common tangents of the circles be called t, and consider, with this, the common tangent which intersects t on the line of centres, FG, of the two circles; let X be the intersection of this latter tangent with the common chord AB. Another common tangent passes through the intersection of the line EF with t; let this meet the line IJ in M, the line XM passing through the limiting point F. The remaining common tangent passes through the intersection of the line EG with t, and meets the line IJ, say, in N. Let XM meet the tangent t, and the tangent through N, respectively in R and R'. (Cf. the diagram of Ex. 8.)



If then RX meet EG in F', there is on the line RX an involution of which F and F' are the double points, of which X, M and R, R' are two pairs, and two other pairs are the intersections of the line XR with the two circles. (Ex. 8.)

Now a circle, Ω, can be drawn with centre X, to contain the limiting points F, G, by what we have shewn above; this will cut both the given circles at right angles, and will, therefore, pass through the points of contact with the circles of the common tangent containing X. As M is on the polar, IJ, of X, in regard to this circle, and X, M are harmonic in regard to F and F', this circle passes also through F'. Thus the points R, R' are inverses of one another in regard to this circle, Ω. In the same way, if XG meet the tangent t, and the tangent through M, respectively in S and S', it follows that S, S' are inverses of one another in regard to this same circle, Ω. The lines XF, XG, likewise, meet the given circles in points which are inverses of one another in regard to this circle, Ω.

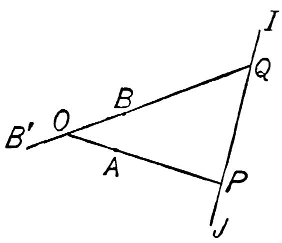
If we now invert the figure in regard to this circle, Ω, both the given circles invert into themselves, but the common tangent t inverts into a circle, passing through the points X, R', S', which touches both the given circles.

Conversely, suppose that the three lines, which appear here as the common tangents containing respectively X, M, N, are given. It can be shewn that there are four circles touching these three lines; the proof has in fact been given (Chap. I, Ex. 17). Also, as F, F' are harmonic in regard to X, M, and XF meets the tangent MS' on IJ, while XG meets the tangent NR' also on IJ, it follows easily that X, R', S' are the mid points, in regard to I, J, of the pairs of points formed by the intersections of the three given lines. Thus the circle $XR'S'$ is determined by these lines. Hence these four circles are all touched by another circle. (See also Chap. I, Ex. 33.)

The present proof (usually based on metrical considerations here not utilised) was given by J. P. Taylor, *Quarterly Journal of Mathematics*, XIII (1875), p. 197; and by Fontené, *Nouvelles Annales*, VII (1907), p. 161. The theorem is considered again, in Chap. III, below.

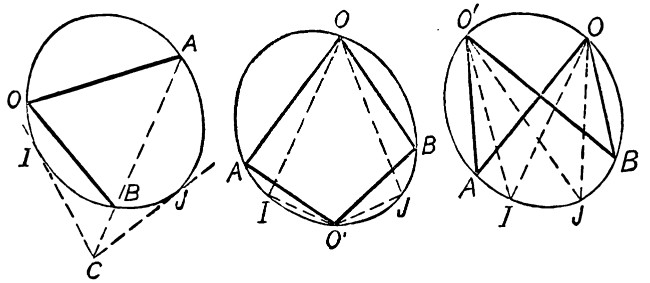
Angle properties for a circle. In the present volume, no use is made of any measure of an angle until Chap. V is reached. In Euclid's treatment of circles great use is made of the fact that the angles in any segment of a circle are equal to one another; it will be convenient to give here a condition under which we may, if we desire, speak of two angles as being equal. In Euclid's theory, if two angles α, β be respectively equal to two angles α', β', then an angle, formed by the *sum* of the two former, is regarded as being equal to the angle formed by the *sum* of the two latter. This is a step which we do not take before Chap. V is reached, the *sum* of two angles being at present undefined.

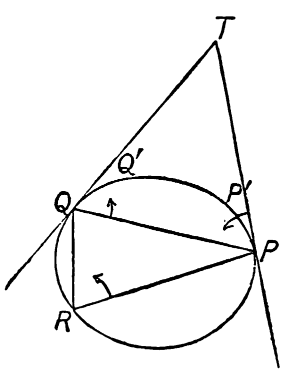
Let OA, OB be two lines, meeting in a point, O; and let $O'A'$, $O'B'$ be two other lines, meeting in O'. We may say that, in regard to the fundamental points I, J, the line OB makes with OA an angle equal to that made with $O'A'$ by $O'B'$, if the pencil $O(B, A, I, J)$ be related to the pencil $O'(B', A', I, J)$. If OB, OA meet the line IJ, respectively, in Q and P, while $O'B'$, $O'A'$ meet IJ in Q' and P', respectively, the ranges (Q, P, I, J), (Q', P', I, J) are then related.



It may be remarked that, when we are dealing with real points, if B' be a point of the line OQ separated from B by O and Q, this provisional definition would render the angle made by OB' with OA equal to the angle made with OA by OB. These, however, are, in general, different from the angle made by OA with OB, or with OB'. The angle made by OB with OA is equal to the angle made by OA with OB, when OA, OB are harmonic conjugates in regard to I, J; that is, in the phraseology here used, when OA, OB are at right angles, in regard to I, J.

From this definition, if the points O, O', A, B lie on a circle, the angle which $O'B$ makes with $O'A$ is equal to the angle which OB makes with OA. And, when the line AB passes through the centre, C, of the circle, in which case the lines joining O to A and B are harmonic conjugates in regard to OI, OJ, the lines OB, OA are at right angles.



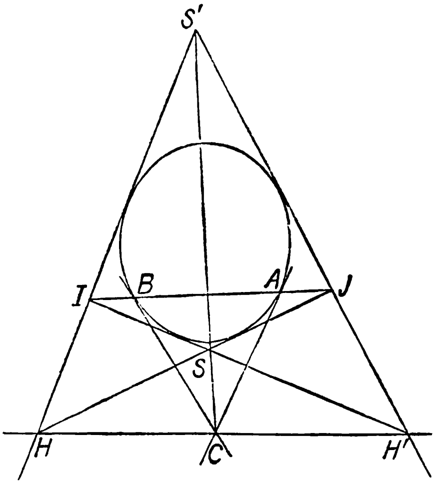


Ex. If the tangents at two points, P, Q, of a circle meet in T, the angle made by QT with QP is equal to the angle made by PQ with PT; and, if R be any other point of the circle, this is equal to the angle made by RQ with RP.

For, if P', Q' be any other two points of the circle, the range P', Q', I, J, of four points of the circle, gives related pencils when joined to any two points of the circle. Thus, the pencils $Q(Q', P', I, J)$, $P(Q', P', I, J)$ are related. Recalling, what has appeared in the definition of a conic, that the tangent contains two coincident points of the conic, we see, by supposing P' to be at P, and Q' to be at Q, that the pencils $Q(T, P, I, J)$, $P(Q, T, I, J)$ are related. Further, the pencils

$Q(Q', P', I, J)$, $R(Q', P', I, J)$ are related, so that each of the preceding pencils is related to $R(Q, P, I, J)$.

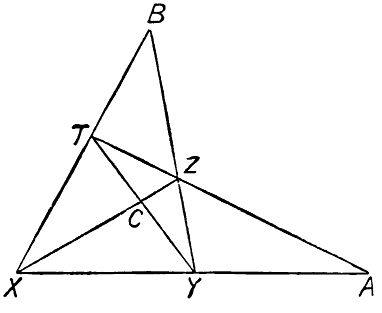
Foci and axes of a conic. The *foci* of a conic, in regard to I and J, are defined as the two pairs of intersections, S, S' and H, H', of the two pairs of tangents to the conic from I, J. By the properties of conics touching four lines (above, p. 24), the three lines SS', HH', IJ form a self-polar triad, the intersection, C, of SS' and HH', being the pole of the line IJ in regard to the conic, that is, the *centre*, in regard to I and J. The lines CSS', CHH' meet IJ in two points which are harmonic conjugates in regard to I and J; these lines are called the *axes* of the conic; they are at right angles. The tangents CA, CB, to the conic, from the centre C, are called the *asymptotes*. Any two lines, drawn through the centre C, conjugate to one another in regard to the conic, that is, harmonic conjugates in regard to the asymptotes CA, CB, are called *conjugate diameters* of the conic. The axes are that single pair of conjugate diameters which are at right angles.



Ex. As a conic can be drawn to have five given tangents, a conic can be drawn to touch the joins BC, CA, AB, of three points A, B, C, and have a given point S for a focus. The tangents, other than IS, JS, drawn to this conic from I and J will intersect one another in a further focus, S', which we may call the focus conjugate to S.

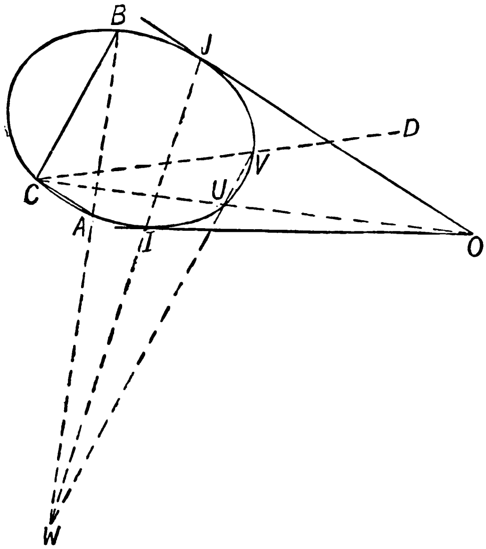
We consider the correspondence of S and S', either of which determines the other. In particular we shew that if S be at the orthocentre of A, B, C, in regard to I, J, then S' is at the centre of the circle A, B, C.

The line pairs AI, AJ; AS, AS'; AB, AC are pairs of tangents drawn from A to particular conics touching the four lines IS, JS, IS', JS'; they are therefore in involution (Chap. I, Ex. 1). Similarly for the pairs of lines joining B to I, J; S, S'; C, A; and for the pairs of lines joining C to I, J; S, S'; A, B. Let the double rays of the first involution, of lines through A, intersect the double rays of the second involution, through B, in the four



points X, Y, Z, T; then it follows, because the lines AYX, AZT, say, are harmonic in regard to AC, AB, and the lines BZY, BTX, say, are harmonic in regard to BA, BC, that the lines XZ, TY, say, meet in C. And, then, as the line IJ is divided harmonically by the line pair AYX, AZT, and also by the line pair BZY, BTX, it is divided harmonically by the line pair XCZ, YCT (above, p. 4); so, likewise, is the line SS'. Wherefore the lines XCZ, YCT are the double lines of the involution containing the line pairs CI, CJ; CS, CS'; CA, CB. Thus the relation of S, S' is that of two points which are conjugate to one another in regard to all conics passing through X, Y, Z, T (as in Ex. 16 of Chap. I), and I, J are conjugate to one another, also, in regard to such conics. Thus when S describes a line, S' describes a conic passing through A, B, C; and conversely.

A point D can be taken so that IJ is divided harmonically by AC, BD and by BC, AD; it will then (above, p. 4) also be divided harmonically by AB, CD. The point D will be the orthocentre of A, B, C, in regard to I, J, and I, J will be conjugate to one another in regard to all conics through A, B, C, D. Let the conic (circle) be drawn through A, B, C, I, J, and let O be the intersection of the tangents of this conic at I, J, the centre of this conic. We shew then that when S is at D, then S' is at O. For let CO, CD meet the conic A, B, C, I, J, again, respectively in U, V, and let BA, JI meet in W. As the points I, J are separated harmonically by the lines AB and CD, while, as points on the conic, U and C are harmonic conjugates in regard to I and J, it follows that VU passes through W. Thus the line

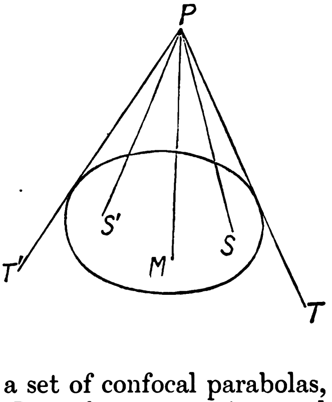


pairs *CI*, *CJ*; *CA*, *CB*; *CO*, *CD* are in involution. By a similar argument the line pairs joining *A* to the point pairs *I*, *J*; *B*, *C*; *O*, *D* are in involution; as, also, those joining *B* to *I*, *J*; *C*, *A*; *O*, *D*. This shews that *O*, *D* are related as was stated.

Confocal Conics. A system of conics having the same foci is called a confocal system. It is the same as a system of conics with four common tangents, of which two meet in the point *I*, and the other two in the point *J*. The four foci are in pairs, on two lines which meet in the centre of the conic; if one of these pairs be common to two conics, so are the other pair.

If the two pairs of foci be denoted, as above, by *S*, *S′* and *H*, *H′*; and if *PT*, *PT′* be the tangents, to one conic of the confocal system, drawn from an arbitrary point *P*, it is known (above, p. 25) that the four pairs of lines *PT*, *PT′*; *PI*, *PJ*; *PS*, *PS′*; *PH*, *PH′*, are in involution. The double lines of this involution are harmonic in regard to the lines of each pair; in particular in regard to *PI*, *PJ*, and so are at right angles. These double lines are, however, the tangents at *P*, of the two conics which can be drawn, through *P*, to touch the four lines *IS*, *IS′*, *JS*, *JS′* (above, p. 25). Thus, through any point *P* can be drawn two conics of the confocal system, and these cut one another at right angles, at the point *P*. It can be shewn, similarly, that they also cut at right angles at each of their other three points of intersection.

Further, if we refer again to the provisional phraseology in regard to equal angles, the angle made by *PS′* with *PT′* is equal to the angle which *PT* makes with *PS*. For, as the pairs of lines, *PS*, *PS′*; *PT*, *PT′*; *PI*, *PJ* are in involution, the pencils *P* (*S′*, *T′*, *I*, *J*), *P* (*S*, *T*, *J*, *I*) are related, and the second is related to *P* (*T*, *S*, *I*, *J*). Also, if one of the double rays of this involution be *PM*, the pencils *P* (*M*, *S′*, *I*, *J*), *P* (*S*, *M*, *I*, *J*) are related; so that the angle made by *PM* with *PS′* is equal to the angle made with *PM* by *PS*. In particular, when *P* is on the conic, the angles *S′PM*, *MPS* are equal.



A particular set of confocal conics is a set of confocal parabolas, that is, conics all touching the line *IJ* at the same point, and having two other common tangents, *IS*, *JS*. [Add.]

Common chords of a circle with a conic. If the axes of a conic meet the line *IJ* in *X* and *Y*, as the axes meet in the pole of the line *IJ* and are at right angles and conjugate in regard to the conic, the points *X*, *Y* are the double points of the involution determined by the two pairs consisting of *I*, *J* and the points, *F*, *F'*, in which the conic meets *I*, *J*; this is the involution determined on the line *IJ* by the conic and any circle. If, then, a pair of chords, *LM*, *L'M'*, of the conic and the circle, meet *IJ* in *P* and *P'*, the pair *P*, *P'* will belong to this involution. Wherefore, the ranges, *P*, *X*, *I*, *J* and *X*, *P'*, *I*, *J*, are related. Thus, the angle made by the common chord, *LM*, of a conic, and any circle, with either axis, *CX*, is equal to the angle made by this axis with the complementary common chord, *L'M'*, of the conic and circle.

The director circle of a conic. The director circles of conics touching four lines are coaxial. This is the conic which has been defined (Chap. I, Ex. 3) as the director conic in regard to *I* and *J*. From its definition it is the locus of points from which the two tangents to the conic are at right angles; it passes through the points in which the conic is met by the polar of any one of the four foci; and its centre coincides with the centre of the conic. As has been shewn (Chap. I, Ex. 25), if, through three points which form a self-polar triad in regard to the conic, the circle be drawn, this cuts the director circle at right angles.

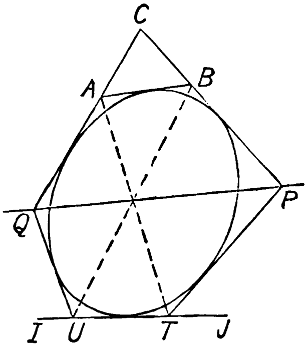
Further, the director circles of all conics which touch four given lines have two points in common, beside *I* and *J*, that is, are a coaxial system of circles. For, let *P* be one of the intersections of the director circles of two particular conics touching these four lines. The pairs of tangents from *P*, to all these conics, are a pencil in involution (above, p. 25); and these meet the line *IJ*, which is supposed to have no special relation to the four lines, in pairs of points in involution. Of this involution, however, the points *I*, *J* are the double points; for, the tangents from *P* to each of the two selected conics are at right angles, and an involution is determined by two of its pairs. Wherefore, the tangents from *P* to any other of the conics are at right angles, and *P* lies on the director circle of this conic. From this, the statement made follows.

Particular, degenerate, conics touching the four lines, are the point pairs, three in number, through which the lines pass in pairs. If *A*, *C* be such a pair, the lines *PA*, *PC* are the tangents to this from a point *P*, and the corresponding director circle is the locus of *P* when the lines *PA*, *PC* are at right angles. The centre of this circle is the middle point of *AC* in regard to *I* and *J*. If *B*, *D*, and *E*, *F*, be the other point pairs, the middle points of *AC*, *BD*, *EF* lie on a line, the line containing the centres of all the coaxial director circles, which are the centres, the poles of *IJ*, in regard to the conics touching the four lines.

One conic can be drawn touching the four lines which also touches *IJ*. The director circle of this, as was remarked, degenerates into the line *IJ* and another line; if the other two tangents which can be drawn, from I, J, to this conic, meet in S, the line in question is the polar of S in regard to this conic. (Cf. Ex. 5 of Chap. I.) This line is then the radical axis of all the director circles, and is at right angles to the line of centres of the conics. [Add.]

Parabolas. The directrix of a parabola. A conic touching the line IJ is called a *parabola*. If this touch IJ in S', and if S be the intersection of the tangents from I, J, the four foci of the parabola are S, S' and I, J. The polar of S in regard to the parabola is called the *directrix*; it was this name which suggested, to Gaskin, to call the director circle of any conic, the *director*. As a particular case of what has been said, since a line cuts a circle at right angles only if it passes through the centre of the circle, it follows that the circle drawn through three points, which are a self-polar triad in regard to a parabola, has its centre on the directrix of the parabola.

The directrix of a parabola also passes through the orthocentre of any three points whose joins are three tangents of the parabola. This follows at once from Brianchon's theorem. For let A, B, C be three points such that BC, CA, AB touch the parabola; let CB, CA, respectively, meet the directrix in P and Q; let the other tangents from P, Q, to the parabola, meet IJ, respectively, in T and U. As then, by definition, the tangents, PT, CB, are at right angles, the line AT is the line drawn from A at right angles to BC. So BU is the line drawn from B at right angles to AC. The point of intersection of these lines is the orthocentre of A, B, C (above, p. 64); by Brianchon's theorem (Chap. I, Ex. 2) this point of intersection is on the directrix PQ. Conversely, it may be seen that a parabola can be drawn, to touch three given lines, to have for directrix any line through the orthocentre of the points formed by the intersections of the lines.



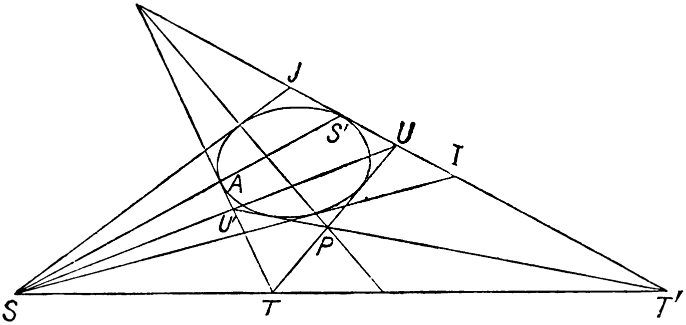
Examples in regard to a parabola. *Ex.* 1. If A, B, C be three points such that the lines BC, CA, AB touch the parabola, the circle through A, B, C contains also the focus, S, of the parabola. For, as the lines joining S to the points I, J are, by the definition of S, tangents of the parabola, and the line IJ is also a tangent, this is the theorem (Chap. I, Ex. 7) that, when the six lines, which are the joins of the pairs of each of two triads of points, touch a conic, the two triads are points of another conic.

Ex. 2. If we have four lines, any three of these, by their intersections in pairs, give rise to a triad of points, through which there passes a circle. The four circles so obtained meet in a point, namely the focus of the parabola which can be drawn to touch the four lines (beside the line IJ). This is a result obtained above (p. 71). It will be seen later that the theorem is equivalent to Moebius' theorem of the in- and circumscribed tetrads (Vol. I, p. 62).

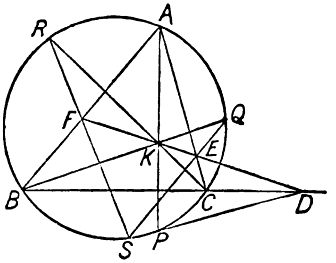
A conic, S, containing a triad of points whose joins touch another conic, Σ (and, therefore, an infinite number of such triads), may be spoken of as triangularly circumscribed to Σ. Thus, any circle passing through the focus of a parabola is triangularly circumscribed to the parabola.

Ex. 3. Let the line joining the focus, S, of a parabola, to the point, S', in which the curve touches IJ, meet the curve again in A. Then A may be called the vertex. It can be shewn that the line drawn through the focus, S, at right angles to any tangent of the curve, meets this tangent at a point lying on the tangent at the vertex, A.

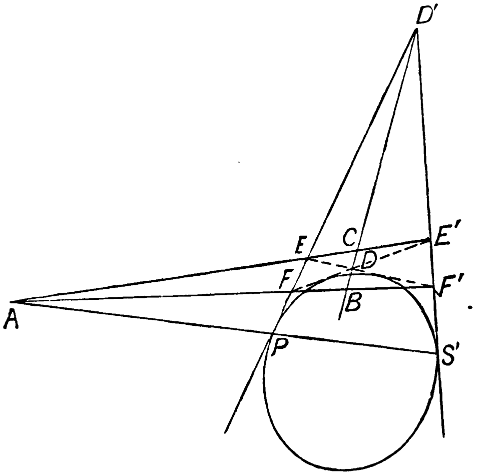
For, take any point P of the directrix, the polar of S. Draw from P the two tangents of the curve; let these meet the line IJ, respectively, in U and T', and meet the tangent at A, respectively, in T and U', so that, as is easy to prove, S, U, U' are in line, and S, T, T' are in line. Then U, T' are harmonic conjugates in regard to I and J. That is, the line ST, drawn from S at right angles to the tangent TU, meets this tangent in a point, T, of the tangent at the vertex. (Cf. Ex. 5, p. 28.)



Combining with the last example, we infer that the lines drawn from the Miquel point of four lines, there obtained, each at right angles to one of the lines, meet these lines respectively in points which are in line. Also, the orthocentres of the four triads, determined by each set of three of the lines, are in line. Further, the pedal line of a point, O, of a circle, in regard to three points of the circle, of which the orthocentre is K, passes through the middle point of OK. (Cf. Ex. 8, of Chap. I; and Ex. 4, above, regarding the circle.)



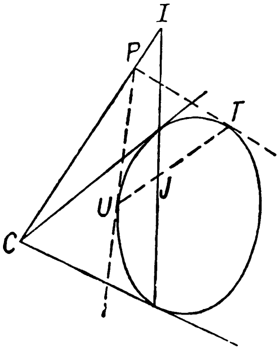
Ex. 4. Any line drawn through the orthocentre, K, of three points, A, B, C, of a circle, meets BC, CA, AB, respectively, in the points D, E, F, and the lines AK, BK, CK meet the circle again, respectively, in P, Q, R. Prove that the lines DP, EQ, FR meet in a point, S, of the circle. And that this is the focus of the parabola which, as has been remarked, can be described to touch BC, CA, AB and have the given line as directrix.



Ex. 5. The joins of three points, A, B, C, which form a self-polar triad in regard to a conic, meet any tangent of the conic, respectively, in D', E', F'; on these joins are taken D, E, F such that D, D' are harmonic conjugates in regard to B, C, and so on. Prove that the lines EF, FD, DE are tangents of the conic. Thus, if A, B, C be a self-conjugate triad in regard to a parabola, the circle through the middle points of BC, CA, AB, contains the focus of the parabola.

Definition of a rectangular hyperbola. A conic which meets the line IJ in two points which are harmonic conjugates of one another in regard to I and J, is called a *rectangular hyperbola* in regard to I and J. In particular, a degenerate rectangular hyperbola consists of two lines which are at right angles. A conic which touches the line IJ, at one of the two points I, J, is both a parabola and a rectangular hyperbola. [Add.]

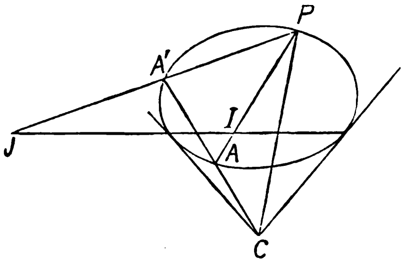
By considering the involution of pairs of points determined on the line IJ by the conics which pass through the four intersections of two rectangular hyperbolas, we see that all these conics are rectangular hyperbolas. In particular, if K be the orthocentre of a triad of points, A, B, C, all conics through A, B, C, K are rectangular hyperbolas; conversely, if any rectangular hyperbola drawn through A, B, C meet the line, which is drawn through A at right angles to BC, in the further point K, the line BK is at right angles to CA; thus any rectangular hyperbola drawn through A, B, C also contains the orthocentre.



The centre, C, of a rectangular hyperbola, and the points I, J, form, by definition, a self-polar triad in regard to the rectangular hyperbola. The lines PI, PJ, when P is any point of the line CI, are thus conjugate in regard to the curve, and are, therefore, harmonic in regard to the tangents, PT, PU, which can be drawn from P to the curve. These tangents are therefore at right angles. Thus we see that the director circle of a rectangular hyperbola degenerates into the line pair joining its centre to the points I and J.

Examples in regard to a rectangular hyperbola. *Ex.* 1. Any pair of lines CP, CD, drawn through the centre, C, of a rectangular hyperbola, which are conjugate lines in regard to the curve, are harmonic in regard to the tangents of the curve, CL and CM, at the points, L and M, where the curve meets the line IJ. In particular CI, CJ are such a pair of conjugate lines. If CP meet the curve in P, and the tangent at P meet CL, CM in L' and M', then P is the middle point of $L'M'$ in regard to IJ. Also the angle which CD makes with CL is equal to the angle which CL makes with CP.

Ex. 2. If the lines joining any point, P, of a rectangular hyperbola, to the points I and J, meet the curve again, respectively, in A and A', the line AA' passes through the centre, C, of the curve, and is at right angles to the line CP. In fact the lines $A'I$, AJ, PC meet in a point of the curve.



Further, if the tangents of the conic at A and A' intersect in T (which will lie on IJ), and any line through T meet the rectangular hyperbola in M and N, prove that PM, PN are at right angles, in regard to I and J.

In general, for any conic, not necessarily a rectangular hyperbola, if through a fixed point, P, of the conic, lines be drawn at right angles, meeting the conic again, respectively, in M and N, the pairs M, N, so arising, belong to an involution of points of the conic.

Thus MN passes through a fixed point. It can be seen that this is on the line, drawn through P, at right angles to the tangent at P.

Ex. 3. The centre of a given rectangular hyperbola is R, and O is any point of the curve. A circle is drawn, with centre O, to cut the curve in A, B, C, D. If we form the polar reciprocal of the rectangular hyperbola in regard to the circle, that is, the envelope of the polars, in regard to the circle, of the points of the rectangular hyperbola, prove that the curve obtained is a parabola touching the tangents of the circle at A, B, C, D, whose focus is the pole, in regard to the circle, of the line through R at right angles to OR, that is, the inverse of R in regard to the circle, the directrix of the parabola passing through O.

Auxiliary circle of a conic. We now explain a method by which we may pass from any conic to another, or conversely from this other to the original, the deduction in the latter case being exactly the dual of the former.

Let Ω be any conic, and C, S any two fixed points, the line CS meeting Ω in A and A'. Let R be any variable point of Ω. Let CR and SR, respectively, meet Ω again in Z and Z'.

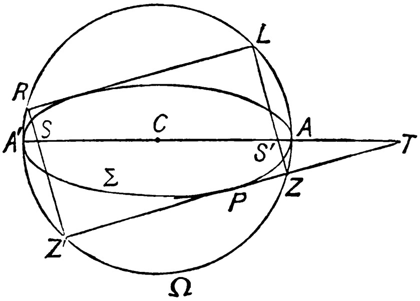
As then Z, R are pairs of an involution of points on the conic Ω, the range (Z) on the conic is related to the range (R). This in turn is, similarly, related to the range (Z'). Wherefore, by a result proved above (Ex. 28, Chap. I), the line ZZ' touches another conic, say, Σ. The points A, A' are the common corresponding points of the two ranges (Z), (Z'), and the conic Σ touches Ω at A and A'. If P be the point of contact of ZZ' with Σ, and T the intersection of ZZ' with AA', it is easy to see that P, T are harmonic, both with respect to Z, Z', and also with respect to the points in which ZZ' meets the tangents at A and A'.

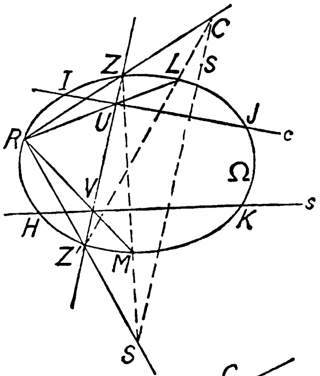
Now denote by c the polar of C in regard to Ω, and by s the polar of S; let c meet Ω in I, J, and s meet Ω in H, K. It can at once be proved that the conic Σ touches CH, CK at the points where these meet the line c, and touches SI, SJ at the points where these meet the line s.

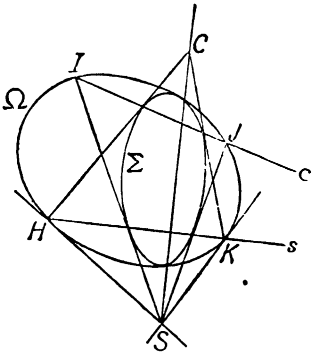
If the line ZZ', which we denote by r, meet the lines c, s, respectively, in U and V, and RU, RV meet the conic Ω in L and M, respectively, C, L, Z' will be in line, as, also, S, M, Z will be in line. The line RL is then a tangent of the conic Σ, being the position of ZZ' when R is at Z'; for a like reason, RM is a tangent of Σ.

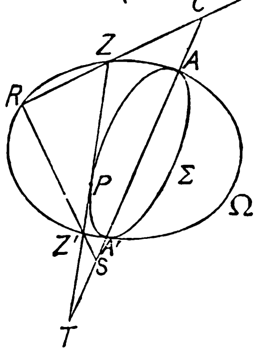
Hence, if the conic Σ be given, and the lines c and s, the conic Ω can be defined by finding the points, U, V, where a variable tangent, r, of Σ, meets c and s, drawing from U, V the tangents (other than r) UL, VM, and finding the locus of their intersection, R. This is exactly the dual of the construction by which Σ is found when Ω

and the points C, S, are given. Further, as the line $Z'L$ passes through the pole of IJ in regard to Ω, the points Z', L are, as points of the conic Ω, harmonic conjugates in regard to the points I, J of Ω; thus, the line SR is the line through S drawn to the point, of the line IJ, which is the harmonic conjugate, in regard to I and J, of the point, U, where the tangent RL, of Σ, meets the line IJ. If we suppose the points S, I, J to be given, this shews how we may determine either of the conics Σ, Ω when the other is given. The lines $Z'R$, LZ meet on IJ; thus, if we take the point, S', of SC, which is the harmonic conjugate of S, in regard to C and the point where SC meets IJ, then the lines $S'LZ$ and RL will meet the line IJ in points which are harmonic conjugates of one another in regard to I and J.





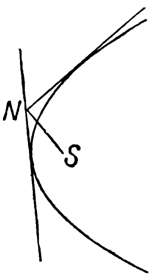




If we now regard I, J as the absolute points, the conic Ω will be a circle, of which C is the centre. The conic Σ will then also have C for centre, and S, S' for foci. The circle, Ω, is, then, the locus of the foot of the perpendicular drawn from S (or from S'), to a tangent of Σ; or, conversely, Σ is thereby determined from Ω.

The circle Ω is that generally called the auxiliary circle of the conic Σ.

Ex. 1. If we be given a fixed point, S, and a line; and from a variable point, N, of this line, the line be drawn at right angles to SN, then this line envelopes a parabola, which touches the given line.



Ex. 2. If two conics, Σ, Ω, have two points of contact, and a variable tangent of one of these, Σ, meet Ω in P and Q, the further tangents from P and Q, drawn to Σ, meet in a point T, whose locus is a further conic touching both of Σ and Ω at their two points of contact.

Ex. 3. If A, B, C, O be four points, and the lines drawn from O at right angles to BC, CA, AB meet these, respectively, in D, E, F, the circle D, E, F is generally called *the pedal circle* of O in regard to A, B, C. It is obviously the auxiliary circle of the conic which can be drawn with O as focus to touch BC, CA, AB.

Let any conic be given, on which O is a fixed point, and A, B, C are variable points. We prove that the pedal circle passes through a fixed point.

For this, let the lines OI, OJ meet the given conic again, respectively, in M and N. There is then, as the six points O, M, N and A, B, C are on the conic, another conic touching BC, CA, AB, OM, ON and MN (Chap. I, Ex. 7). This will be the same as the conic having O for focus which touches BC, CA, AB; which conic, therefore, touches MN. Therefore, the pedal circle of O in regard to A, B, C passes through the fixed point in which MN is met by the line drawn from O at right angles to MN.

In particular, we have remarked (Ex. 2, p. 84) that, when the conic is a rectangular hyperbola, this point is the centre. Thus the pedal circle of any point of a rectangular hyperbola, in regard to any other three points of the curve,. passes through the centre of the rectangular hyperbola.

When the conic is a circle, or passes through the points I, J, it has been seen (Chap. I, Ex. 8, and p. 71, above) that the pedal circle, defined with reference to I and J, degenerates into a line, together with the line IJ. It can, however, be shewn, in this case (see below, Chap. III, p. 139), that, if we consider three variable points, A, B, C, of the circle, which are a self-polar triad in regard to another fixed conic (which must then be taken so that this is possible, being inpolar to the circle; see Chap. I, Ex. 11), then the pedal line of a fixed point of the circle in regard to these points A, B, C, passes through a fixed point.

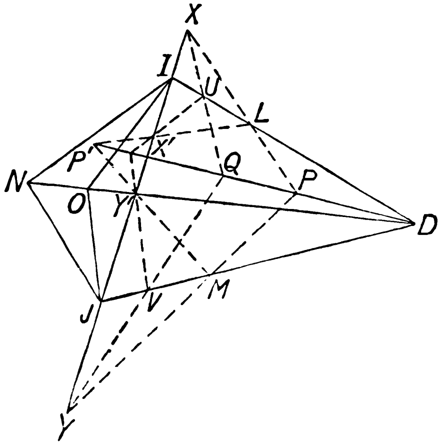
The pedal circle of a point O, in regard to three points A, B, C, being the auxiliary circle of a conic, having O for focus, which touches *BC*, *CA*, *AB*, also arises as the pedal circle, in regard to *A*, *B*, *C*, of another point, *O'*, the conjugate focus of this conic. We have shewn above (p. 78), that when *O* describes any conic passing through *A*, *B*, *C*, then *O'* describes a line; and that, when *O* is at the orthocentre of *A*, *B*, *C*, then *O'* is at the centre of the circle through *A*, *B*, *C*. Thus, when the point *O* is on a rectangular hyperbola through *A*, *B*, *C*, which then also passes through the orthocentre (above, p. 84), the point *O'* lies on a line through the centre of the circle *A*, *B*, *C*. We thus have the result, that, if a point *O'* describe any definite line passing through the centre of the circle *A*, *B*, *C*, the pedal circle of *O'* in regard to *A*, *B*, *C*, passes through a fixed point, which is in fact the centre of the rectangular hyperbola through *A*, *B*, *C* which corresponds to the line. It will be seen, below, that this point is the middle point, in regard to *I*, *J*, of the two points consisting of the orthocentre, and the fourth intersection of the hyperbola with the circle *A*, *B*, *C*.

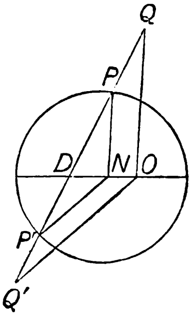
Ex. 4. If a circle be described, with centre at a point, *O*, of a rectangular hyperbola, to meet this in *A*, *B*, *C*, *D*, and *DO* meet the circle again in *S*, prove that the pedal line of *S*, in regard to *A*, *B*, *C*, passes through the middle point of *O*, *S*. Hence shew that the directrix of the parabola, described with focus at *S* to touch *BC*, *CA*, *AB*, passes through *O*; and obtain this result by the transformation referred to above.

Ex. 5. Prove that to any point *P* of the conic Σ there corresponds a point *P'* of the conic Ω such that *CP'*, *SP* meet on the line *IJ*, while *CP*, *SP'* meet on the line *HK*. Taking two arbitrary points, *C*, *S*, and two arbitrary lines *IJ*, *HK*, investigate the correspondence between an arbitrary point *P* and the point *P'* determined by these two conditions. (Boscovich, *Sectionum Conicarum Elementa nova quadam methodo concinnata*, *Elementa Universae Matheseos*, Venetiis, 1757. See Taylor's *Ancient and Modern Geometry of Conics*, p. 3, etc.)

The locus of the centres of rectangular hyperbolas passing through three given points. We considered in Chap. I (Ex. 18) the locus of poles of a given line in regard to all conics passing through four given points, say, *A*, *B*, *C*, *D*. We found that it is a conic whose intersections with the line are two points, *I* and *J*, which are conjugate in regard to all conics passing through *A*, *B*, *C*, *D*; and we specified nine other points thereon, namely, first, the three intersections of the line pairs passing through these four points, and, second, the points, each on the join of two of these points, harmonic, in regard to these two points, to the point in which the join meets the given line *IJ*. When we take the points *I*, *J* as absolute points, each of the points *A*, *B*, *C*, *D* is the orthocentre of the other three, and the conics passing through these four points are rectangular hyperbolas. We thus have the result that, the locus of the centres of the rectangular hyberbolas which pass through three given points A, B, C (and therefore, also, through the orthocentre, D, of these) is a circle, which contains the three points where AD, BD, CD, respectively, meet BC, CA, AB, and contains, also, the middle points, in regard to the line IJ, of each of the six pairs of points, BC, CA, AB, AD, BD, CD. This is usually called the nine points circle of A, B, C. It is, however, equally the nine points circle of any three of the four points A, B, C, D.

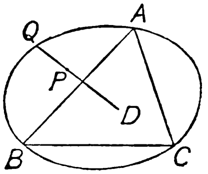
The nine points circle can however be defined as the locus of the middle point, in regard to the line IJ, of the points D, Q, where Q is any point of the circle A, B, C, the point D being the orthocentre of A, B, C.



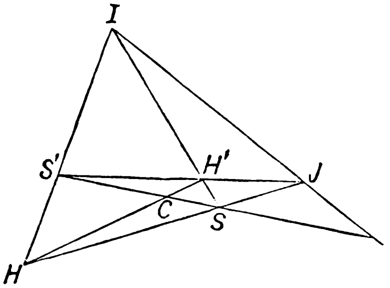


It is, in fact, the case that if a variable line be drawn, through a fixed point, D, to meet a given circle in P and P', and a point Q be taken on DP, such that P is the middle point of DQ in regard to the line IJ, then the locus of Q is another circle. This contains the point, Q', of the line DPP', which is such that P' is the middle point of DQ'; and, if the centre of the given circle be N, the tangents of the new circle at I, J meet in a point O on ND such that IO, ID are harmonic in regard to IJ and IN, namely N is the middle point of DO. To prove the result, let DI, DJ meet the original circle in L, M, respectively; take U harmonically conjugate to D, in regard to I and L, and take V similarly on DJ, in regard to J and M. Then QU, PL meet, in X, on IJ; and QV, PM meet, in Y, on IJ. Thus the pencil, of fixed centre U, denoted by $U(Q)$, is related to the range (X), and, thence, to the pencil $L(P)$; this last is related to $M(P)$, and, thence, to $V(Q)$. Thus the locus of Q is a conic containing U and V. In the same way UQ', LP' meet, in X', on IJ, and VQ', MP' in Y'; and the proof of the statement may be completed.

If the given circle be the nine points circle of A, B, C, of which D is the orthocentre, the point Q, as P describes the nine points circle, describes a circle. We have seen however that the nine points circle passes through the middle points of DA, DB, DC; the new circle thus passes through A, B, C. Thus the suggested definition of the nine points circle is justified; and we see that its centre, N, is the middle point of D and O, where O is the centre of the circle A, B, C. The point P, of the nine points circle, is the centre of a rectangular hyperbola containing A, B, C; this hyperbola, as it contains D, also passes through Q. Three other points of this hyperbola can be assigned, lying respectively on AP, BP, CP. [Add.]



The polars of a point in regard to a system of confocal conics touch a parabola. The theorem obtained from the dually corresponding figure deserves mention also. The polars of a point in regard to a system of conics touching four given lines envelope a conic, of which eleven tangents can be easily assigned.



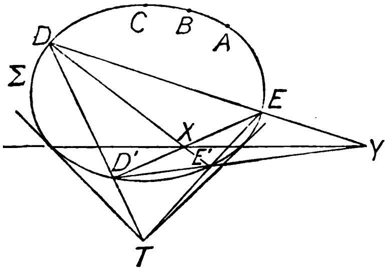
Let the point pairs through which the four lines pass be the absolute points I, J, together with the pairs S, S' and H, H'. The conics are then a system of confocals in regard to I and J, whose pairs of conjugate foci are S, S' and H, H', their common centre being the intersection, C, of the axes SS' and HH'. Denote the fixed point by O.

Then three of the eleven tangents of the envelope are, by what has been seen above, the line IJ, and the lines CS, CH; thus the envelope is a parabola touching the axes of the confocal conics. And, as these axes are at right angles, in regard to I and J, the directrix of the parabola passes through the common centre, C. Two other tangents of the envelope are the tangents at O of the two confocals which pass through O; these tangents, being harmonic in regard to OI, OJ, are at right angles, and the directrix of the parabola passes through O. Other six tangents of the envelope are lines passing through the points I, J, S, S', H, H', in which the four given lines intersect; to find the line in question through one of these six points, we are to join this point to O, and take the harmonic conjugate of this join, in regard to the two of the four given lines which meet in the point selected. In particular, let Q be the point such that, IQ, IO are harmonic in regard to IS, IH, while JQ, JO are harmonic in regard to JS', JH; then QI, QJ are tangents of the envelope, and Q is the focus of this. This point Q is the conjugate of O in regard to all conics through the four foci S, S', H, H'.

Now let Σ denote a particular one of the confocal conics, and let one of the four common tangents, of Σ and the parabola, touch Σ in P; as this tangent touches the parabola there is one of the confocal conics in regard to which O is the pole of this line. On the other hand, the poles of this tangent in regard to all the confocals lie on a line, through P, at right angles to the tangent, this new line being conjugate to the tangent in regard to all the confocals, and, in particular, in regard to the point pair I, J. (Chap. I, Ex. 15.) Wherefore, OP is the line drawn through P at right angles to the tangent at P, which is called the normal at P. It is thus possible to draw through O four normals to the particular conic Σ.

If we take the poles, in regard to this particular conic Σ, of all the tangents of the parabola, these lie upon another conic, the polar reciprocal (p. 47) of the parabola in regard to Σ. This new conic evidently contains the four points of Σ, such as P, whereat the normal of Σ passes through O. It is easy to see that it is a rectangular hyperbola, containing the centre C of all the confocal conics, and the point O, and the points of the line IJ which lie upon the axes, CS, CH, of the confocal conics. The lines CS, CH, IJ are in fact tangents of the parabola, and their poles, in regard to Σ, are three of the points spoken of; the point O is, by definition of the parabola, the pole of a tangent of this, in regard to Σ. That the four normals to a conic, Σ, from a point O, can be constructed by this rectangular hyperbola, was known to Apollonius (Conics, Lib. V, Props. 58–63); we consider the theorem again below (p. 93).

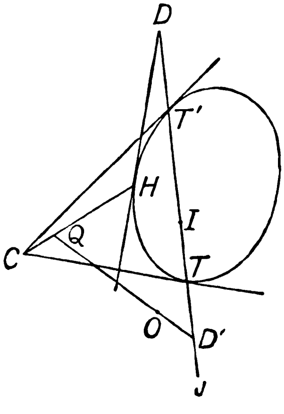
A particular theorem. For clearness we give here a particular result which will be found to be of interest.



Let A, B, C, D be any four points, and X, Y two points which are conjugate to one another in regard to all conics passing through these. Take one such conic, say, Σ, and let T be the pole of XY in regard to Σ. Let TD meet Σ again in D'. We prove that the six points A, B, C, X, Y, D' lie on a conic. The theorem has already been proved (above, p. 89). For, with X, Y as the absolute points, the point D is the orthocentre of A, B, C, and the conic Σ is a rectangular hyperbola of which T is the centre; the conic A, B, C, X, Y is the circle A, B, C, which was proved to meet the rectangular hyperbola in a point D', such that T is the middle point of DD' in regard to the line XY, as here. But we give another proof. If the lines YD, YD' meet the conic Σ, again, in E and E', respectively, the lines DD', EE' meet on the polar of Y, in T; and the lines DE', $D'E$ meet on the polars of Y and T, at X. As DB, AC meet the line XY in two points harmonic in regard to X and Y, as, likewise, do DC, AB, the pencils, $D\,(X, Y, B, C)$ and $A\,(X, Y, C, B)$, are related; the former is the pencil $D\,(E', E, B, C)$, which is related to the pencil $D'\,(E', E, B, C)$ or $D'\,(Y, X, B, C)$, which is related to $D'\,(X, Y, C, B)$. This is therefore related to $A\,(X, Y, C, B)$. Thus the points D', A, X, Y, C, B lie on a conic.

Conversely, let two conics, Σ, Σ', intersect in A, B, C, D', and a chord, XY, of one conic, Σ', meet the other conic, Σ, in two points harmonic in regard to X and Y; and let the line joining the pole, T, of this chord, in regard to Σ, to one of the four common points, D', of the two conics, meet Σ again in D. Then the points X, Y are conjugate to one another in regard to all conics through A, B, C, D. Wherefore, if I, J be any two points of the line XY which are harmonic in regard to X and Y, a conic can be drawn through A, B, C, D, I, J.

From this, if we regard I, J as the absolute points, in which case the conic Σ' is a rectangular hyperbola, we have the theorem that, if a conic, Σ, of centre T, be met by a rectangular hyperbola, Σ', which meets the line IJ in two points which are conjugate in regard to the conic Σ, and meets Σ in A, B, C, D'; and D be the other point in which TD' meets Σ; then the four points A, B, C, D lie on a circle. We shall see that this result is, particularly, of interest when A, B, C are such that the rectangular hyperbola contains the centre, T.

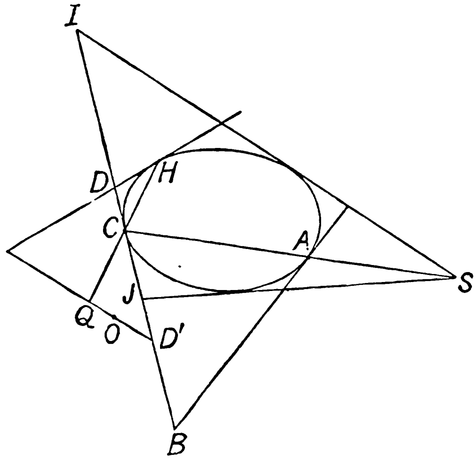


The normals of a conic which pass through a given point. Let O be any fixed point, and H a variable point of a given conic. Let C be the centre of the conic. If through O the line be drawn which is at right angles to the tangent at H, and this line meet CH in Q, we consider the locus of Q as H varies. If QO meet the line IJ in D', and the tangent at H meet the line IJ in D, so that D, D' are harmonic conjugates in regard to I and J, the pencil $O(Q)$, or $O(D')$, is related to the range (D), on the line IJ. The line CH, through the pole, C, of the line IJ, and through the point of contact, H, of a tangent from D, is, however, the polar of D; the line CH meets IJ in a point which is the harmonic of D in regard to the points, T and T', in which the line IJ meets the conic. Thus the pencil $C(Q)$, or $C(H)$, is related to the range (D), and, hence, to the pencil $O(Q)$. Therefore the locus of Q is a conic, passing through the centre C, and the point O. If the axes of the conic meet IJ in A and B, these points are harmonic conjugates both in regard to T, T' and in regard to I, J. Thus, when D is at A, the line CH goes through B, and the point D' is at B; in this case Q is at B. The conic locus of Q is thus a rectangular hyperbola, containing both A and B.

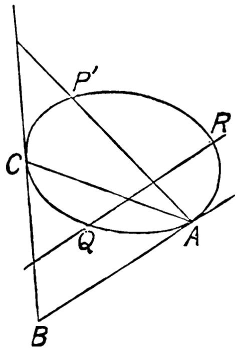
At a position of Q which is on the given conic, and coincides with H, the line OQ is at right angles to the tangent of the given conic at Q, namely is the normal at Q. The four normals of the given conic, which pass through O, are then the normals of this conic at the points where it is met by the rectangular hyperbola.

It follows from what is said in the last section that, if these be the points Q_1, Q_2, Q_3, Q_4, and CQ_4 meet the given conic again in Q', then the points Q_1, Q_2, Q_3, Q' lie on a circle.

The preceding construction remains valid when the given conic is a parabola, touching the line IJ at C. If then, S being the focus, the line SC meet the parabola again in A, and the tangent at A meet the line IJ in B, the locus of Q passes through O and C, but also passes through B, and has the line CS for its tangent at C. As B is the pole of CS, and C, B are harmonic conjugates in regard to I, J, the locus of Q is still a rectangular hyperbola. To see that it passes through B, we have only to take H at C; then D is at C, and D' is at B; to see that it has CS for its tangent at C, we have only to take H at A, in which case D is at B and D' is at C; so that the ray CA of the pencil $C(Q)$ corresponds to the ray OC of the pencil $O(Q)$. In this case, one of the four normals through O is always OC; and there are three others.



If OP, OQ, OR be these normals, it can be shewn, in this case, that the circle P, Q, R passes through A. For take P' on the given parabola, such that AP' and QR meet the line IJ in points which are harmonic in regard to C and B. As the parabola itself, touching IJ at C, has also this property, it follows, by considering the involution on the line CB by all conics through A, Q, R, P', that each of the line pairs AQ, RP' and AR, $P'Q$ also meets IJ in a pair of points which are harmonic in regard to C and B. Thus the pencil $P'(C, B, R, Q)$ is related to the pencil $A(C, B, Q, R)$; this, however, is related to the pencil of lines joining any point of the parabola to C, A, Q, R, and, thus, to the pencil $C(B, A, Q, R)$, and, therefore, to the pencil $C(A, B, R, Q)$. As, then, the pencils $P'(C, B, R, Q)$, $C(A, B, R, Q)$ are related, we can infer that a conic constructed to pass through P', Q, R, C, B has CA for its tangent at C. Conversely, then, the rectangular hyperbola containing the points of the parabola whereat the normals pass through O, having been shewn to contain Q, R, C, B and to have CA for its tangent at C, must pass through P'; so that P' is the same as P. We thus infer that any conic through P, Q, R, A meets the line IJ in points which are harmonic in regard to C and B; or, conversely, that the conic through P, Q, R, and any two points of the line CB which are harmonic in regard to C and B, passes through A. Of such conics, the circle P, Q, R is one; for we have seen that C, B are harmonic in regard to I and J.

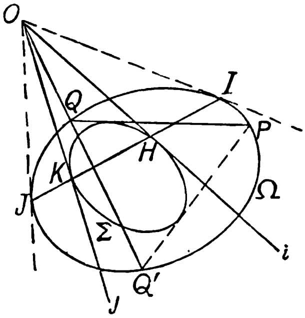


Ex. 1. Prove that an arbitrary given line is a normal of one conic of a given confocal system. If this line be normal at P, and meet this conic again in P', and if it meet another conic of the confocal system at Q and Q', prove that the normals of this other conic, at Q and Q', meet on the tangent at P', of the former conic.

Ex. 2. The dual conception to a normal of a conic is found by taking two arbitrary fixed lines i and j, and finding, upon a variable tangent of the conic, which touches this at P, the point P', which is the harmonic conjugate of P in regard to i and j. Prove that the locus of P' is a curve which meets an arbitrary line in four points, passes twice through the point of intersection of the lines i, j, and twice through each of two other points, which lie on the polar, in regard to the conic, of this point of intersection.

The dual of the director circle of a conic. The tangents to a conic from a point of the director circle are such as meet the fixed line IJ in a pair of an involution of points on this line, of which I, J

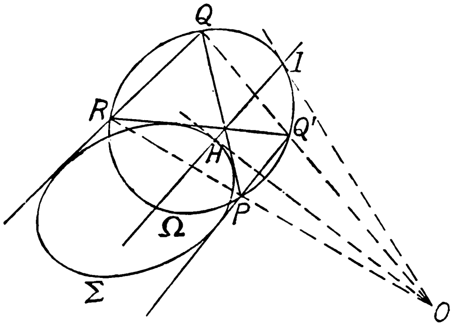
are the double points. Dually, if, from a given point, be drawn a pair of lines, belonging to an involution, and one of the points of intersection, with a given conic, of one of these lines, be joined to one of the intersections of the other line, then the join of the two intersections envelopes another conic. If i, j be the double rays of the involution, the tangent of this second conic is any line whose intersections with the given conic are harmonic in regard to its intersections with the given lines i and j.



In fact both the constructions, that for the director circle, and that we have now described, arise in the same figure. Let the points P, Q, of a given conic, Ω, be such that the lines, OP, OQ, joining them to a fixed point O, are a pair of a pencil in involution, of which the lines, i, j, passing through O, are the double rays. Thus the line PQ is met by the lines i, j, respectively, in two points which are conjugate in regard to the conic Ω. Now, to any point on the line i, there may be made to correspond the point of the line j, which is conjugate to the former in regard to the conic Ω; as these two points describe, on i and j, respectively, two ranges which are related, the line which joins them envelops a conic, say, Σ. This conic touches the lines i and j, say, in H and K, respectively. It also touches the four tangents, of the conic Ω, at the points where Ω is met by the lines i and j. If OQ meet Ω again in Q', the conic Σ also touches PQ'. And, if the other possible tangents be drawn to Σ from Q and Q', these meet, on the conic Ω, in the further point of the line OP which lies on Ω. Further, by considering the position of the line PQ in which it coincides with the line i, we see that O, H are conjugate to one another in regard to Ω; as, likewise, are O and K; thus HK is the polar of O in regard to Ω, meeting Ω at points, I, J, whereat the tangents pass through O. From this we infer that the lines PI, PJ are conjugate to one another in regard to the conic Σ. The conic Ω is thus the director circle of Σ in regard to the points I, J; while Σ is the dual of the director circle of Ω in regard to the lines i and j. (Cf. the diagram on p. 96.)

It is seen that P, Q, Q' is a triad of points, on the conic Ω, of which two joins PQ, PQ' touch the conic Σ, while the third join QQ' passes through one point, O, of the self-polar triad common to Ω and Σ. Similarly, if the second tangent to Σ from Q' meet Ω in R, then RQ, QP, PQ' is a triad of three tangents of Σ, two of whose intersections, Q and P, lie on Ω, while the third, the intersection of RQ and PQ', lies on the line, HI, of the common self-polar triad of

Ω and Σ. The tetrad P, Q, R, Q', of points of Ω, is such that the joins of these, taken in order, are tangent lines of Σ.



Conversely, if any two conics, Ω, Σ, be such that there exists a tetrad of points, P, Q, R, Q', of Ω, whose four joins, when the points are taken in order, are tangents of Σ, the diagonals PR and QQ' meet in one point of the common self-polar triad of the two conics; and there is then an infinite number of such tetrads of points. A sufficient condition for this relation is that the tangents of Σ, at two of its intersections with Ω, should meet in a point lying on Ω. Particular examples of two conics in this relation are, (1) Two circles Ω, Σ, of which Ω contains the centre of Σ, (2) A circle Ω passing through a pair of conjugate foci of Σ, (3) A circle Ω and a conic Σ which is the envelope of a chord PQ of Ω which subtends a right angle at a fixed point (not lying on Ω). In this last case, the middle point of P, Q describes a circle whose centre is the middle point of the two points constituted by O and the centre of Ω. [Cf. p. 56; also Add.]

CHAPTER III

THE EQUATION OF A LINE, AND OF A CONIC

Preliminary remarks. All the properties of conics so far given have been proved without the use of the symbols; and the same plan could be carried out to the end. For many of these properties it is, at present, more usual to give either a proof with the help of the symbols, or a proof by the metrical methods of what is called elementary geometry, in which, to a segment, or to an angle, a number is associated called its measure. We shall see that this metrical geometry can be regarded as an abbreviated use of algebraical symbols; it is, moreover, in the writer's view, in virtue of the system of symbols which it presupposes, founded on an arbitrary limitation of the geometrical possibilities. There is, therefore, logical interest in shewing that the symbols are not necessary; and in finding, if, for practical reasons, it is desired to reach the usual geometrical results, what are the narrowest geometrical limitations sufficient for this. But the employment of the symbols, by fixing the ideas, often renders a demonstration easier to follow. Moreover it happens that, since the time of Descartes, much labour has been devoted to elaborating systematic methods of algebraic computation; and, thus, methods which, from a geometrical point of view, are highly artificial, have come to be regarded as more natural.

The coordinates of a point in a plane. If A, B, C be three given points in a plane, not lying in line, of which the symbols are also represented by A, B, C, any other point in the plane has a symbol of the form $xA+yB+zC$, wherein x, y, z are algebraic symbols, of the system employed. These we suppose commutative in multiplication. If the point be specified for which the symbol is $A+B+C$, the symbols x, y, z are definite when P is assigned, save that they may be replaced, respectively, by mx, my, mz, where m is any symbol other than 0; thereby the symbols $x^{-1}y$, $x^{-1}z$ would be unaffected. The aggregate (x, y, z) are then called the coordinates of P, in regard to A, B, C, it being understood that (mx, my, mz) are equally the coordinates of P.

If we take any other three points, A', B', C', not lying in line, we may, similarly, specify the coordinates of all points of the plane in terms of these. In particular, if A, B, C be given in terms of these by the respective syzygies

$$A=a_1A'+a_2B'+a_3C',\quad B=b_1A'+b_2B'+b_3C',$$
$$C=c_1A'+c_2B'+c_3C',$$

the symbol for P, with respect to A', B', C', becomes

$$x(a_1A' + a_2B' + a_3C') + y(b_1A' + b_2B' + b_3C') + z(c_1A' + c_2B' + c_3C'),$$

or, say, $$x'A' + y'B' + z'C',$$

where

$$x' = a_1x + b_1y + c_1z, \quad y' = a_2x + b_2y + c_2z, \quad z' = a_3x + b_3y + c_3z.$$

The coordinates are thus changed by a linear transformation.

There can be no objection to agreeing to represent the relations involved, respectively, by

$$(A, B, C) = \left|\begin{matrix} a_1, & a_2, & a_3 \\ b_1, & b_2, & b_3 \\ c_1, & c_2, & c_3 \end{matrix}\right| (A', B', C'), \quad (x', y', z') = \left|\begin{matrix} a_1, & b_1, & c_1 \\ a_2, & b_2, & c_2 \\ a_3, & b_3, & c_3 \end{matrix}\right| (x, y, z);$$

herein the matrix of transformation by which we pass from the coordinates, x, y, z, to the new coordinates, x', y', z', is obtained from that by which we pass from the *new* points of reference, A', B', C', to the *original* points of reference, A, B, C, by the change, often called transposition, of rows into columns. This is often expressed by saying that (x, y, z) and (A, B, C) are transformed *contragrediently*.

The equation of a line. Let two points which determine a line be of respective symbols

$$P_1 = x_1A + y_1B + z_1C, \quad P_2 = x_2A + y_2B + z_2C;$$

any other point of the line is then of symbol $P_1 + \lambda P_2$, and has coordinates $x_1 + \lambda x_2$, $y_1 + \lambda y_2$, $z_1 + \lambda z_2$. Now consider the three symbols

$$u = y_1z_2 - y_2z_1, \quad v = z_1x_2 - z_2x_1, \quad w = x_1y_2 - x_2y_1;$$

we notice, first, that these are unaffected, save by multiplication with the same factor, if (x_1, y_1, z_1), (x_2, y_2, z_2) be, respectively, replaced by the coordinates, (x_1', y_1', z_1'), (x_2', y_2', z_2'), of any other two points of the line; thus, when the line is given, the symbols u, v, w are determined, save for a common multiplier; then we notice that, if (x, y, z) be the coordinates of any point whatever, of the line, we have

$$ux + vy + wz = 0;$$

finally, if u, v, w be given, any point whose coordinates (x, y, z) satisfy this equation, is a point of the line. For, (x_1, y_1, z_1), (x_2, y_2, z_2) being two points of the line, this equation, coupled with

$$ux_1 + vy_1 + wz_1 = 0, \quad ux_2 + vy_2 + wz_2 = 0,$$

enables us to infer that there are two symbols λ_1, λ_2 such that

$$x = \lambda_1x_1 + \lambda_2x_2, \quad y = \lambda_1y_1 + \lambda_2y_2, \quad z = \lambda_1z_1 + \lambda_2z_2.$$

The equation $$ux + vy + wz = 0,$$
wherein u, v, w are given (save for a common multiplier), and x, y, z have any values for which the equation is verified, being the relation satisfied by the coordinates of all points of the line, and by no other points, is called the *equation of the line.*

The coordinates of a line. The three symbols u, v, w, which, as we have seen, determine a line, are called the *coordinates of the line.* If m be any algebraic symbol, other than 0, the symbols mu, mv, mw are equally the coordinates of the line.

In particular, the coordinates of the fundamental points B, C, being, respectively, $(0, 1, 0)$ and $(0, 0, 1)$, the coordinates of the line BC, joining these, are $(1, 0, 0)$. If, then, we represent the *lines* BC, CA, AB, respectively, by the symbols $\mathrm{a}, \mathrm{b}, \mathrm{c}$, we may regard the line whose coordinates are u, v, w as represented by the symbol

$$l = u\mathrm{a} + v\mathrm{b} + w\mathrm{c}.$$

This is analogous to the representation of any point of the plane by means of the three fundamental points A, B, C. The analogy extends further. For we can shew that if l_1, l_2 be the symbols of any two lines, the symbol, formed in the same way, for any line through the intersection of these two, is of the form $pl_1 + ql_2$. To this end, let (x_0, y_0, z_0) be the coordinates of the point of intersection, O, of the lines, (x_1, y_1, z_1) of any other point of the first line, and (x_2, y_2, z_2) of any other point of the second line. Any line through O is determined by O and a point, say P, not lying on either of the two given lines; if we put

$$O = x_0A + y_0B + z_0C, \quad P_1 = x_1A + y_1B + z_1C, \quad P_2 = x_2A + y_2B + z_2C,$$

we can suppose the symbol of P to be

$$P = \xi O + \eta P_1 + \zeta P_2;$$

thus, if P be $xA + yB + zC$, we have

$$x = \xi x_0 + \eta x_1 + \zeta x_2, \quad y = \xi y_0 + \eta y_1 + \zeta y_2, \quad z = \xi z_0 + \eta z_1 + \zeta z_2,$$

and these give

$$yz_0 - y_0z = \eta(y_1z_0 - y_0z_1) + \zeta(y_2z_0 - y_0z_2),$$

with similar expressions for $zx_0 - z_0x$ and $xy_0 - x_0y$. Therefore, in terms of the coordinates of the two given lines, the coordinates of the line OP are

$$\eta u_1 + \zeta u_2, \quad \eta v_1 + \zeta v_2, \quad \eta w_1 + \zeta w_2,$$

and the symbol for this line is, therefore,

$$(\eta u_1 + \zeta u_2)\,\mathrm{a} + (\eta v_1 + \zeta v_2)\,\mathrm{b} + (\eta w_1 + \zeta w_2)\,\mathrm{c},$$

or $$\eta l_1 + \zeta l_2.$$

The analogy between the expression of any point in terms of three points, and of any line in terms of three lines, is, thus, complete. And, as in the former case, so in the latter, when the symbols, a, b, c, of three fundamental lines are given, in order to specify without ambiguity the symbol of any other line, it is necessary to specify the symbol of some one fourth definite line beside a, b, c; we may, in particular, specify the line of which the symbol is a + b + c.

The equation of a point. We introduced the equation of a line as the equation satisfied by the coordinates of all points of the line. From what has just been said, we may, similarly, speak of the equation of a point, this being the equation satisfied by the coordinates of all the lines which contain this point. Clearly, if the point be of coordinates (x_0, y_0, z_0), the equation of the point will be

$$ux_0 + vy_0 + wz_0 = 0,$$

where u, v, w are variable line coordinates. For the sake of distinctness, the coordinates of a line are often called the *tangential* coordinates, and the equation of a point, its *tangential* equation.

And, just as the coordinates of the line joining the two points, whose coordinates are (x_1, y_1, z_1) and (x_2, y_2, z_2), are

$$u = y_1z_2 - y_2z_1, \quad v = z_1x_2 - z_2x_1, \quad w = x_1y_2 - x_2y_1,$$

so the coordinates of the point, which is the intersection of the lines of coordinates (u_1, v_1, w_1) and (u_2, v_2, w_2), are

$$x_0 = v_1w_2 - v_2w_1, \quad y_0 = w_1u_2 - w_2u_1, \quad z_0 = u_1v_2 - u_2v_1.$$

For, if (x_1, y_1, z_1) and (x_2, y_2, z_2) be the coordinates of two points, one on each line, the coordinates u_1, v_1, w_1 are the cofactors of x_2, y_2, z_2, respectively, in the determinant

$$\begin{vmatrix} x_0, & y_0, & z_0 \\ x_1, & y_1, & z_1 \\ x_2, & y_2, & z_2 \end{vmatrix},$$

and u_2, v_2, w_2 are, similarly, the cofactors of x_1, y_1, z_1, respectively. If we form the determinant whose elements are the minors of this determinant, the minors of the new determinant are known to be proportional to the elements of this one; this gives the statement made.

Thus, instead of regarding the symbols of the *points* of a plane as being fundamental, we might equally well have regarded the symbols of the *lines* as fundamental. Or, if we regard the *coordinates* as fundamental, we may regard that which we have from the first spoken of as the symbol of a point, as being, in fact, that expression, linear in undetermined line coordinates, which occurs above as the first member, or left side, of the equation of a point.

The equation of a conic. That the coordinates of any point of a line are connected by an equation may be regarded as a consequence of the fact that these coordinates are functions of a varying parameter, that is, of the forms

$$x = \theta x_1 + x_2, \quad y = \theta y_1 + y_2, \quad z = \theta z_1 + z_2,$$

wherein θ varies from point to point of the line. Now, we have shewn (Chap. I, above) that the symbol of any point of a non-degenerate conic is of the form

$$P = \theta^2 A + \theta B + C,$$

A, C being any two points of the conic, and B the pole of AC in regard to the conic; with reference to these points, the coordinates of any point of the conic are, then, $x = \theta^2$, $y = \theta$, $z = 1$. Thus every point of the conic is such that its coordinates satisfy the equation

$$xz = y^2.$$

With reference, however, to any three general points of the plane, A', B', C', which are not in line, the coordinates of a point of the conic, by what we have seen above, will be of the forms

$$x' = a_1\theta^2 + b_1\theta + c_1, \quad y' = a_2\theta^2 + b_2\theta + c_2, \quad z' = a_3\theta^2 + b_3\theta + c_3,$$

wherein the coefficients $a_1, b_1, \ldots, c_3$ remain the same, but θ varies from point to point of the conic. As we suppose that the conic does not degenerate into two straight lines, so that there is no relation of the form $Lx' + My' + Nz' = 0$, holding for all values of θ, these equations lead to equations

$$\theta^2 = A_1x' + A_2y' + A_3z', \quad \theta = B_1x' + B_2y' + B_3z', \quad 1 = C_1x' + C_2y' + C_3z',$$

and, hence, to

$$(A_1x' + A_2y' + A_3z')(C_1x' + C_2y' + C_3z') = (B_1x' + B_2y' + B_3z')^2.$$

Thus, referred to any three general points of the plane, the coordinates of all the points of a conic satisfy a homogeneous equation of the second order.

Conversely, any such equation, say

$$ax^2 + by^2 + cz^2 + 2fyz + 2gzx + 2hxy = 0,$$

connecting the coordinates x, y, z of a point, involves that the point lies on a definite conic. This we now prove:

(*a*) The quadric expression on the left side of this equation may be the product of two factors, both linear in x, y, z, being identically equal, say, to

$$(l_1x + m_1y + n_1z)(l_2x + m_2y + n_2z),$$

for all values of x, y, z. When this is so, by forming the partial differential coefficients in regard to x, y, z, we see that all the three linear functions of x, y, z given by

$$ax + hy + gz, \quad hx + by + fz, \quad gx + fy + cz$$

vanish for the same set of values of x, y, z, namely for that set of values which satisfies both the equations

$$l_1x + m_1y + n_1z = 0, \quad l_2x + m_2y + n_2z = 0;$$

for the moment we suppose that the lines of which these last are the equations are not the same. The simultaneous vanishing of the three linear functions requires, however, that the determinant

$$\Delta, = \begin{vmatrix} a, & h, & g \\ h, & b, & f \\ g, & f, & c \end{vmatrix},$$

should vanish. And, conversely, it will appear that it is easy to prove that when this determinant vanishes, the quadric expression, on the left side of the given equation, necessarily breaks up into the product of two linear factors. These two factors may be the same; but, then, there are other conditions connecting the coefficients $a, b, c, \ldots$; in fact the minors, of two rows and columns, in Δ, also vanish. Also, it is true that if the given quadric equation is satisfied by the coordinates of every point of a line, say, the line of which the equation is $L = 0$, where L is linear in x, y, z, then the quadric expression on the left of the equation breaks up into the product of L and another linear factor. For, by ordinary division, we can, if L contain x, write this quadric expression in such a form as

$$LM + A(y - mz)(y - nz),$$

where M is linear in x, y, z, and A, m, n are independent of x, y, z. This cannot be satisfied by every point for which $L = 0$ unless the coefficient A be zero.

(*b*) Now, suppose the determinant Δ is not zero. Let P_1, P_2 be any two points whose coordinates satisfy the given equation. From the fact that the given equation is of the second order, it can be shewn that every line drawn through P_1 contains another point, say P, whose coordinates also satisfy the given equation, so that there is associated to every line drawn through P_1, a definite line through P_2, joining this to P. If the coordinates of P_1 and P_2 be, respectively, (x_1, y_1, z_1) and (x_2, y_2, z_2), the equations of lines through P_1 and P_2, respectively, are of the forms

$$yz_1 - y_1z = \theta(xz_1 - x_1z), \quad yz_2 - y_2z = \phi(xz_2 - x_2z),$$

for proper values of θ and ϕ. By what we have seen, to every θ we can associate a definite ϕ, and conversely. Thus (cf. the Preliminary remarks to this volume, p. 8, above), the pencils $P_1(P)$ and $P_2(P)$ are related. Therefore P describes a conic in accordance with our original definition.

(*c*) We may reach this conclusion more directly, as follows: Let the quadric expression on the left side of the given equation be denoted by F, and the results of substituting therein, for x, y, z, respectively x_1, y_1, z_1 and x_2, y_2, z_2, by F_1 and F_2; let p, q, r denote, respectively, $ax+hy+gz$, $hx+by+fz$, $gx+fy+cz$, and p_1, q_1, r_1 what these become when x_1, y_1, z_1 are put for x, y, z, with, similarly, p_2, q_2, r_2, when x_2, y_2, z_2 are put for x, y, z; we then have

$$x_1p_2+y_1q_2+z_1r_2=x_2p_1+y_2q_1+z_2r_1,$$

either of these being the same as

$$ax_1x_2+by_1y_2+cz_1z_2+f(y_1z_2+y_2z_1)+g(z_1x_2+z_2x_1)+h(x_1y_2+x_2y_1),$$

which we denote by F_{12}. If we now put

$$X=xp_1+yq_1+zr_1, \quad Z=xp_2+yq_2+zr_2,$$
$$Y=x(y_1z_2-y_2z_1)+y(z_1x_2-z_2x_1)+z(x_1y_2-x_2y_1),$$

and suppose the points (x_1, y_1, z_1), (x_2, y_2, z_2) to satisfy the given equation $F=0$, so that both F_1 and F_2 vanish, we can shew that, for all values of x, y, z, the equation $F=0$ is the same as

$$XZ-\mu Y^2=0,$$

where $\mu=\frac{1}{2}\Delta/F_{12}$. For, whatever x_1, y_1, z_1 and x_2, y_2, z_2 may be, we have, by multiplication of determinants, the product

$$\begin{vmatrix} x, & y, & z \\ x_1, & y_1, & z_1 \\ x_2, & y_2, & z_2 \end{vmatrix} \begin{vmatrix} x, & y, & z \\ x_1, & y_1, & z_1 \\ x_2, & y_2, & z_2 \end{vmatrix} \begin{vmatrix} a, & h, & g \\ h, & b, & f \\ g, & f, & c \end{vmatrix}$$

equal to

$$\begin{vmatrix} x, & y, & z \\ x_1, & y_1, & z_1 \\ x_2, & y_2, & z_2 \end{vmatrix} \begin{vmatrix} p, & q, & r \\ p_1, & q_1, & r_1 \\ p_2, & q_2, & r_2 \end{vmatrix},$$

and, hence, equal to

$$\begin{vmatrix} F, & X, & Z \\ X, & F_1, & F_{12} \\ Z, & F_{12}, & F_2 \end{vmatrix};$$

namely, we have the identity,

$$Y^2\Delta=F(F_1F_2-F_{12}^2)+2XZF_{12}-F_1Z^2-F_2X^2.$$

When we substitute for x, y, z, in F, respectively, $x_1+\lambda x_2, y_1+\lambda y_2, z_1+\lambda z_2$, the result is $F_1+2\lambda F_{12}+\lambda^2F_2$; we are supposing $F_1=0$, $F_2=0$, and that the line joining (x_1, y_1, z_1) and (x_2, y_2, z_2) does not consist of points all satisfying $F=0$; thus F_{12} does not vanish. The identity obtained thus leads to

$$F_{12}^2F=2F_{12}(XZ-\mu Y^2),$$

where $\mu=\frac{1}{2}\Delta/F_{12}$. Wherefore, the equation $F=0$ is satisfied by all points (x, y, z) which, for any value of θ, satisfy the equations

$$X=\theta^2, \quad \mu Y=\theta, \quad \mu Z=1;$$

thus the equation $F=0$ belongs to a conic, provided the linear functions of x, y, z which we have denoted by X, Y, Z, are independent, that is, provided the lines $X=0$, $Y=0$, $Z=0$ do not meet in a point; and, in fact, $X=0$, $Y=0$ intersect in the point (x_1, y_1, z_1), while $Z=0$, $Y=0$ meet in the distinct point (x_2, y_2, z_2).

A particular form of the equation of a conic. We have seen that, with reference to three points, consisting of any two points of a conic and the pole of the line joining them, the equation of the conic can be supposed to have the form $xz-y^2=0$, any point of the conic having coordinates of the form $(\theta^2, \theta, 1)$. Many results which hold for the general form of the equation can be well illustrated by this case.

(1) Evidently the line represented by the equation

$$x-y(\theta+\phi)+z\theta\phi=0$$

contains both the points $(\theta^2, \theta, 1)$ and $(\phi^2, \phi, 1)$; this is, then, the equation of the chord of the conic. Or, a line represented by the equation $ax+by+cz=0$ meets the conic in two points for which the values of the parameter θ are those given by the equation $a\theta^2+b\theta+c=0$. In particular the tangent of the conic at the point $x'=\theta^2$, $y'=\theta$, $z'=1$ has the equation $x-2y\theta+z\theta^2=0$; it is to be remarked that this is the same as $xz'+x'z-2yy'=0$, and, again, that this is the same as

$$\left(x'\frac{\partial}{\partial x}+y'\frac{\partial}{\partial y}+z'\frac{\partial}{\partial z}\right)(xz-y^2)=0.$$

From this remark we can at once find the equation of the tangent at any point of the conic represented by the general equation

$$aX^2+bY^2+cZ^2+2fYZ+2gZX+2hXY=0;$$

for, if X, Y, Z be any linear functions of x, y, z, say

$$X=a_1x+b_1y+c_1z,\quad Y=a_2x+b_2y+c_2z,\quad Z=a_3x+b_3y+c_3z,$$

and X', Y', Z' be precisely the same linear functions of x', y', z', it is easy to see that

$$X'\frac{\partial}{\partial X}+Y'\frac{\partial}{\partial Y}+Z'\frac{\partial}{\partial Z}=x'\frac{\partial}{\partial x}+y'\frac{\partial}{\partial y}+z'\frac{\partial}{\partial z};$$

now we have shewn that the general equation of the conic, say $F=0$, in variable coordinates X, Y, Z, can, by choosing x, y, z to be suitable linear functions of these, be reduced to the form $xz-y^2=0$. Wherefore, the equation of the tangent, at a point of coordinates X', Y', Z', is

$$\left(X'\frac{\partial}{\partial X}+Y'\frac{\partial}{\partial Y}+Z'\frac{\partial}{\partial Z}\right)F=0.$$

This, however, can be obtained, also, as follows: The point

(X', Y', Z') being upon the conic, and (X, Y, Z) being any other point, the point $(X' + \lambda X, Y' + \lambda Y, Z' + \lambda Z)$, on the line joining these, lies upon the conic, $F = 0$, if

$$\lambda^2 F + \lambda \left(X' \frac{\partial F}{\partial X} + Y' \frac{\partial F}{\partial Y} + Z' \frac{\partial F}{\partial Z}\right) + F' = 0,$$

where F' is what F becomes when X', Y', Z' are written for X, Y, Z, and is therefore zero. The equation will be satisfied by $\lambda = 0$ only, and the line joining (X', Y', Z') to (X, Y, Z) will meet the conic only at (X', Y', Z'), if, and only if, (X, Y, Z) satisfy the equation which we have given as the equation of the tangent at (X', Y', Z').

We can hence infer the equation of the polar of a point in regard to a conic. For the equation just obtained for the tangent is symmetrical in regard to (X, Y, Z) and (X', Y', Z'). Therefore, if the tangents of the conic at the points (x_1, y_1, z_1) and (x_2, y_2, z_2) intersect in the point (ξ, η, ζ), so that we have two equations, arising as expressing this fact, say

$$(x_1, y_1, z_1;\ \xi, \eta, \zeta) = 0, \quad (x_2, y_2, z_2;\ \xi, \eta, \zeta) = 0,$$

each linear in both the two sets of coordinates which it contains, and symmetrical in regard to these two sets, we can infer that the line expressed by the equation

$$(x, y, z;\ \xi, \eta, \zeta) = 0,$$

wherein x, y, z are the coordinates of a varying point, passes through (x_1, y_1, z_1) and (x_2, y_2, z_2). It is thus the polar line of (ξ, η, ζ). Its equation is therefore

$$\left(\xi \frac{\partial}{\partial x} + \eta \frac{\partial}{\partial y} + \zeta \frac{\partial}{\partial z}\right) F = 0,$$

where now, in F, the coordinates x, y, z are written for X, Y, Z. The same result is obtained by regarding the polar as the locus of a point, (x, y, z), which is the harmonic conjugate of (ξ, η, ζ), in regard to the points in which the conic is met by a line through (ξ, η, ζ). For these intersections must then have coordinates of the respective forms $(x + \lambda\xi, y + \lambda\eta, z + \lambda\zeta)$ and $(x - \lambda\xi, y - \lambda\eta, z - \lambda\zeta)$; the quadratic equation for λ which expresses that one of these points satisfies the equation $F = 0$, must then be without the term in λ.

In particular, the polar of the point (ξ, η, ζ), in regard to the conic $xz - y^2 = 0$, is given by the equation $x\zeta + z\xi - 2y\eta = 0$.

With this form for the equation of the conic, the tangent line, whose equation, we have seen, is $x - 2y\theta + z\theta^2 = 0$, has coordinates $u = 1$, $v = -2\theta$, $w = \theta^2$. Wherefore the coordinates of all tangent lines of the conic are such as to satisfy the equation

$$4wu - v^2 = 0.$$

This equation is often called the tangential equation of the conic. In view of what has been said in regard to the point equation, and as to the dual nature of a conic, and from the similarity of the relations for the coordinates of a line and of a point, it is at once clear, (1) that for a conic whose equation is given in general form, the tangential equation must be homogeneously of the second order in the coordinates, u, v, w, of any tangent of the conic, (2) that any such quadric equation connecting u, v, w must be the tangential equation of a conic, becoming a point pair when the equation breaks into two linear factors. But we may prove directly that the condition for the line, whose equation is $ux + vy + wz = 0$, to touch the conic given by

$$ax^2 + by^2 + cz^2 + 2fyz + 2gzx + 2hxy = 0,$$

is $$Au^2 + Bv^2 + Cw^2 + 2Fvw + 2Gwu + 2Huv = 0,$$

where A, B, C, F, G, H are respectively the cofactors of a, b, c, f, g, h in the determinant Δ, so that $A = bc - f^2$, $F = gh - af$, etc. And then, from the well-known determinant identities such as

$$BC - F^2 = a\Delta, \quad GH - AF = f\Delta,$$

we see that we can pass from the tangential equation to the point equation by the same rule as that by which the former equation is deduced from the latter. To prove the statement made, we express that the line $ux + vy + wz = 0$ is the tangent at some point, (x', y', z'), of the conic, so that this equation is of the form

$$x(ax' + hy' + gz') + y(hx' + by' + fz') + z(gx' + fy' + cz') = 0.$$

Whence we have

$$\frac{ax' + hy' + gz'}{u} = \frac{hx' + by' + fz'}{v} = \frac{gx' + fy' + cz'}{w},$$

which, however, lead to

$$\frac{x'}{Au + Hv + Gw} = \frac{y'}{Hu + Bv + Fw} = \frac{z'}{Gu + Fv + Cw};$$

these, when we express that $ux' + vy' + wz' = 0$, give the condition specified.

As examples, the reader may prove the simple facts that the conic whose equation is obtained by rationalising $(fx)^{\frac{1}{2}} + (gy)^{\frac{1}{2}} + (hz)^{\frac{1}{2}} = 0$ has for its tangential equation $fvw + gwu + huv = 0$, the tangent at any point (x', y', z') of the conic having the equation

$$x(f/x')^{\frac{1}{2}} + y(g/y')^{\frac{1}{2}} + z(h/z')^{\frac{1}{2}};$$

this conic touches the joins, BC, CA, AB, of the three points of reference for the coordinates. Dually, the conic, through A, B, C, whose equation is $fyz + gzx + hxy = 0$, has a tangential equation obtainable from $(fu)^{\frac{1}{2}} + (gv)^{\frac{1}{2}} + (hw)^{\frac{1}{2}} = 0$, the tangent at any point (ξ, η, ζ) having the equation $\xi^{-2}fx + \eta^{-2}gy + \zeta^{-2}hz = 0$. [Add.]

We return now again to the equation $xz - y^2 = 0$. Let X, Z be any points of the line AC which are harmonic conjugates in regard to A and C, say, of symbols $mA - C$, $mA + C$, respectively, in terms of the symbols of the points A and C; their coordinates will then be, referred to A, B, C, respectively $(m, 0, -1)$ and $(m, 0, 1)$. The equations of the lines BX, BZ will then be, respectively, $x + mz = 0$ and $x - mz = 0$. Now we have agreed that our system of symbols shall be such that there is a symbol i for which $i^2 = -1$ (Vol. I, p. 165); for this we use always the same sign; the other symbol satisfying the same equation will then be $-i$. This being understood, let

$$\xi = i(x - mz), \quad \zeta = (x + mz), \quad \eta = 2m^{\frac{1}{2}}y,$$

where $m^{\frac{1}{2}}$, as usual, is one of the symbols, t, for which $t^2 = m$. We then have, as another form of the equation $xz - y^2 = 0$, the equation

$$\xi^2 + \zeta^2 = \eta^2;$$

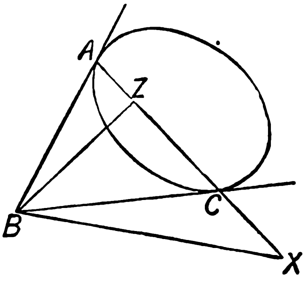
and we have, writing $m^{-\frac{1}{2}}$ for $(m^{\frac{1}{2}})^{-1}$,

$$\begin{aligned} xA + yB + zC &= \tfrac{1}{2}(\zeta - i\xi)A + \tfrac{1}{2}m^{-\frac{1}{2}}\eta B + \frac{1}{2m}(\zeta + i\xi)C \\ &= \frac{\xi}{2im}(mA - C) + \eta\frac{1}{2m^{\frac{1}{2}}}B + \frac{\zeta}{2m}(mA + C). \end{aligned}$$

The triad, B, X, Z, is self-polar in regard to the conic. Conversely, if, in the general equation

$$ax^2 + by^2 + cz^2 + 2fyz + 2gzx + 2hxy = 0,$$

the coordinates are referred to a triad which is self-polar in regard to the conic, we must have $f = 0$, $g = 0$, $h = 0$. For the polar of the point $(1, 0, 0)$, which in general is of equation $ax + hy + gz = 0$, must then be expressed by $x = 0$, with a similar remark for the points $(0, 1, 0)$, $(0, 0, 1)$. If, then, we put $\xi = xa^{\frac{1}{2}}$, $\eta = iyb^{\frac{1}{2}}$, $\zeta = zc^{\frac{1}{2}}$, the equation reduces to $\xi^2 + \zeta^2 = \eta^2$. The algebraic problem of reducing the general equation to this form, equivalent to the problem of finding a self-polar triad of the conic given by the general equation, is solved below (p. 141).



Equation of a circle. In the phraseology of the preceding chapter, with reference to the points A, C, taken as absolute points, the conic is a circle, whose centre is B; the lines BX, BZ are any two lines through its centre which are at right angles to one another in regard to A and C.

If, retaining X, Z as two of the points of reference, we take for the third point, instead of B, another point, B', the equation of the circle takes the form

$$(\xi' - a\eta)^2 + (\zeta' - c\eta)^2 = \eta^2.$$

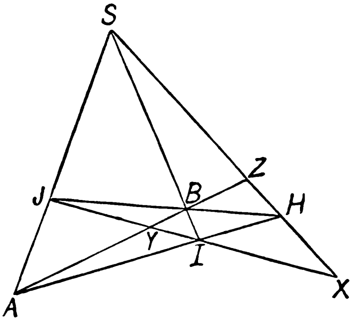
In fact, writing (see p. 107)

$$X_1 = \frac{1}{2im}(mA - C), \quad Z_1 = \frac{1}{2m}(mA + C), \quad B_1 = \frac{1}{2m^{\frac{1}{2}}}B,$$

and taking B' so that

$$B' = B_1 - aX_1 - cZ_1,$$

the symbol of a general point found above, $\xi X_1 + \eta B_1 + \zeta Z_1$, is $(\xi + a\eta) X_1 + \eta B' + (\zeta + c\eta) Z_1$, and this we write in the form $\xi' X_1 + \eta B' + \zeta' Z_1$. The points of reference are now, any point B' of the plane, together with any two points X, Z, on the absolute line AC, which are such that $B'X$, $B'Z$ are at right angles in regard to A and C. The centre of the circle is now the point for which the coordinates ξ', ζ', η are, respectively, a, c, 1.



In further illustration of the point of view adopted in the last chapter, let us now find the equation of a general circle of a coaxial system, that is, of a conic through four given points. Denote these points by I, J, A, B, using I, J as the notation for the two absolute points. The points of intersection, S, H, respectively of AJ, BI and of AI, BJ, are (Chap. II, above, p. 66) the limiting points of the coaxial system of circles. Let AB, IJ meet in Y, also IJ, SH in X, and AB, SH in Z; the triad S, H, Y is self-polar in regard to all conics through I, J, A, B. We refer the circles to the points Z, X, Y, and suppose the symbols so chosen that $I = \frac{1}{2}(X + iY)$, $J = \frac{1}{2}(X - iY)$, as is possible since I, J are harmonic in regard to X and Y.

For any particular one of the circles, let the pole of the line IJ, which lies on XZ, be of symbol $Z + aX$; then, by what we have seen above, the symbol of any point of this circle is expressible, with a parameter θ, in the form

$$\theta^2 I + \theta m (Z + aX) + J,$$

where m is a fixed appropriate symbol. Denoting this by $xX + yY + zZ$, we have

$$x = \tfrac{1}{2}(\theta^2 + 1) + ma\theta, \quad y = \tfrac{1}{2}i(\theta^2 - 1), \quad z = m\theta,$$

which satisfy the equation

$$(x - az)^2 + y^2 = m^{-2}z^2,$$

other circles with the same centre having the same form of equation with a different value for m. But, if the points A, B be $Z \pm hY$, that is, be of coordinates $(0, \pm h, 1)$ with reference to X, Y, Z, this circle passes, by hypothesis, through A, B, and we have $m^{-2} = a^2 + h^2$. The circle may therefore be represented by

$$x^2 + y^2 - 2axz - h^2z^2 = 0,$$

and the other circles of the coaxial system, through A and B, have the same form of equation with a different value for a. The triad of reference for the coordinates, Z, X, Y, is determined by, (1) the line of centres of all the circles, which is the line XZ, (2) the common chord, YZ, of all the circles, (3) the absolute line, XY. The symbol h is such that the common points of the circles are of coordinates $(0, \pm h, 1)$.

The relation, to the points I, J, and the triad X, Y, Z, of the points S, H, is similar to that of A, B. But while A, B have symbols $Z \pm hY$, the symbols of S, H are $Z \pm kX$. Thus the general circle passing through the limiting points S, H has an equation

$$x^2 + y^2 - 2byz - k^2z^2 = 0,$$

where k is the same for all of these, but b varies from circle to circle. Here, as the points J, B, H, which may be supposed to have respective symbols $X - iY$, $Z + hY$, $Z + kX$, are in line, we may suppose $h = ik$; so that the general circle through the limiting points has an equation of the form

$$x^2 + y^2 - 2byz + h^2z^2 = 0.$$

We may now verify, what was proved in Chap. II (p. 66, above), that any one of these circles cuts any one of the coaxial circles at right angles. For this purpose we first obtain the condition that, at a point (x_0, y_0, z_0) where they intersect, two conics should cut at right angles, in regard to I and J, according to the definition we have given for this (Chap. II, p. 63). With regard to the points X, Y, Z, by which the coordinates are defined, we assume only that X, Y are on the absolute line, IJ, and are harmonic in regard to I and J; for these two absolute points, then, we take, as symbols, $X \pm iY$. If the equations of the two conics be, respectively, $\phi = 0$ and $\psi = 0$, and the values, at their common point (x_0, y_0, z_0), of the partial derivatives $\partial\phi/\partial x$, $\partial\phi/\partial y, \ldots, \partial\psi/\partial z$, be denoted, for brevity, by u, v, w, p, q, r, the tangents of these conics, at this point, are, we have seen, of equations $ux + vy + wz = 0$, and $px + qy + rz = 0$. These meet the absolute line, for which $z = 0$, respectively where $ux + vy = 0$ and $px + qy = 0$, that is, at the points whose symbols are $vX - uY$ and $qX - pY$. These symbols, however, are, respectively,

$$(v + iu)(X + iY) + (v - iu)(X - iY),$$
$$(q + ip)(X + iY) + (q - ip)(X - iY),$$

or $$(v + iu) I + (v - iu) J, \quad (q + ip) I + (q - ip) J;$$

the condition that the two tangents should be at right angles, in regard to I and J, is that these points should be harmonic conjugates in regard to I, J, namely, that

$$(v + iu)^{-1}(v - iu) + (q + ip)^{-1}(q - ip) = 0,$$

or $$up + vq = 0;$$

more fully this is, that, at the common point of the conics $\phi = 0$, $\psi = 0$, we should have

$$\frac{\partial\phi}{\partial x}\frac{\partial\psi}{\partial x} + \frac{\partial\phi}{\partial y}\frac{\partial\psi}{\partial y} = 0.$$

Applying this to the case of the circles whose equations are

$$x^2 + y^2 - 2axz - h^2z^2 = 0, \quad x^2 + y^2 - 2byz + h^2z^2 = 0,$$

it becomes $$(x - az)x + y(y - bz) = 0;$$

this is satisfied at each common point of the two circles, as we see by adding their equations.

Incidentally, we have seen that the condition that any two lines

$$ux + vy + wz = 0, \quad px + qy + rz = 0,$$

should be at right angles, in regard to I and J, is $up + vq = 0$.

Examples of the algebraic treatment of the theory of conics. The preceding explanations are probably sufficient to exhibit the application of the algebraic symbols to the theory of conics. We collect together now a succession of illustrations, with, in many cases, omission of detailed discussion. Most of the results obtained will be known to the reader of the preceding chapters; but there are some, of which the symbolic treatment is briefer than a purely geometrical treatment would be, which have not been referred to previously. The reader will be able to convince himself, by devising a geometrical method, that the symbols are not indispensable even for these. But there is one assumption which is made in some of the concluding examples to which reference should be made. It is assumed in these examples that the system of symbols employed is such that a rational algebraic equation of order n has n roots, and can be written as the product of n corresponding linear factors. Logically, the examples in which this assumption is made should have been deferred till after the considerations given in Chap. IV; it seemed more convenient to include them here.

Ex. 1. *Condition that a pair of points should be harmonic conjugates in regard to another pair.* On a line, determined by two points

O, U, we consider two points whose symbols are $O+\alpha U$, $O+\beta U$, where α, β are the values of x for which $ax^2+2hx+b=0$, and also two points $O+\alpha' U$, $O+\beta' U$, where α', β' are the values of x for which $a'x^2+2h'x+b'=0$. Prove that the condition, that the two latter points should be harmonic conjugates in regard to the two former, is that $(\alpha'-\alpha)(\alpha'-\beta)^{-1}+(\beta'-\alpha)(\beta'-\beta)^{-1}=0$, and that this is the same as $ab'+a'b-2hh'=0$.

Ex. 2. *A result in regard to involutions.* If A, B and A', B' be two pairs of points, on a line, or on a conic, and X, Z be the double points of the involution which is determined by these two pairs, prove that the three pairs of points, A, A'; B, B'; X, Z, are in involution, as also are the three pairs, A, B'; A', B; X, Z.

Ex. 3. *Representation of all the pairs of an involution.* If, as in Ex. 1, two points, $A, = O+\alpha U$, and $B, = O+\beta U$, be determined by the roots α, β of the equation $ax^2+2hx+b=0$, and, also, two points $A', = O+\alpha' U$, and $B', = O+\beta' U$, by the equation $a'x^2+2h'x+b'=0$, then the two points, $O+\xi U$, $O+\eta U$, where ξ, η are the roots of the equation $\theta(ax^2+2hx+b)+a'x^2+2h'x+b'=0$, for any symbol θ, are a pair of the involution determined by the two pairs A, B and A', B'. Further, every pair of this involution is so determined, with an appropriate value for θ.

Ex. 4. *A general result for involutions.* In the previous example, the points $O+\xi U$, $O+\eta U$ can be expressed by the points A and A'; let the expressions, for the symbols of the points, be

$$O+\xi U = m(A+\lambda A'), \quad O+\eta U = n(A+\mu A').$$

Prove, then, that $\lambda\mu^{-1}=(\xi-\alpha)(\xi-\alpha')^{-1}/(\eta-\alpha)(\eta-\alpha')^{-1}$; and, denoting this by ϵ, prove that

$$\frac{4\epsilon}{(1+\epsilon)^2}=\frac{\theta\,[2(\Delta\Delta')^{\frac{1}{2}}-H]}{[\theta(\Delta)^{\frac{1}{2}}+(\Delta')^{\frac{1}{2}}]^2},$$

where $\Delta=h^2-ab$, $\Delta'=h'^2-a'b'$, $H=2hh'-ab'-a'b$.

In particular, (Ex. 1), the points $O+\xi U$, $O+\eta U$ are harmonic conjugates of one another, in regard to A and A', when θ is such that

$$\theta^2(h^2-ab)=h'^2-a'b'.$$

Ex. 5. *Condition that two circles, in general form, should cut at right angles.* Shewing, from the text, that the equations of any two circles can be taken in the forms

$$x^2+y^2+2gxz+2fyz+cz^2=0, \quad x^2+y^2+2g'xz+2f'yz+c'z^2=0,$$

prove that the condition that they should cut at right angles is

$$2gg'+2ff'=c+c'.$$

Ex. 6. *The radical axis of two circles; the radical centre of three circles.* If the equations of any two conics, referred to any triad of points, be $F=0$, $F'=0$, prove that the equation of any conic which passes through their four intersections is $\theta F + F' = 0$, for an appropriate symbol θ. In particular, shew that the radical axis of the two circles in the preceding example is (by $\theta = -1$)

$$2(g-g')x + 2(f-f')y + (c-c')z = 0.$$

Also that the three radical axes, for the pairs of any three circles, meet in a point. Shew, further (see Ex. 3), that the conics which pass through the common points of two given conics cut an arbitrary line in pairs of points belonging to the same involution.

Ex. 7. *The common tangents and centres of similitude of two circles.* Prove that the condition that the line whose equation is

$$ux + vy + wz = 0$$

should touch the circle whose equation is

$$(x-az)^2 + (y-bz)^2 = h^2z^2$$

is that $$(au + bv + w)^2 = h^2(u^2 + v^2).$$

Hence, find the equations of the four tangents, common to this circle and the circle given by $(x-a'z)^2 + (y-b'z)^2 = h'^2z^2$. There are three point pairs such that every one of the four tangents passes through one or other of the two points of a pair; and the three lines, each containing the points of a pair, form a triad self-polar in regard to both the circles. Shew that these lines have for intersections the two limiting points of the two circles and a point on the absolute line, IJ. The centres of the two circles, in terms of the points of reference, X, Y, Z, have, for respective symbols, $C = aX + bY + Z$, and $C' = a'X + b'Y + Z$; shew that there are two points on the line joining the centres, with symbols $hC' \pm h'C$, through each of which pass two of the common tangents of the circles. These two points are called the centres of similitude of the two circles. It may be proved that the six centres of similitude of three circles lie, in threes, upon four lines.

The circle passing through the centres of similitude of two circles, with its centre on the line joining the centres of these, is of importance. Prove that the equation of this circle is $h^2F' - h'^2F = 0$, where $F=0$, $F'=0$ are the equations of the two circles, written as in this example.

Ex. 8. *Feuerbach's theorem. Apolar triads.* Let A, B, C be three points such that the joins BC, CA, AB touch a circle, say, Ω; and let D, E, F be the middle points, respectively, of B, C; of C, A; and of A, B. Then the circle D, E, F touches Ω. The definitions of a circle, and of middle points, are with reference to two absolute points I, J.

Let K be the centre of Ω, and take coordinates in regard to I, J, K, any point of the plane being $xI + zJ + yK$. The equation of Ω may then be supposed to be $xz - y^2 = 0$. Any point of this has, then, coordinates of the form $(\theta^2, \theta, 1)$; in particular, let the points of contact of BC, CA, AB be given, respectively, by the parameters α, β, γ, so that, for instance, the equation of BC is $x - 2y\alpha + z\alpha^2 = 0$. The coordinates of A are then easily found to be $\beta\gamma$, $\frac{1}{2}(\beta + \gamma)$, 1, and the coordinates of D to be

$$\alpha(\alpha\beta + \alpha\gamma + 2\beta\gamma), \quad (\alpha + \beta)(\alpha + \gamma), \quad \beta + \gamma + 2\alpha.$$

Now write, for brevity,

$$p = \alpha + \beta + \gamma, \quad q = \beta\gamma + \gamma\alpha + \alpha\beta, \quad r = \alpha\beta\gamma, \quad \mu = q/p$$

and consider the conic whose equation is

$$(xz - y^2)(rp^{-2} - \mu) + y(x - 2y\mu + z\mu^2) = 0.$$

It can be verified that this equation is satisfied by the coordinates of D, E and F. The points common to this conic and $xz - y^2 = 0$ are the points of intersection of $xz - y^2 = 0$ with the two lines whose equations are $y = 0$, $x - 2y\mu + z\mu^2 = 0$. The former of these meets $xz - y^2 = 0$ in the points I and J; the latter meets it in two coincident points of coordinates $(\mu^2, \mu, 1)$. Thus the equation written down represents the circle D, E, F; and this touches Ω at the point $(\mu^2, \mu, 1)$.

As has appeared (Chap. I, Ex. 33; Chap. II, p. 89) the circle D, E, F is the locus of the centres of rectangular hyperbolas passing through A, B, C. This may be verified directly. The equation

$$\Sigma P(x - 2y\alpha + z\alpha^2)^{-1} = 0,$$

containing three terms with undetermined coefficients P, Q, R, evidently represents a conic through the three points A, B, C; by suitable choice of P, Q, R this can be taken to pass through two other arbitrary points; it is therefore the general conic through the points A, B, C. It is a rectangular hyperbola if its intersections with the line $y = 0$ are harmonic in regard to I and J; for this the equation, involving terms in x^2, xz, z^2, which gives its intersections with $y = 0$, must contain no term in xz; it is at once seen that the condition for this is $\Sigma P(\beta^2 + \gamma^2) = 0$. If we now form, by the rule given above, the equation for the polar of a point (x', y', z'), in regard to this conic, and express that this reduces to $y = 0$, (in which case (x', y', z') will be the centre of the conic), we obtain two further conditions for P, Q, R; in virtue of the first condition these become

$$\Sigma P[x' - y'(\beta + \gamma)] = 0 \quad \text{and} \quad \Sigma P\beta\gamma[y'(\beta + \gamma) - z'\beta\gamma] = 0.$$

Eliminating P, Q, R from the three conditions, we find that (x', y', z') must satisfy the equation

$$(xz - y^2)(r - pq) + y(xp^2 - 2ypq + zq^2) = 0,$$

which is that of the conic D, E, F.

The values of the parameters α, β, γ, for the points of contact of BC, CA, AB with the circle Ω, are the values of θ for which the polynomial $u = \theta^3 - p\theta^2 + q\theta - r$, vanishes. If we similarly take together the values of the parameter for the points I, J, of the circle Ω, and the point where it is touched by the circle D, E, F, these being, respectively, ∞, 0, μ, these may be said to be the roots of the polynomial $v = \theta^2 - \mu\theta$, regarded as a cubic polynomial. Now, for any two quadratic polynomials, say $a\theta^2 + 2h\theta + b$ and $a'\theta^2 + 2h'\theta + b'$, we have remarked (above, p. 111) an expression involving their coefficients, $ab' - 2hh' + ba'$, which is of geometrical interest. For any two cubic polynomials $a\theta^3 + 3b\theta^2 + 3c\theta + d$ and $a'\theta^3 + 3b'\theta^2 + 3c'\theta + d'$, there is a similar expression, which is also of geometrical interest, namely $ad' - 3bc' + 3cb' - da'$. Two cubics are said to be *apolar* to one another when the expression vanishes; this is the case for the two cubics, u, v, considered here. We may, therefore, say, that the circle D, E, F touches the circle Ω at the point of Ω which is the apolar complement of I and J, with reference to the points where Ω is touched by BC, CA, AB. (See Ex. 26, below.) [Add.]

Ex. 9. *Continuation of the preceding example.* The point where the nine points circle, of A, B, C, that is, the circle D, E, F, touches the inscribed circle Ω, may also be described as the fourth intersection of Ω with a particular conic, which we now explain, passing through the points where Ω touches BC, CA, AB. Let these points of contact be called P, Q, R ; the equation of the line QR is

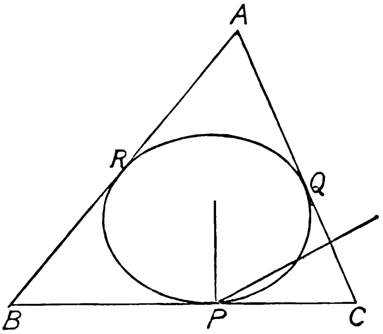
$$x - y(\beta + \gamma) + z\beta\gamma = 0.$$

Denote this by $U = 0$. Similarly, let RP and PQ be $V = 0$ and $W = 0$. The conic represented by the equation

$$\left(x'\frac{\partial}{\partial x} + y'\frac{\partial}{\partial y} + z'\frac{\partial}{\partial z}\right) UVW = 0,$$

may be called the polar conic of the point (x', y', z') in regard to the degenerate cubic locus represented by $UVW = 0$. When (x', y', z') is the centre, $(0, 1, 0)$, of the circle Ω, this polar conic becomes $\Sigma(\beta + \gamma)VW = 0$. It may easily be verified that this conic passes through the point $(\mu^2, \mu, 1)$ of Ω, and that it passes through P, Q and R. Its tangent at P is the harmonic conjugate, in regard to PQ, PR, of the line joining P to the centre of the inscribed circle Ω, as is easy to verify, with a similar statement for Q and R; this suffices to identify the conic. Thus, the nine points circle of A, B, C touches the inscribed circle on the polar conic of the centre of the inscribed circle, taken in regard to the degenerate cubic formed of the three joins of the points of contact of the inscribed circle with BC, CA, AB.

Another conic which touches the inscribed circle Ω at the point



$(\mu^2, \mu, 1)$ is obtained as follows: Consider again the line drawn through P harmonic, in regard to PQ, PR, to the line joining P to the centre of the inscribed circle; and the similar lines through Q and R. A conic can be drawn touching these lines to have a focus at the centre of the inscribed circle. We may prove that this conic has the equation

$$[x - 2y(\mu - rp^{-2}) + z\mu^2]^2$$
$$= 4xzr^2p^{-4};$$

in fact, it is clear that this conic meets each of the lines $x = 0$, $z = 0$ only in one point, or touches these, and so has the centre, $(0, 1, 0)$, of the inscribed circle, as a focus. It is also clear that it meets the inscribed circle $xz - y^2 = 0$ where this is met by the two lines

$$x - 2y\mu + z\mu^2 = 0, \quad x - 2y(\mu - 2rp^{-2}) + z\mu^2 = 0,$$

of which the former is the tangent at $(\mu^2, \mu, 1)$, and so touches the inscribed circle at this point. That it touches the line, spoken of, through P, whose equation is $W(\alpha + \gamma) + V(\alpha + \beta) = 0$, or $x(\alpha + p) - 2y(\alpha^2 + q) + z(\alpha q + r) = 0$, may be verified by shewing that the result of eliminating y between this equation and the equation of the conic, is a perfect square in x and z; or by first finding the tangential equation of the conic, which is

$$[2u(pq - r) + vp^2][2w(pq - r) + vq^2] = v^2r^2,$$

and then verifying that this is satisfied by $u = \alpha + p$, $v = -2(\alpha^2 + q)$, $w = \alpha q + r$. The algebra is the same in both cases.

We may also give an algebraic proof of Feuerbach's theorem with coordinates which are referred to the points A, B, C. Without any loss of generality the equation of the circle touching BC, CA, AB may be taken to be

$$x^2 + y^2 + z^2 - 2yz - 2zx - 2xy = 0,$$

the absolute line, IJ, having the equation $lx + my + nz = 0$. Now consider the conic, say, N, expressed by the equation

$$2lmnC + fgh(lx + my + nz)(f^{-1}x + g^{-1}y + h^{-1}z) = 0,$$

where C is the expression $x^2 - 2yz + \dots$ which occurs on the left side of the equation of the inscribed circle, and $f = m - n$, $g = n - l$, $h = l - m$. Its intersections with the circle expressed by $C = 0$ are the intersections of this with the line $lx + my + nz = 0$, and with the line $f^{-1}x + g^{-1}y + h^{-1}z = 0$. The former is the absolute line, so that the conic considered, N, is also a circle; the latter is in fact a tangent of the circle $C=0$; thus the conic considered, N, is a circle touching the circle $C=0$. To prove that the line $f^{-1}x+\ldots=0$ touches the circle $C=0$, we remark, more generally, that a conic whose equation is that obtained by rationalising the equation

$$(ax)^{\frac{1}{2}}+(by)^{\frac{1}{2}}+(cz)^{\frac{1}{2}}=0,$$

which is the most general conic touching BC, CA, AB, has for its tangent at any point, (x', y', z'), the line given by

$$x\,(a/x')^{\frac{1}{2}}+y\,(b/y')^{\frac{1}{2}}+z\,(c/z')^{\frac{1}{2}}=0,$$

and has the tangential equation $avw+bwu+cuv=0$. Consider now the intersections of the conic N with BC, CA, AB; it is easily verified that three of these are the middle points, respectively, of B, C, of C, A, and of A, B, in regard to the absolute line. This suffices to identify the conic N with the nine points circle; and so we have proved Feuerbach's theorem. If the other intersections of N, respectively with BC, CA, AB, be D, E, F, and D' be the harmonic conjugate of D in regard to B and C, with a similar definition for E' and F', on CA and AB, it may be proved that D', E', F' lie on the line whose equation is

$$(x+y+z)\,(mn+nl+lm)-(l^2x+m^2y+n^2z)=0.$$

Ex. 10. *Hamilton's modification of Feuerbach's theorem. Introductory results.*

The following results can be verified (cf. Chap. I, Ex. 33). Let A, B, C be any triad of points, not in line, and O, O' be two further points. Let AO, BO, CO meet BC, CA, AB, respectively, in D, E, F, and AO', BO', CO' meet BC, CA, AB, respectively, in D', E', F'; let EF, $E'F'$ meet in P, while FD, $F'D'$ meet in Q, and DE, $D'E'$ meet in R. Then the lines QR, RP, PQ, respectively, contain A, B, C, while the lines AP, BQ, CR meet in a point. Also, the lines DP, EQ, FR meet in a point, say, K, and the lines $D'P$, $E'Q$, $F'R$ meet in a point, say, K'. Further, the line KK' passes through the intersection of QR with BC, of RP with CA, and of PQ with AB.

A conic, say, S, can be drawn to touch BC, CA, AB, respectively, in D, E, F, and a conic, say, Ω, can be drawn to touch BC, CA, AB, respectively, in D', E', F'. And a conic, say, T, can be drawn to contain the six points D, D', E, E', F, F'. The points K, K' are the points of contact, respectively, with S and Ω, of their fourth common tangent, and these points lie on T. The triad P, Q, R is self-polar in regard to each of the three conics S, Ω, T. Further, if EF, FD, DE, respectively, meet BC, CA, AB in U, V, W, these points are in line, and the two intersections of this line with the conic Ω form, with K', a triad of points of Ω which is apolar (see below) with the triad D', E', F', of points thereon. Incidentally we have a construction, when three common tangents of two conics, and their points of contact, are given, for finding the points of contact of the remaining common tangent.

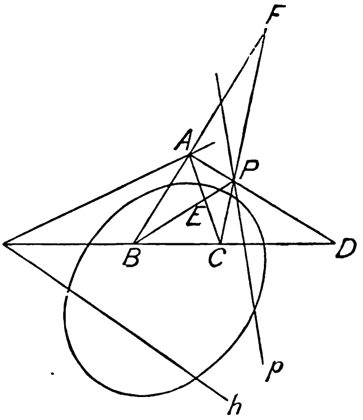
If the conics S and Ω be expressed, respectively, by the equations

$$(lx)^{\frac{1}{2}} + (my)^{\frac{1}{2}} + (nz)^{\frac{1}{2}} = 0, \quad (l'x)^{\frac{1}{2}} + (m'y)^{\frac{1}{2}} + (n'z)^{\frac{1}{2}} = 0,$$

and we denote $mn' - m'n$, $nl' - n'l$, $lm' - l'm$, respectively, by p, q, r, it will be found that the point P is $(-p, q, r)$, with similar forms for Q and R, and that K and K' are, respectively, $(p^2 l, q^2 m, r^2 n)$ and $(p^2 l', q^2 m', r^2 n')$. We can express the points of the conic Ω in terms of a parameter, θ, by the equations $l'x = \theta^2$, $m'y = (\theta - 1)^2$, $n'z = 1$, the points D', E', F' being then given, respectively, by $\theta = 0$, $\theta = 1$, $\theta = \infty$, and the point K' by $rn'\theta + pl' = 0$. The line UVW, whose equation is $lx + my + nz = 0$, meets Ω in points, I, J, given by the equation $\theta^2 (l/l') + (1-\theta)^2 (m/m') + n/n' = 0$. For the three points I, J, K' the parameter values are then given by an equation of the form $\mathrm{a}\theta^3 + \theta^2 - \theta + \mathrm{b} = 0$, while the cubic equation for D', E', F' reduces to $\theta^2 - \theta$. This is what is meant by saying that the triad I, J, K' is apolar with the triad D', E', F' (see, above, Ex. 8). The equation of the conic T is

$$\Sigma ll'x^2 - \Sigma (mn' + m'n) yz = 0.$$

Ex. 11. *Hamilton's modification of Feuerbach's theorem.* Let the lines joining a point, P, of a conic, to three other points of the conic, A, B, C, meet BC, CA, AB, respectively, in D, E, F, so that D, E, F is a self-polar triad for the conic. We have remarked that the tangents at A, B, C meet BC, CA, AB, respectively, in the points of a line (Chap. I, Ex. 9), which we denote by h; we denote the tangent at P by p. We have already proved (Chap. I, Ex. 33) that if any conic having D, E, F for a self-polar triad be drawn, its four intersections with the lines p and h lie on a conic passing through A, B, C. We can take coordinates referred to D, E, F, in such a way that the tangents of the original conic at P, A, B, C have, respectively, the equations



$$x + y + z = 0, \quad -x + y + z = 0, \quad x - y + z = 0, \quad x + y - z = 0;$$

the original conic will then have an equation of the form

$$a^{-1}x^2 + b^{-1}y^2 + c^{-1}z^2 = 0,$$

wherein $a + b + c = 0$; any conic having D, E, F for self-polar triad will have an equation of the form $Ax^2 + By^2 + Cz^2 = 0$. The conic containing the four intersections of this with the lines p, h, and also the points A, B, C, will then have the equation

$$(Aa^2 + Bb^2 + Cc^2)(ax + by + cz)(x + y + z) = 4abc\,(Ax^2 + By^2 + Cz^2).$$

Conversely, if any conic be taken through A, B, C, meeting h and p, then a conic can be drawn through the four intersections, having D, E, F for a self-polar triad. If we take coordinates referred to A, B, C, and the equation of the original conic be put in the form $yz + zx + xy = 0$, while the conic taken through A, B, C has the equation $fyz + gzx + hxy = 0$, then the conic, through the four intersections of this with p and h, which has D, E, F for a self-polar triad, is

$$(f\eta\zeta + g\zeta\xi + h\xi\eta)(\xi^{-2}x + \eta^{-2}y + \zeta^{-2}z)(x + y + z) \\ + fyz + gzx + hxy = 0,$$

where (ξ, η, ζ) are the coordinates of P.

Ex. 12. *Conic referred to its centre and axes.* The two lines drawn through the centre, C, of a conic, (the pole of the absolute line, IJ, in regard thereto), which are harmonic conjugates of one another both in regard to the two tangents which can be drawn to the conic from C, and in regard to CI, CJ, are, as we have previously said, called the axes of the conic. If these meet the line IJ in A and B, the triad A, B, C is self-polar, and, in reference to these, the equation of the conic is of the form $px^2 + qy^2 = z^2$. This fails if the conic is a parabola, that is, touches the line IJ, a possibility we exclude. We may suppose the coordinates x, y so chosen that the points I, J are on the lines $x \pm iy = 0$, so that, in any circle the terms of the second degree in x and y are $x^2 + y^2$. We replace p, q, respectively, by a^{-2} and b^{-2}. The expression in terms of a parameter, t, of the points of the conic, may then be taken to be

$$x = a(1 - t^2), \quad y = 2bt, \quad z = 1 + t^2,$$

so that $t = b^{-1}y/(z + a^{-1}x)$. It is usual to develop many results in this notation.

The equation

$$a^{-1}x(1 - t_1t_2) + b^{-1}y(t_1 + t_2) = z(1 + t_1t_2)$$

is at once verified to be that of the line joining the points t_1 and t_2; it gives the equation of the tangent by putting $t_2 = t_1$. The tangents to the curve from the points I, J pass through one of the two foci, S, H, given by $x = \pm (a^2 - b^2)^{\frac{1}{2}}$, $y = 0$, $z = 1$, and also through one of the other two foci, S', H', given by $x = 0$, $y = \pm (b^2 - a^2)^{\frac{1}{2}}$, $z = 1$. The normal of the conic at the point (ξ, η, ζ) has the equation

$$a^2\xi^{-1}x - b^2\eta^{-1}y = (a^2 - b^2)\,\zeta^{-1}z,$$

and this same equation, if we regard (x, y, z) as given, and ξ, η, ζ as variable, is that of the rectangular hyperbola of Apollonius, meeting the given conic at the feet of the four normals from (x, y, z), (p. 93).

If we consider the intersections of any circle with the given conic, we immediately verify that any one of the three pairs of chords common to the conic and the circle meets the line IJ in two points which are harmonic in regard to A and B (a proposition often expressed by saying that these chords are equally inclined to one of the axes, cf. Chap. II, p. 79); and further, substituting the above parametric expressions for the points of the conic in the equation of the circle, if t_1, t_2, t_3, t_4 be the parameters of the four intersections, and we assume (in illogical anticipation of the limitation of the symbols which is explained in the following Chapter) that the equation of the fourth order which these satisfy is capable of being written in the form $(t-t_1)(t-t_2)(t-t_3)(t-t_4)=0$, we infer that $p_1=p_3$, where p_r is the sum of the products of sets of r of t_1, t_2, t_3, t_4. In a similar way, from the equation for the Apollonius rectangular hyperbola, we infer that the parameters of the feet of the four normals which can be drawn to the conic from any point satisfy $1-p_2+p_4=0$. This last changes into the former if we replace t_4 by $-t_4^{-1}$. Thus if P_1, P_2, P_3, P_4 be the feet of the four normals, and Q_4 be the other point of the conic lying on the line P_4C, it follows that P_1, P_2, P_3, Q_4 lie on a circle, as has already been proved (Chap. II, p, 93). If three points of the conic, with parameters t_1, t_2, t_3, be such that the normals thereat meet in a point, it can be verified that

$$\Sigma t_2 t_3 = \Sigma (t_2 t_3)^{-1}.$$

Lastly, if a line be drawn through one of the foci $(c, 0, 1)$, where $c^2=a^2-b^2$, at right angles to the tangent of the conic at any point, of equation $a^{-1}x(1-t^2)+2b^{-1}yt-z(1+t^2)=0$, this line will have the equation $2b^{-1}t(x-cz)-a^{-1}(1-t^2)y=0$, and will meet the tangent in the point whose coordinates are $x=a(1-\lambda^2)$, $y=2a\lambda$, $z=1+\lambda^2$, where $\lambda=(a-c)b^{-1}t$, this being a point of the circle $x^2+y^2=a^2z^2$. This has been called the auxiliary circle (Chap. II, p. 85).

Ex. 13. *Confocal conics.* The points I, J, S, H, S', H', in the preceding example, having, respectively, the coordinates

$$(1, i, 0),\ (1, -i, 0),\ (c, 0, 1),\ (-c, 0, 1),\ (0, ic, 1),\ (0, -ic, 1),$$

where $c^2=a^2-b^2$, any two conics touching the four lines $IH'S$, $JS'S$, $IS'H$, $JH'H$, may be taken to have equations

$$a^{-2}x^2+b^{-2}y^2=z^2,\quad (a^2+\lambda)^{-1}x^2+(b^2+\lambda)^{-1}y^2=z^2;$$

these are *confocals*, in regard to I and J. The condition that any line, of equation $lx+my+nz=0$, should touch the second of these conics is $a^2l^2+b^2m^2-n^2+\lambda(m^2+l^2)=0$; the tangential equation of the first conic is $a^2l^2 + b^2m^2 - n^2 = 0$, and the tangential equation of the point pair I, J is $l^2 + m^2 = 0$. We have previously remarked (p. 112, above) that if $f = 0, f' = 0$ be the point equations of any two conics, the equation of the general conic through their four intersections is $\kappa f + f' = 0$, for a proper parameter κ; thus the tangential equation of a confocal conic appears, as it should, as that of the general conic touching the tangents from the points I, J to any one conic of the system. It is easy to verify the properties of a system of confocal conics, many of which have already been referred to (pp. 79, 90, 93), by means of these equations. In particular, the polar of a point (ξ, η, ζ), in regard to the conic

$$(a^2 + \lambda)^{-1}x^2 + \dots - z^2 = 0,$$

has the equation

$$(a^2 + \lambda)^{-1}\xi x + (b^2 + \lambda)^{-1}\eta y - \zeta z = 0,$$

which we may write in the form $\lambda^2 Z + \lambda Y + X = 0$, where

$$Z = \zeta z, \quad Y = (a^2 + b^2)\,\zeta z - \xi x - \eta y, \quad X = a^2b^2\zeta z - a^2\eta y - b^2\xi x.$$

By what we have previously seen, this is the equation of the tangent of the conic whose equation is $4XZ - Y^2 = 0$. It can be verified that this is the same as is obtained by rationalising the equation

$$(\xi x)^{\frac{1}{2}} + (-\eta y)^{\frac{1}{2}} + c\,(\zeta z)^{\frac{1}{2}} = 0.$$

This conic touches the line $x = 0$ (for $\lambda = -a^2$), the line $y = 0$ (for $\lambda = -b^2$), and the line $z = 0$ (for $\lambda = \infty$); it is thus a parabola, in regard to I and J, the point C, at which two perpendicular tangents meet, being on the directrix. The point (ξ, η, ζ) is equally on the directrix; for there are two of the confocals passing through this point, those namely for which λ has either of the values for which $(a^2 + \lambda)^{-1}\xi^2 + \dots - \zeta^2 = 0$, and these cut at right angles; for the tangents are $(a^2 + \lambda_1)^{-1}\xi x + \dots - \zeta z = 0$ and $(a^2 + \lambda_2)^{-1}\xi x + \dots - \zeta z = 0$, which are at right angles (p. 110, above), if

$$(a^2 + \lambda_1)^{-1}(a^2 + \lambda_2)^{-1}\xi^2 + (b^2 + \lambda_1)^{-1}(b^2 + \lambda_2)^{-1}\eta^2 = 0,$$

an equation obtainable from

$$(a^2 + \lambda_1)^{-1}\xi^2 + \dots - \zeta^2 = 0 \quad \text{and} \quad (a^2 + \lambda_2)^{-1}\xi^2 + \dots - \zeta^2 = 0;$$

and these tangents are the polars of (ξ, η, ζ) in regard to these two confocals. The focus of the parabola is the intersection of two of its tangents passing respectively through I and J; the polar $(a^2 + \lambda)^{-1}\xi x + \dots - \zeta z = 0$ passes through $(1, i, 0)$ for the value of λ given by $(a^2 + \lambda)^{-1}\xi + (b^2 + \lambda)^{-1}i\eta = 0$; and we similarly find the polar passing through $(1, -i, 0)$. The intersection of these polars gives the focus, which is found to be $(c^2\xi\zeta, \ -c^2\eta\zeta, \ \xi^2 + \eta^2)$. It is easy to verify that the general conic passing through the four foci has the equation $x^2 - y^2 - c^2z^2 + 2hxy = 0$, where h is variable, and hence that the focus of the parabola is conjugate to (ξ, η, ζ) in regard to all these conics. Further we may verify that the polar reciprocal of the parabola in regard to $a^{-2}x^2 + b^{-2}y^2 - z^2 = 0$, is the Apollonius rectangular hyperbola containing the feet of the normals of this conic which pass through (ξ, η, ζ); for, in order that the polar of a point (x', y', z'), in regard to the conic $a^{-2}x^2 + b^{-2}y^2 - z^2 = 0$, may coincide with a tangent of the parabola whose equation is

$$(a^2 + \lambda)^{-1}\xi x + (b^2 + \lambda)^{-1}\eta y - \zeta z = 0,$$

it is necessary and sufficient that

$$a^{-2}x'/(a^2 + \lambda)^{-1}\xi = b^{-2}y'/(b^2 + \lambda)^{-1}\eta = z'/\zeta;$$

this can be satisfied by a proper value of λ if

$$a^2\xi(x')^{-1} - b^2\eta(y')^{-1} = (a^2 - b^2)\zeta(z')^{-1}.$$

Ex. 14. *Conics derived from a conic intersecting the joins of three points.* If a conic, S, which meets the lines BC, CA, AB, respectively, in D, D', E, E'; F, F', have the equation

$$ax^2 + by^2 + cz^2 + 2fyz + 2gzx + 2hxy = 0,$$

the lines AD, AD' are given by $by^2 + cz^2 + 2fyz = 0$. The coordinates of either of these lines, whose equation may be written $vy + wz = 0$, are then such that, $b^{-1}v^2 + c^{-1}w^2 - 2b^{-1}c^{-1}fvw = 0$. The six lines AD, AD', BE, BE', CF, CF' are thus tangents of the conic, Σ', whose tangential equation is

$$bcu^2 + cav^2 + abw^2 - 2afvw - 2bgwu - 2chuv = 0,$$

or, say, $\Sigma' = 0$. If $\Sigma = 0$ be the tangential equation of the conic S, so that Σ is the sum of three pairs of terms such as

$$(bc - f^2)u^2 + 2(gh - af)vw,$$

we see that $\Sigma' - \Sigma$ is the sum of three pairs of terms such as $f^2u^2 - 2ghvw$. We have remarked that a conic whose equation is obtained by rationalising the equation $(lx)^{\frac{1}{2}} + (my)^{\frac{1}{2}} + (nz)^{\frac{1}{2}} = 0$ touches BC, CA, AB; similarly a conic whose tangential equation, $\Omega = 0$, is obtained by rationalising $(fu)^{\frac{1}{2}} + (gv)^{\frac{1}{2}} + (hw)^{\frac{1}{2}} = 0$, is one which passes through A, B, C; its point equation is, in fact, $fyz + gzx + hxy = 0$. In the case in hand we have $\Sigma' - \Sigma = \Omega$. The four common tangents of the conics S and Σ' are thus touched by the conic Ω, which passes through A, B, C. Similarly, by taking the point equation of the conic Σ', we see that there is a conic passing through the four common points of S and Σ' which touches BC, CA, AB, its point equation being $(afx)^{\frac{1}{2}} + (bgy)^{\frac{1}{2}} + (chz)^{\frac{1}{2}} = 0$.

A particular case of the preceding is when S is such that Σ' degenerates into a point pair, so that the lines AD, BE, CF meet in a point, say, O, and AD', BE', CF' also meet in a point, say, O'.

Then the points, on BC, CA, AB, which are the respective harmonic conjugates of D, E, F with regard to B, C; C, A; A, B, lie on a line, say, l; and the points, on BC, CA, AB, similarly derived from D', E', F', also lie on a line, say, l'. In general, these derived six points lie on the conic whose equation is

$$ax^2 + by^2 + cz^2 - 2fyz - 2gzx - 2hxy = 0,$$

as is easy to see; in the case now considered, this conic breaks into the two lines, l and l'. When this is so, it follows, from what has been said, that there is a conic through A, B, C which touches the tangents drawn to S from O and O'. From the equations it also follows easily that this conic passes through the intersections of S with the lines l and l'; and also, through these intersections there passes a conic in regard to which A, B, C are a self-polar triad, the lines l and l' being the polars, respectively, of O' and O, in regard to this. The point equation of a conic, given in tangential form, which breaks into a point pair, represents the line joining these points, taken twice over, as is easy to see. Thus, in the case now considered, there is a conic touching BC, CA, AB which touches S at its two intersections with the line OO'; and, further, the tangents of the conics, at their two points of contact, meet in the intersection of the lines l, l'. In the present case, we may regard S as the nine points circle of the triad, A, B, C; we have only to take for absolute points the intersections of S with the line l; it can be proved that these are conjugate points in regard to all conics through the four points A, B, C, O', so that, for instance, AO' is at right angles to BC in reference to these points. Thus the results here stated are equivalent to saying that the two points O, O', respectively the intersection of the lines from A, B, C to the middle points of B, C, of C, A, and of A, B, and the orthocentre of A, B, C, are the centres of similitude of the nine points circle and the circle A, B, C, the radical axis of these circles being the line l', derived from the orthocentre, O', by the rule given; further that there is a circle, coaxial with these two circles, with centre at the orthocentre, for which A, B, C is a self-polar triad, and for which O is the pole of the radical axis spoken of; and, also, that there is a conic touching BC, CA, AB, which touches the nine points circle at two points of the line OO' whereat the tangents are parallel (with regard to the absolute line l) to this radical axis. (See also Chap. I, Ex. 29.)

It would seem to be worth while to speak of the conic whose equation, referred to three points A, B, C, is

$$ax^2 - 2fyz + by^2 - 2gzx + cz^2 - 2hxy = 0,$$

as the harmonically conjugate of the conic whose equation is

$$ax^2 + 2fyz + by^2 + 2gzx + cz^2 + 2hxy = 0.$$

If the latter meet BC in P_1 and P_2, the former meets BC in two points, P_1', P_2', which are the harmonic conjugates, in regard to B and C, respectively, of P_1 and P_2, with a similar statement for CA and AB. And, further, to speak of the latter conic as being bipunctual, in regard to A, B, C, when the six lines such as AP_1, AP_2, meet in two points. The condition for this is that the harmonically conjugate conic break up into two lines.

If X, Y, Z be a self-polar triad in regard to a conic, and O be any point, and XO, YO, ZO meet YZ, ZX, XY, respectively, in A, B, C, then the conic is bipunctual in regard to A, B, C. For if we suppose O to be $(1, 1, 1)$, relatively to X, Y, Z, and the equation of the conic relatively to these be $ax^2 + by^2 + cz^2 = 0$, by taking

$$\xi = \tfrac{1}{2}(-x+y+z), \quad \eta = \tfrac{1}{2}(x-y+z), \quad \zeta = \tfrac{1}{2}(x+y-z),$$

we have, for the equation in regard to A, B, C, the form

$$a(\eta+\zeta)^2 + b(\zeta+\xi)^2 + c(\xi+\eta)^2 = 0.$$

The harmonically conjugate conic, in regard to A, B, C, is then

$$a(\eta-\zeta)^2 + b(\zeta-\xi)^2 + c(\xi-\eta)^2 = 0,$$

which is evidently a line pair.

Conversely, if a conic be bipunctual in regard to A, B, C, it is possible, and in only one way, to draw lines, YZ, ZX, XY, passing, respectively, through A, B, C, such that the triad X, Y, Z, formed by their intersections, is self-polar in regard to the conic; and the lines AX, BY, CZ meet in a point. For, if, referred to A, B, C, the conic be

$$ll'\xi^2 + mm'\eta^2 + nn'\zeta^2 - (mn'+m'n)\eta\zeta - (nl'+n'l)\zeta\xi - (lm'+l'm)\xi\eta = 0,$$

and we attempt to write this equation in the form

$$P(\eta+p\zeta)^2 + Q(\zeta+q\xi)^2 + R(\xi+r\eta)^2 = 0,$$

we find

$$p = (nl'-n'l)(lm'-l'm)^{-1}, \quad -2Pp = mn'+m'n,$$

with similar values for q, Q, r, R, (so that $pqr = 1$).

We may similarly consider a conic such that the tangents to it from A, B, C meet BC, CA, AB in points lying, in threes, upon two lines.

Ex. 15. *Two triads reciprocal in regard to a conic are in perspective.* If P, Q, R be the poles, with regard to any conic whose tangential equation referred to A, B, C is

$$Au^2 + Bv^2 + Cw^2 + 2Fvw + 2Gwu + 2Huv = 0,$$

respectively of BC, CA, AB, then the lines AP, BQ, CR meet in a point (Ex. 10, Chap. I). For P, Q, R have the respective coordinates (A, H, G), (H, B, F), (G, F, C), and the lines AP, BQ, CR meet in the point given by

$$Fx = Gy = Hz.$$

Dually, the polars of A, B, C meet BC, CA, AB, respectively, in three points lying in line. If the equation of the conic be

$$ax^2+\ldots+2fyz+\ldots=0,$$

the equation of this line is $f^{-1}x+g^{-1}y+h^{-1}z=0$.

Ex. 16. *The Hessian line of three points of a conic.* If the tangents at three points, A, B, C, of a conic, meet BC, CA, AB, respectively in D, E, F, the points D, E, F are in line (Chap. I, Ex. 9). If the points of the conic be expressed by a parameter, and the values of this for the points A, B, C be the values of x/y for which $ax^3+3bx^2y+3cxy^2+dy^3=0$, the values of the parameter at the two points, H, K, at which the line D, E, F meets the conic, are the two values of x/y for which

$$\frac{\partial^2 F}{\partial x^2}\cdot\frac{\partial^2 F}{\partial y^2}-\left(\frac{\partial^2 F}{\partial x\partial y}\right)^2=0,$$

where $F=0$ is the equation above (cf. Vol. I, p. 174). Further, if the left side of the last quadratic be multiplied by $x+my$, *where m is arbitrary*, and the result be written $a'x^3+3b'x^2y+3c'xy^2+d'y^3=0$, it may be proved that $ad'-3bc'+3cb'-da'=0$. In other words, any three points of a conic are apolar with the Hessian points of these taken with a third arbitrary point. If we take the equation of the conic in the form $fyz+gzx+hxy=0$, the points (x, y, z) can be expressed in terms of a parameter by $x=-f\theta^{-1}$, $y=g(\theta-1)^{-1}$, $z=h$, so that A, B, C correspond, respectively, to $\theta=0$, 1, ∞; the points H, K are then given by $\theta^2-\theta+1=0$, and it is easy to verify the relation in question for the two cubics

$$x^2y-xy^2=0,\quad (x+my)(x^2-xy+y^2)=0.$$

The relation is unaffected if, instead of θ, we use a parameter ϕ connected with θ by an equation $A\theta\phi+B\theta+C\phi+D=0$, wherein A, B, C, D are constants. Similar remarks hold for the dual case of three given tangents of a conic.

Ex. 17. *The director circle of a conic, and generalisations.* It can be proved that the equation of the two tangents drawn from a point (x', y', z') to touch the conic $U=0$ is $UU'-T^2=0$, where U' is what U becomes when x', y', z' are written in place of x, y, z; and T is one half of what is obtained by operating upon U by

$$x'\partial/\partial x+y'\partial/\partial y+z'\partial/\partial z,$$

and is symmetrical in regard to x, y, z and x', y', z'. This result follows by considering that the points, with coordinates of the forms $(x+\theta x', y+\theta y', z+\theta z')$, on the line joining (x, y, z) to (x', y', z'), which lie on the conic, are given by $U+2\theta T+\theta^2 U'=0$.

Further, if these tangents meet the line joining the points, I, J, which have coordinates $(1, \pm i, 0)$, in two points harmonic in regard to these, that is, if the tangents be at right angles, then (x', y', z') lies on the locus whose equation is

$$(a+b)\,U = (ax + hy + gz)^2 + (hx + by + fz)^2,$$

or

$$C\,(x^2 + y^2) - 2Gxz - 2Fyz + (A + B)\,z^2 = 0\,;$$

here U is $ax^2 + \ldots + 2fyz + \ldots$, and $A = bc - f^2$, $F = gh - af$, etc. This gives the equation of the director circle in regard to I and J.

More generally, the locus of the point of intersection of two lines, conjugate to one another in regard to the conic, drawn respectively through the points (x_1, y_1, z_1), (x_2, y_2, z_2), is $UT_{12} = T_1T_2$, where T_1 and T_2 are the forms of T when (x', y', z') are replaced, respectively, by (x_1, y_1, z_1) and (x_2, y_2, z_2), while T_{12} is obtained from T by replacing (x, y, z) and (x', y', z'), respectively, by (x_1, y_1, z_1) and (x_2, y_2, z_2). This locus becomes the director circle when the points (x_1, y_1, z_1), (x_2, y_2, z_2) are the points $(1, \pm i, 0)$.

This however may be generalised; we may seek the locus of a point from which the tangents to a conic are conjugate in regard, not to a point pair but, to another general conic, that is, the locus of a point from which the pair of tangents to one conic are harmonic conjugates of one another in regard to the tangents from that point to another conic. The locus is still a conic; and it is obvious by the definition that this contains the eight points of contact with the two conics of their four common tangents. If the tangential equation of one of the conics be $Au^2 + \ldots + 2Fvw + \ldots = 0$, that of the other being of the same form with $A', \ldots, F', \ldots$ in place of $A, \ldots, F, \ldots$, the pair of tangents to the former from the point (ξ, η, ζ) is given by

$$A\,(y\zeta - \eta z)^2 + \ldots + 2F\,(z\xi - \zeta x)\,(x\eta - \xi y) + \ldots = 0,$$

and these meet $z = 0$ in two points given, say, by $\mathrm{a}x^2 + 2\mathrm{h}xy + \mathrm{b}y^2 = 0$, where

$$\mathrm{a} = B\zeta^2 - 2F\zeta\eta + C\eta^2, \quad \mathrm{h} = -H\zeta^2 + F\xi\zeta + G\eta\zeta - C\xi\eta,$$
$$\mathrm{b} = A\zeta^2 - 2G\zeta\xi + C\xi^2\,;$$

the corresponding values for the second conic being denoted by a', h', b', we require to express that $\mathrm{ab}' - 2\mathrm{hh}' + \mathrm{ba}' = 0$. On reduction this shews that (ξ, η, ζ) describes the conic whose equation is

$$(BC' + B'C - 2FF')\,x^2 + \ldots + 2\,(GH' + G'H - AF' - A'F)\,yz + \ldots = 0.$$

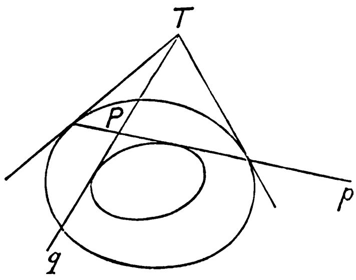
Dually, a line whose intersections with one conic,

$$ax^2 + \ldots + 2fyz + \ldots = 0,$$

are harmonic in regard to its intersections with another such conic, envelopes the conic whose tangential equation is

$$(bc' + b'c - 2ff')\,u^2 + \ldots + 2\,(gh' + g'h - af' - a'f)\,vw + \ldots = 0\,;$$

this conic evidently touches the eight tangents of the two conics at their common points.



For the former case, of two conics given tangentially, we may, by taking a pair of the intersections of their common tangents as the absolute points, I, J, regard the two conics as belonging to a system of confocals, their equations being

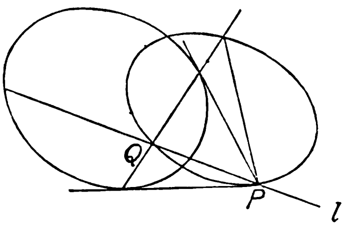
$$a^{-2}x^2+b^{-2}y^2-z^2=0,$$

$$(a^2+\lambda)^{-1}x^2+(b^2+\lambda)^{-1}y^2-z^2=0.$$

The tangents from a point, P, to the former conic, say, p and q, will be conjugate in regard to the second conic, if q passes through the pole, T, of the line p in regard to the second conic. The locus of P, with these coordinates, is found to be

$$2a^2b^2\left[a^{-2}x^2+b^{-2}y^2-z^2\right]+\lambda\left[x^2+y^2-(a^2+b^2)z^2\right]=0;$$

it meets either of the two conics in the four points where this is met by its director circle.



For the latter case, of two conics given in point coordinates, we may regard both the conics as circles. A line, l, will meet the circles harmonically if it join a point P, of one circle, to one of the points, Q, where this circle is met by the polar of P taken in regard to the other circle. The circles being supposed to have equations

$$x^2+y^2+2gxz+cz^2=0,\quad x^2+y^2+2g'xz+cz^2=0,$$

as we have shewn to be possible (above, p. 109), the envelope is found to be given by

$$(u^2+v^2)(c-gg')+(gu-w)(g'u-w)=0.$$

The equation $u^2+v^2=0$ represents the absolute points I, J, and the equation $(gu-w)(g'u-w)=0$ represents the centres of the two circles. The envelope has the centres of the two circles for foci, and touches the tangents of the circles drawn at their intersections. A particular case is that in which the two circles cut at right angles; then $c=gg'$, and the envelope reduces to the point pair given by the centres of the circles. We have previously seen (Chap. II, p. 66) that when two circles cut at right angles, any line through the centre of either is divided harmonically by the circles. [Add.]

A particular case is when one of the two conics is a line pair. For example, if the conic be the circle $x^2+y^2-(a^2+b^2)z^2=0$, and the line pair be $a^{-2}x^2 + b^{-2}y^2 = 0$, the envelope is found to be $a^2u^2 + b^2v^2 - w^2 = 0$, which is the tangential equation of the conic $a^{-2}x^2 + b^{-2}y^2 - z^2 = 0$. Thus any tangent of a conic meets the director circle in two points which are harmonic in regard to the points in which the tangent meets the asymptotes of the conic.

The director circle, S, of a conic Σ, has been shewn (Chap. II, p. 96) to be such that sets of four points can be taken thereon whose joins, in order, are four tangents of the conic. It may be proved that for two conics $S = 0$, $\Sigma = 0$, where

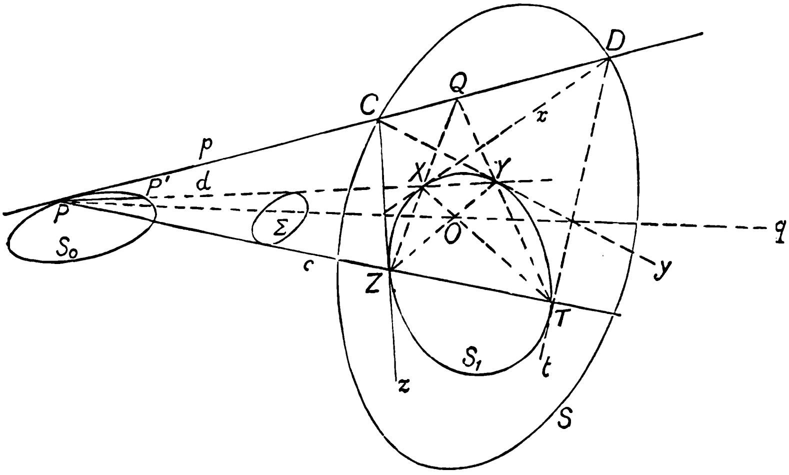
$$S = ax^2 + by^2 + cz^2, \quad \Sigma = Au^2 + Bv^2 + Cw^2,$$

the condition for this possibility is that the sum of two of the quantities aA, bB, cC should be equal to the third.

Ex. 18. *Envelope of a line joining points of two conics which are conjugate in regard to a third.* We now prove the following theorem, which will be found to include many particular results: let

$$S_0 = x^2 + y^2 + z^2, \qquad \Sigma_0 = u^2 + v^2 + w^2,$$
$$S_1 = ax^2 + by^2 + cz^2, \quad \Sigma_1 = a^{-1}u^2 + b^{-1}v^2 + c^{-1}w^2,$$

so that $\Sigma_0 = 0$ is the tangential equation of the conic $S_0 = 0$, and $\Sigma_1 = 0$ is the tangential equation of the conic $S_1 = 0$. In general, any two conics have four distinct intersections, and their equations can be reduced to these forms. Any conic touching the four common tangents of Σ_0 and Σ_1 has a tangential equation $\Sigma_0 - \theta^2\Sigma_1 = 0$. We prove that this conic is the envelope of a line joining two points, lying respectively on the conics S_0 and S_1, say P and Z, which are conjugate to one another in regard to the conic $(abc)^{\frac{1}{2}}S_0 + \theta S_1 = 0$, which passes through the common points of S_0 and S_1; and



conversely. Further, any conic through the intersections of S_0 and S_1 has an equation of the form $\phi^2 S_0 - S_1 = 0$. We prove that this conic is the locus of the intersection of two tangents, respectively of the conics S_0 and S_1, say p and z, which are conjugate to one another in regard to the conic $\phi\Sigma_0 + (abc)^{\frac{1}{2}}\Sigma_1 = 0$, which touches the common tangents of S_0 and S_1. But further, when $\phi = \theta$, the two dually corresponding facts arise in the same figure, the lines p and z being the tangents at the points P, Z, of the conics S_0 and S_1.

Let S_0, S_1 and S be any three conics which have four points in common. Let the tangent line, p, at any point, P, of the conic S_0, meet S in two points of which C is one. Let the two tangents be drawn from C to the conic S_1, the point of contact of one of these being Z. Denote the line PZ by c. From the second intersection, D, with the conic S, of the line p, draw a tangent to S_1, touching this in X. Let ZX meet p in Q. Let the line joining P to the intersection of the tangents of S_1 at X and Z be q.

Let the equations of S_0, S_1 be, respectively $S_0 = 0$, $S_1 = 0$, where $S_0 = x^2 + y^2 + z^2$, $S_1 = ax^2 + by^2 + cz^2$, and the equation of S be $\theta^2 S_0 - S_1 = 0$; let the coordinates of the point P be (ξ, η, ζ), and of the line p be (λ, μ, ν), so that we have $\xi^2 + \eta^2 + \zeta^2 = 0$, $\lambda^2 + \mu^2 + \nu^2 = 0$, $\lambda\xi + \mu\eta + \nu\zeta = 0$. Let (x, y, z) be any other point, and (l, m, n) any other line; let $P_0 = x\xi + y\eta + z\zeta$, and $P_1 = ax\xi + by\eta + cz\zeta$. Also let $\Sigma_0 = l^2 + m^2 + n^2$, $\Sigma_1 = a^{-1}l^2 + b^{-1}m^2 + c^{-1}n^2$, $\Pi_0 = l\lambda + m\mu + n\nu$, $\Pi_1 = a^{-1}l\lambda + b^{-1}m\mu + c^{-1}n\nu$. We can at once verify the following equations, identically true in regard to x, y, z and l, m, n:

$$(\theta^2 - a)(by\zeta - cz\eta)^2 + (\theta^2 - b)(cz\xi - ax\zeta)^2 + (\theta^2 - c)(ax\eta - by\xi)^2$$
$$= -(bc\xi^2 + ca\eta^2 + ab\zeta^2) S_1 + abcP_0^2 - \theta^2 P_1^2,$$

$$abc\{(a^{-1}\theta^2 - 1)(y\zeta - z\eta)^2 + (b^{-1}\theta^2 - 1)(z\xi - x\zeta)^2$$
$$+ (c^{-1}\theta^2 - 1)(x\eta - y\xi)^2\}$$
$$= \theta^2(a\xi^2 + b\eta^2 + c\zeta^2) S_1 + abcP_0^2 - \theta^2 P_1^2,$$

$$(\theta^{-2} - a^{-1})(b^{-1}m\nu - c^{-1}n\mu)^2 + (\theta^{-2} - b^{-1})(c^{-1}n\lambda - a^{-1}l\nu)^2$$
$$+ (\theta^{-2} - c^{-1})(a^{-1}l\mu - b^{-1}m\lambda)^2$$
$$= -[(bc)^{-1}\lambda^2 + (ca)^{-1}\mu^2 + (ab)^{-1}\nu^2]\Sigma_1 + (abc)^{-1}\Pi_0^2 - \theta^{-2}\Pi_1^2,$$

$$(abc)^{-1}\{(a\theta^{-2} - 1)(m\nu - n\mu)^2 + (b\theta^{-2} - 1)(n\lambda - l\nu)^2$$
$$+ (c\theta^{-2} - 1)(l\mu - m\lambda)^2\}$$
$$= \theta^{-2}(a^{-1}\lambda^2 + b^{-1}\mu^2 + c^{-1}\nu^2)\Sigma_1 + (abc)^{-1}\Pi_0^2 - \theta^{-2}\Pi_1^2,$$

which we shall call, respectively, (1), (2), (3) and (4). It will be seen that (3) and (4) are at once deducible from (1) and (2), and it is easy to deduce (2) from (1).

Now, regarding x, y, z as the coordinates of a variable point, the left side of the equation (1) vanishes when the point, which is the intersection of the line p with the polar line of (x, y, z) in regard to S_1, lies on the conic $\theta^2 S_0 - S_1 = 0$, or S; that is, when (x, y, z) is the pole, in regard to S_1, of any line through C or D. In other words, the left side of equation (1), put equal to zero, is the equation of the line pair consisting of the polars, in regard to S_1, of the points C and D. These lines pass, respectively, through Z and X, and meet S_1 in the points of contact of the other tangents to S_1 drawn from C and D, say Y and T. On the right side of equation (1), the terms $abcP_0^2 - \theta^2 P_1^2$, put equal to zero, would represent the line pair consisting of the polars of (ξ, η, ζ) in regard to the two conics $(abc)^{\frac{1}{2}} S_0 \pm \theta S_1 = 0$. Thus, the right side of equation (1), put equal to zero, would represent a conic passing through the points where these two polar lines meet the conic S_1. Therefore, these two polar lines are either the pair XZ, YT, or else the pair XY, ZT. We prove that they are the former pair. For we have shewn (Chap. I, Ex. 30) that the tangents of the conic S_1, at the points where it is met by the line PZ, are such as to meet the tangent, p, of S_0, in points lying on a conic through the common points of S and S_1; and such conic is identified by the single point C in addition to these four common points. Thus P, Z, T are in line, and, similarly, P, X, Y are in line. Wherefore, the three points consisting of the point P, the point of intersection, say, O, of XT and YZ, and the point of intersection of ZX and TY, form a self-polar triad in regard to S_1. Then, as O, the intersection of the polars of C and D in regard to S_1, is the pole of CD, it follows that ZX and TY meet on CD, so that Q, Y, T are in line. The lines whose equations are $(abc)^{\frac{1}{2}} P_0 \pm \theta P_1 = 0$, not containing the point P, save for one particular value of θ, are thus the lines ZX, TY. Therefore, the point Q is the point of intersection of the polars of P taken in regard to all the conics passing through the common points of S_0 and S_1. It follows, thence, that the points P, X are harmonic conjugates of one another in regard to the two points in which the line PX meets one of the two conics $(abc)^{\frac{1}{2}} S_0 \pm \theta S_1 = 0$, while the points P, Y are harmonic conjugates of one another in regard to the two points in which this line meets the other of these two conics. If P' be the other point in which the line PX meets the conic S_0, it will appear that P' and Y are conjugate in regard to the same conic as that for which P, X are conjugate, while P' and X and P, Y are, likewise, two pairs of conjugate points with respect to the same one of the two conics $(abc)^{\frac{1}{2}} S_0 \pm \theta S_1 = 0$.

Next, consider the equation (2). The left side vanishes when the line joining the points (x, y, z) and (ξ, η, ζ) touches the conic whose tangential equation is $\theta^2 \Sigma_1 - \Sigma_0 = 0$. This is a particular conic touching the common tangent lines of S_0 and S_1. The left side of equation (2), put equal to zero, thus represents the two tangents drawn from P to the conic $\theta^2\Sigma_1 - \Sigma_0 = 0$. The right side of equation (2), put equal to zero, represents, however, a conic passing through the points X, Y, Z, T; this consists, then, of the lines PXY, PZT. These lines, therefore, touch the conic $\theta^2\Sigma_1 - \Sigma_0 = 0$, which we may denote by Σ; we may denote the lines PXY, PZT, respectively, by d and c.

Now consider the equation (3). Regarding l, m, n as coordinates of a variable line, the left side vanishes when the pole $(a^{-1}l, b^{-1}m, c^{-1}n)$, in regard to Σ_1, of this line, and the pole, P, or (λ, μ, ν), of the line p, in regard to Σ, determine a line touching $\theta^{-2}\Sigma_0 - \Sigma_1 = 0$, which is the conic Σ. In other words, the left side of equation (3) vanishes for all lines (l, m, n) which are polars, in regard to Σ_1, of points of either of the two lines PXY, PZT; thus, put equal to zero, it represents, tangentially, the point pair constituted by the poles, in regard to Σ_1, of the lines d and c; if the tangents of S_1, at the points X, Y, Z, T, be called, respectively, x, y, z, t, these poles are the points (x, y) and (z, t). On the right side of the equation (3), the terms $(abc)^{-1}\Pi_0^2 - \theta^{-2}\Pi_1^2$ vanish when the line (l, m, n) passes through the pole, in regard to one of the conics $(abc)^{-\frac{1}{2}}\Sigma_0 \pm \theta^{-1}\Sigma_1 = 0$, of the line (λ, μ, ν); that is, these terms, put equal to zero, are the tangential equation of the point pair consisting of the poles of the line p in regard to these two conics. The right side of equation (3), put equal to zero, is, tangentially, the equation of a conic touching the tangents drawn from these poles to the conic S_1. We thus infer that the poles of the line p, in regard to the conics $\theta\Sigma_0 \pm (abc)^{\frac{1}{2}}\Sigma_1 = 0$, are a complementary pair of intersections of the tangents drawn from C and D to the conic S_1, other than the pair (x, y) and (z, t); they are also other than C and D. These poles are then the points (x, z) and (y, t). It is known that these points lie on a line, q, passing through P. Thus, the tangent, z, drawn from C to the conic S_1, is the conjugate of the tangent, p, drawn from C to the conic S_0, in regard to one of the conics $\theta\Sigma_0 \pm (abc)^{\frac{1}{2}}\Sigma_1 = 0$, and the other tangent, y, is the conjugate of p in regard to the other of these conics. It will appear that the other tangent drawn from C to the conic S_0 may be similarly coupled, respectively, with y and z.

Lastly, consider the equation (4). The left side, equated to zero, is the tangential equation of lines meeting the line p upon the conic $S_1 - \theta^2 S_0 = 0$, or the conic S. Thus it represents the point pair C, D. The equation thus expresses the fact we have already found, that the tangents from the points (x, z), (y, t), to the conic S_1, have the points, C, D, as a complementary pair of intersections.

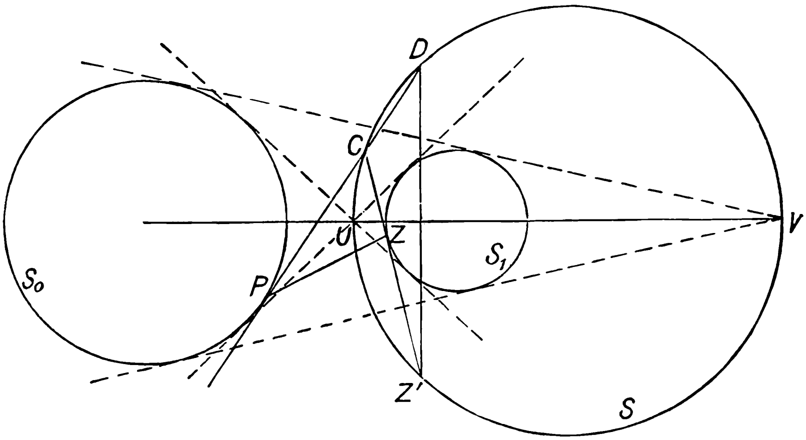
We have thus proved the results stated at the beginning of the example. We consider some particular cases.

A particular case arises when the conic $(abc)^{\frac{1}{2}}S_0 - \theta S_1 = 0$ is a pair of common chords of the conics S_0 and S_1, so that, in brief, the line PZ is divided harmonically by these two lines. The common chords will intersect in one of the three points which form the common self-polar triad for these two conics S_0, S_1. The line joining the other two points of this triad will contain two complementary intersections each of two of the common tangents of S_0 and S_1. It can be shewn that, in this case, the envelope $\Sigma_0 - \theta^2\Sigma_1 = 0$ touches both the common chords considered, and that the conic $\theta^2 S_0 - S_1 = 0$ passes through the two intersections of common tangents spoken of. For, when $(abc)^{\frac{1}{2}}S_0 - \theta S_1 = 0$ is a line pair, say, for $\theta = (bc/a)^{\frac{1}{2}}$, the envelope $\theta\Sigma_0 - (abc)^{\frac{1}{2}}\Sigma_1 = 0$ is the point pair consisting of the two intersections of common tangents spoken of. The coordinates (t, m, n) of the line pair $(abc)^{\frac{1}{2}}S_0 - (bc/a)^{\frac{1}{2}}S_1 = 0$, are, respectively, $l = 0$, $m = (a-b)^{\frac{1}{2}}$, $n = \pm(c-a)^{\frac{1}{2}}$; these touch $\Sigma_0 - (bc/a)\Sigma_1 = 0$, which is $a^{-1}(a^2 - bc)l^2 - (c-a)m^2 + (a-b)n^2 = 0$. The common tangents of S_0 and S_1 have coordinates $[a(b-c)]^{\frac{1}{2}}$, $\pm[b(c-a)]^{\frac{1}{2}}$, $[c(a-b)]^{\frac{1}{2}}$; when $\theta = (bc/a)^{\frac{1}{2}}$, the envelope $\theta\Sigma_0 - (abc)^{\frac{1}{2}}\Sigma_1 = 0$ reduces to $[b(c-a)]^{-1}m^2 - [c(a-b)]^{-1}n^2 = 0$, which represents the two points of intersection of common tangents spoken of. The coordinates of these two points are $x = 0$, $y = [b(c-a)]^{-\frac{1}{2}}$, $z = \pm[c(a-b)]^{-\frac{1}{2}}$; these points lie on the conic $\theta^2 S_0 - S_1 = 0$, which is

$$(bc - a^2)x^2 + b(c-a)y^2 - c(a-b)z^2 = 0.$$

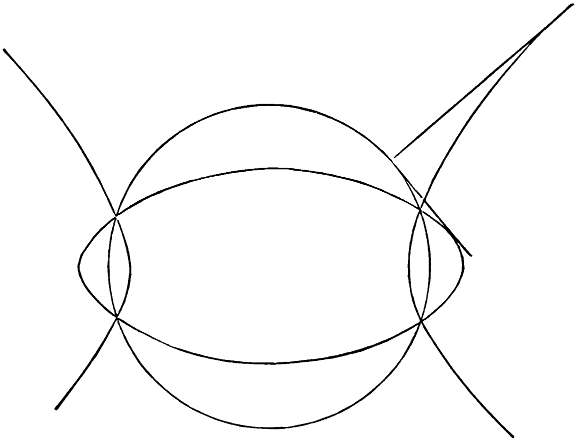
If the two intersections of common tangents spoken of, be called U and V, it appears that the tangents CP, CZ, respectively to S_0 and S_1, drawn from C, are harmonic conjugates in regard to CU and CV; if these tangents meet the conic $\theta^2 S_0 - S_1 = 0$ in further points D and Z', these points will, then, be harmonic conjugates in regard to the points U, V, of this conic. The line DZ' will, thus, pass through the pole of the chord UV of this conic; this is that one originally considered of the points, which are the common self-polar triad of S_0 and S_1, through which the common chords of this conic pass. Thus we have triads of points, C, D, Z', lying on the conic S, of which two joins touch, respectively, the conics S_0 and S_1, while the remaining join, DZ', passes through one of the triad of common conjugate points for S_0 and S_1. (In the general case, Chap. I, Ex. 31, the line DZ' touches a certain conic through the common points of S_0 and S_1.) As, however, the particular case in which the conic $(abc)^{\frac{1}{2}}S_0 - \theta S_1 = 0$ is a pair of common chords of S_0 and S_1, is, as has been remarked, also the particular case in which the envelope $\theta\Sigma_0 - (abc)^{\frac{1}{2}}\Sigma_1 = 0$ is a pair of intersections of common tangents of S_0 and S_1, the fact that $\Sigma_0 - \theta^2\Sigma_1 = 0$ touches the common chords corresponds dually to the fact that the conic

$\theta^2 S_0 - S_1 = 0$ passes through these intersections of common tangents. We have remarked that the tangents CP, CZ are harmonic in regard to CU and CV; these last are, in fact, the double rays of a pencil in involution, of which CP, CZ are a pair, and two other pairs are the lines drawn from C to the pairs of intersections of S_0 and S_1, two intersections being paired when they lie on one of the common chords which we considered. This is obvious because all these four intersections lie on the conic $\theta^2 S_0 - S_1 = 0$ which contains C, and the chords which join these pairs pass through the pole, in regard to this conic, of the line UV. Dually, if we denote the common chords considered by u and v, and consider the envelope $\Sigma_0 - \theta^2\Sigma_1 = 0$ for the particular value of θ necessary that the line c may be a tangent, the tangents, u, v, of this envelope, meet the tangent c in the double points of an involution, of which one pair are the points where c meets S_0 and S_1, and another pair are the points where c meets either pair of common tangents of S_0 and S_1 which meet on the line UV.



We may suppose the conics S_0, S_1 to be two circles, the common chords considered being the radical axis, and the line IJ. Then, if U, V be the intersections of the common tangents of the two circles which lie on the line of centres, the circle, S, coaxial with S_0 and S_1, which passes through U and V, is such that tangents CP, CZ, drawn from a point, C, of S, respectively to S_0 and S_1, meet S again in points, D, Z', lying on a line at right angles to the line of centres; further, the lines joining C to the absolute points I, J, common to the circles, as, also, the lines joining C to the other intersections of the circles, are harmonic in regard to CU and CV. Also, the line PZ is bisected by the radical axis; and this line envelopes a parabola which touches the radical axis, and touches the common tangents of the circles, and has for focus the middle point of the centres of the two circles. The two common tangents which meet in U are met by PZ in two points whose middle point is on the radical axis, as are the two common tangents which meet in V.

We may also regard the conics Σ_0, Σ_1 as two conics of a confocal system, the points of intersection, U, V, of pairs of common tangents, being taken for the absolute points, I, J. There is, then, a circle, passing through the common points of the two confocals, at every point of which intersect a tangent of one conic, and a tangent of the other at right angles to this. The two common chords of the confocals which meet in their centre subtend right angles at any point of this circle. The line joining the points of contact of the two perpendicular tangents envelopes a conic confocal with the given ones, which touches the common central chords of these; this line is divided harmonically by these chords, and divided harmonically by the lines joining I (or J) to the two foci, S, H, of the two conics.



A still more particular case of the general theorem is the fact that if a line be drawn, from a focus, S, of a conic, at right angles to the tangent, at a point, P, of the conic, meeting this in N, then N describes a circle, whose centre is the centre of the conic, having two points of contact with the conic. If the point equation of the conic be $a^{-1}x^2 + b^{-1}y^2 - z^2 = 0$, the lines NP, NS are tangents of the two envelopes expressed by $al^2 + bm^2 - n^2 = 0$ and $(a-b)l^2 - n^2 = 0$, and are harmonic conjugates in regard to the two lines drawn from N which belong to the envelope expressed by

$$al^2 + bm^2 - n^2 - [(a-b)l^2 - n^2] = 0, \text{ or by } l^2 + m^2 = 0;$$

this envelope is the point pair I, J. The point N thus lies on the locus whose point equation is $a^{-1}x^2 + b^{-1}y^2 - z^2 - (b^{-1} - a^{-1})y^2 = 0$, or $x^2 + y^2 - az^2 = 0$; this is the auxiliary circle of the conic. (See Chap. II, p. 86, above.)

Ex. 19. *Indication of a generalisation of the preceding results.* Referring back to the result given above in Ex. 4 (p. 111), we see that, if from the four elements defined by the two roots of the quadratic $f = 0$, and the two roots of the quadratic $f' = 0$, we form two pairs, by taking each root of $f = 0$ with one of the roots of $f' = 0$, which is possible in two ways, then the elements which are harmonic in regard to the constituents of both the pairs are given by one of the equations $(\Delta')^{\frac{1}{2}}f \pm (\Delta)^{\frac{1}{2}}f' = 0$. But the result of Ex. 4 leads to a result for two conics of which the corresponding corollary is in connexion with the result of the preceding Example 18. Let $S = 0$, $\Sigma = 0$ be the point equation, and the tangential equation, of the same conic, where

$$S = ax^2 + \dots + 2fyz + \dots,$$
$$\Sigma = -(bc - f^2)u^2 - \dots - 2(gh - af)vw - \dots;$$

let S', Σ' be what these become when a', b', ... are written, respectively, for a, b, ...; also let $T = 0$ be the condition for a line, of coordinates u, v, w, whose intersections with $S = 0$ are harmonic in regard to its intersections with $S' = 0$ (above, Ex. 17), where

$$T = -(bc' + b'c - 2ff')u^2 - 2(gh' + g'h - af' - a'f)vw - \dots.$$

Then, let the line (u, v, w) meet $S = 0$ in the points A, B, meet $S' = 0$ in the points A', B', and meet $\theta S + \theta' S' = 0$ in the points X, Y. In terms of the symbols of A, A', let the symbols of X and Y be $X = A + \xi A'$ and $Y = A + \eta A'$; and let $\epsilon = \xi^{-1}\eta$. It follows from Ex. 4 that

$$\frac{4\epsilon}{(1+\epsilon)^2} = \frac{\theta\theta'[2(\Sigma\Sigma')^{\frac{1}{2}} - T]}{[\theta(\Sigma)^{\frac{1}{2}} + \theta'(\Sigma')^{\frac{1}{2}}]^2}.$$

Thus, in particular, when X, Y are harmonic in regard to A, A', and so $\epsilon = -1$, the line (u, v, w) envelopes the conic whose tangential equation is $\theta^2\Sigma - \theta'^2\Sigma' = 0$.

Ex. 20. *Of correspondences, in particular of general involutions, upon a conic.* Taking the conic of which any point has coordinates of the form θ^2, θ, 1, we may consider two points, P and Q, of the conic, with parameters, respectively, θ and ϕ, which are so related that there exists an equation of the form

$$\theta^m(a\phi^n + b\phi^{n-1} + \dots) + \theta^{m-1}(a_1\phi^n + b_1\phi^{n-1} + \dots) + \dots$$
$$+ a_m\phi^n + b_m\phi^{n-1} + \dots = 0,$$

wherein the polynomial on the left is supposed to be general, containing every term $\theta^r\phi^s$ with $0 \leqq r \leqq m$ and $0 \leqq s \leqq n$. A particular case is that in which m and n are both 1, so that P and Q describe related ranges upon the conic (Vol. I, p. 140). In general, we say that there is a (m, n) correspondence between P and Q, there being m positions of P corresponding to any position of Q, and n positions of Q corresponding to any position of P. In saying this we are again assuming that a polynomial expression in a parameter vanishes for a number of values of this parameter equal to the degree of the polynomial. See Chap. IV, below.

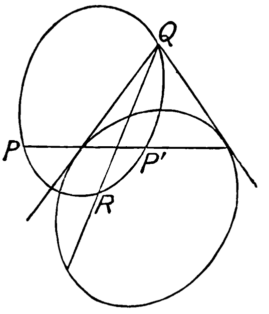
As a rule, it is not the case, in such a correspondence, that when Q takes the position P, then P takes one of the corresponding positions Q. This will be so if $m = n$, and the equation connecting θ, ϕ be symmetrical in regard to these. When $m = n = 1$ this arises if P, Q are pairs of an involution upon the conic. When $m = n = 2$ it arises if the relation be of the form

$$\theta^2 (a\phi^2 + h\phi + g) + \theta (h\phi^2 + b\phi + f) + g\phi^2 + f\phi + c = 0\,;$$

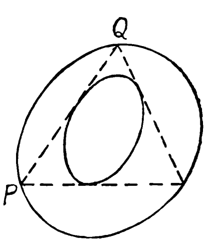
then the two positions of P which correspond to any position of Q are the intersections of the fundamental conic, $xz - y^2 = 0$, with the polar of Q in regard to the conic $ax^2 + 2fyz + \ldots = 0$. The polar of P in regard to this last conic then passes through Q, but meets the fundamental conic, in general, in a new point, R; thus, when Q takes the position P, one of the corresponding positions of P coincides with Q but the other is generally a fresh point. Another interpretation of the relation is obtained by remarking that, if the line joining P and Q, be written $ux + vy + wz = 0$, so that $u = 1$, $v = -(\theta + \phi)$, $w = \theta\phi$, we have

$$aw^2 - hvw + g(v^2 - 2wu) + bwu - fuv + cu^2 = 0,$$

and the line PQ envelopes a conic, of which this is the tangential equation. (Cf. pp. 125, 126.)



A particular case of the general symmetrical correspondence just described, is that in which any point Q, and the m points P which correspond to it, form a set of $(m + 1)$ points which remains the same set when Q takes the position of any one of the $(m + 1)$ points which form the set. Such a series of sets of $(m + 1)$ points is called an *involution* of sets of $(m + 1)$ points, and is of great importance. In the case $m = 2$, $n = 2$, this, clearly, requires that it be possible to take triads of points of $xz - y^2 = 0$ which are self-polar in regard to $ax^2 + 2fyz + \ldots = 0$, or that it be possible to take triads of points of $xz - y^2 = 0$ whose joins touch



the conic whose tangential equation is that written above. We have previously seen (Chap. I, Exx. 12 and 7) that, in either case, if one such triad be possible, an infinite number of such triads is possible. For general values of m, it is convenient to consider the equation satisfied by all the $(m+1)$ points forming the symmetrical set consisting of Q and the m corresponding points P. It can be shewn that this equation must necessarily be of the form

$$\theta^{m+1}(a+\lambda b)+\theta^m(a_1+\lambda b_1)+\ldots+\theta(a_m+\lambda b_m)+a_{m+1}+\lambda b_{m+1}=0,$$

where a, b, a_1, b_1, ... are constants, but λ varies from set to set. Thus the points of a set are given by values of θ satisfying an equation $u+\lambda v=0$, but the points of another set by values of θ satisfying an equation $u+\lambda' v=0$; here u, v are two definite polynomials in θ of degree $m+1$, which, corresponding to $\lambda=0$, $\lambda^{-1}=0$, respectively, give the points of two particular sets of the series. The whole involution is thus determined by two of its sets.

We may give the proof of this result: the m points P corresponding to Q will be given by an equation

$$\theta^m u_0+\theta^{m-1}u_1+\ldots+u_m=0,$$

where $u_0, u_1, \ldots, u_m$ are polynomials in the parameter, ϕ, by which Q is determined. By the definition of the involution, if we replace θ, in this equation, by one of its roots, say θ_1, and ϕ by any other of the roots, say θ_2, the equation remains true. Thus, forming the equation

$$(\sigma-\phi)(\sigma^m u_0+\sigma^{m-1}u_1+\ldots+u_m)=0,$$

or, say,

$$\sigma^{m+1}u_0+\sigma^m v_1+\sigma^{m-1}v_2+\ldots+v_{m+1}=0,$$

each of $u_0, v_1, v_2, \ldots, v_{m+1}$ is a polynomial in ϕ, and this equation is satisfied not only by $\sigma=\phi$, but, also, by each of the values, $\sigma=\theta_1, \sigma=\theta_2, \ldots, \sigma=\theta_m$, which, with ϕ, make up the set of $m+1$ values belonging to a set. These $(m+1)$ roots are, however, also obtained from the equation

$$\sigma^{m+1}u_0'+\sigma^m v_1'+\sigma^{m-1}v_2'+\ldots+v'_{m+1}=0$$

which differs from the preceding in having any one of $\theta_1, \theta_2, \ldots, \theta_m$ written in place of ϕ, in the coefficients; for instance, θ_2. If then we take a value of r for which v_r/u_0 does actually contain ϕ, and denote this by $F(\phi)$, we have $F(\phi)=F(\theta_1)=F(\theta_2)=\ldots=F(\theta_m)$. Thus the $m+1$ points of any set are given by $F(\phi)=\lambda$, for a proper value of λ; it follows, since u_0 is at most of order m in ϕ, that v_r, in $F(\phi)=v_r/u_0$, must be of order $m+1$, at least, if the values $\phi, \theta_1, \theta_2, \ldots, \theta_m$ are all different; and it cannot be of higher order, since none of $u_1, u_2, \ldots, u_m$ is of higher than order m in ϕ. For it is assumed that $\phi, \theta_1, \ldots, \theta_m$ are all different, save for particular values of ϕ.

The equation $\sigma^{m+1}u_0 + \sigma^m v_1 + \ldots = 0$ can thus be arranged in the form $P + \lambda Q = 0$, where P, Q are polynomials in σ, not containing ϕ, being the same as $F(\sigma) - \lambda = 0$. If s be another suffix such that v_s/u_0 does actually contain ϕ, so that, by the same argument, v_s is of order $m+1$ in ϕ, and the values $\phi, \theta_1, \ldots, \theta_m$ are given by the roots of $v_s/u_0 = \mu$, for a proper value of μ, it follows that $v_s/u_0 = AF(\phi) + B$, where A, B do not depend upon ϕ.

We may apply the preceding theory to find when two points $(\theta^2, \theta, 1)$, $(\phi^2, \phi, 1)$, of the conic $xz - y^2 = 0$, which are in $(2, 2)$ correspondence expressed by the symmetrical equation before written,

$$\theta^2(a\phi^2 + h\phi + g) + \ldots = 0,$$

or, say $F(\theta, \phi) = 0$, are two points of a set of three points belonging to a series in involution. For this it is necessary, and sufficient, that there should be two polynomials of the third degree, in the parameter x, say $u(x)$, $w(x)$, such that the $(2, 2)$ relation above written, $F(\theta, \phi) = 0$, is obtainable by elimination of λ from the two equations $u(\theta) + \lambda w(\theta) = 0$, $u(\phi) + \lambda w(\phi) = 0$, the equation $F(\theta, \phi) = 0$ being then of the form $(\theta - \phi)^{-1}[u(\theta)w(\phi) - u(\phi)w(\theta)] = 0$. But, if the two values of θ, corresponding to ϕ in virtue of $F(\theta, \phi) = 0$, taken with ϕ itself, constitute such a set, the equation in σ, $(\sigma - \phi)F(\sigma, \phi) = 0$, will give the set; therefore, by the theory given above, the various sets can be found from the equation $v_3/u_0 = \lambda$, namely

$$-\phi(g\phi^2 + f\phi + c)/(a\phi^2 + h\phi + g) = \lambda,$$

for varying values of λ. In particular, for $\lambda^{-1} = 0$, one set will be that given by $\phi^{-1} = 0$, and $a\phi^2 + h\phi + g = 0$, and another set will be that given by $\phi(g\phi^2 + f\phi + c) = 0$. If we write

$$u(\phi) = a\phi^2 + h\phi + g, \quad w(\phi) = \phi(g\phi^2 + f\phi + c),$$

it is easy to verify the identity

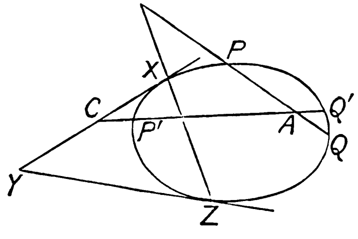
$$(\phi - \theta)^{-1}[u(\theta)w(\phi) - u(\phi)w(\theta)]$$
$$= gF(\theta, \phi) + [hf - bg - (ca - g^2)]\phi\theta.$$

Therefore, we see, supposing g not to be zero, that the condition that the $(2, 2)$ relation in question should connect two points of a set of three points of such a series in involution, is

$$hf - bg = ca - g^2.$$

This condition can also be shewn, if we write $(\sigma - \phi)F(\sigma, \phi)$ in the form $u(\phi).(\sigma^3 + H\sigma^2 + K\sigma + \lambda)$, to secure that $H = g^{-1}(a\lambda + f)$, $K = g^{-1}(h\lambda + c)$, in accordance with the theory given above. It will be obtained below (Ex. 24) as the condition that it be possible to find triads of points of the conic $xz - y^2 = 0$ which are self-polar in regard to the conic $ax^2 + 2fyz + \ldots = 0$.

Taking a fixed point, O, of the conic $xz - y^2 = 0$, and three other fixed points, A, B, C, not lying on this conic, the general conic through these four points will have an equation of the form $U+\lambda V=0$. The three intersections of this conic with $xz-y^2=0$, other than O, will then be given by an equation $u+\lambda v=0$, where u, v are cubic polynomials in the parameter, ϕ, of a point of $xz-y^2=0$; these three intersections will then be a set of an involution lying on this conic, of which the different sets are given by different values of λ. Conversely, let P, Q, R and P', Q', R' be any two triads of points of this conic; take, upon the conic, an arbitrary fixed point, O; then draw any definite conic through P, Q, R, O, and any other definite conic through P', Q', R', O; these two conics will have in common three further points, A, B, C, not generally lying upon the given conic $xz-y^2=0$. The general conic through A, B, C, O will then meet this given conic in three further points P'', Q'', R'', other than O, and these will belong to the involution of sets of three points determined by the two sets P, Q, R and P', Q', R'. Evidently, in this construction, the point O, and one of the points A, B, C may be taken arbitrarily; in particular, denoting by X, Z the points of contact of the given conic, $xz-y^2=0$, with $z=0$, $x=0$, respectively, there will be a set of the involution containing X; say this consists of X, P, Q; and there will be a set, say Z, P', Q', containing Z; assuming that Z is not one of P, Q and X is not one of P', Q', we may write the equations of the lines PQ, $P'Q'$ in the respective forms $ax+hy+gz=0$, $gx+fy+cz=0$. Then the sets of the involution will be given by



$$\lambda\,(a\phi^2+h\phi+g)+\phi\,(g\phi^2+f\phi+c)=0,$$

for varying values of λ, the points X, Z being given by $\phi^{-1}=0$, $\phi=0$, respectively; this is the same as given above. But this involution is obtained by the intersections of the conic $xz-y^2=0$ with the conics of equation $\lambda z\,(ax+hy+gz)+y\,(gx+fy+cz)=0$, for varying λ. These conics have for four common points; first, the point X, on $xz-y^2=0$; then the point, A, where the lines, PQ, $P'Q'$ meet; then B, where XZ, PQ meet; and, finally, C, where XY and $P'Q'$ meet.

A particular result, referred to in Chap. II (above, p. 87), furnishes an example of the theorem obtained here, that the sets of an involution, of three points, are given by an equation $\lambda u+v=0$, for varying values of λ, where u, v are cubic polynomials in the parameter which determines a point. For, if we assume, with continued anticipation of a limitation introduced in Chap. IV, that a cubic equation, in σ, whose roots are a, b, c, is capable of the form $(\sigma - a)(\sigma - b)(\sigma - c) = 0$, this shews that if a, b, c be the values belonging to any set of the involution, we have equations $a + b + c = P + Qabc$, $bc + ca + ab = R + Sabc$, where P, Q, R, S are the same for all the sets.

Now consider the pedal lines of a fixed point of the circle $x^2 + y^2 = z^2$ (the absolute points being $z = 0$, $x \pm iy = 0$), taken in regard to the joins of three points of the circle which are a set of an involution, of sets of three points, lying on the circle. We shew that, for all these sets, the pedal lines have a point in common. Putting $x + iy = X$, $x - iy = Y$, so that the circle is $XY = z^2$, the parameter for a point of the circle may be taken to be $\theta = X/z$. If for the fixed point this be λ, and for the points of a set of the involution the values be $\theta = a$, $\theta = b$, $\theta = c$, it is easy to prove that the equation of the pedal line is

$$2\lambda(Yabc - X\lambda) = [abc + \lambda(bc + ca + ab) - \lambda^2(a + b + c) - \lambda^3]z;$$

with the conditions given above, the right side is, save for the factor z,

$$abc(1 + \lambda S - \lambda^2 Q) + \lambda R - \lambda^2 P - \lambda^3;$$

thus the pedal line passes through the fixed point given by

$$Xz^{-1} = \tfrac{1}{2}(\lambda + P - \lambda^{-1}R),\quad Yz^{-1} = \tfrac{1}{2}(-\lambda Q + S + \lambda^{-1}).$$

(Third year problems, St John's College, Cambridge, Dec. 1889. Cf. Weill, *Liouville's J.* IV, 1878, 270.)

In general, in an involution of sets of n points, there will be $(n - 1)^2$ sets whereof two of the n points coincide, as is easy to see. For $n = 3$, taking two such sets as the fundamental sets, the parameter being chosen so that the points of coincidence are given by $\theta = 0$, $\theta = \infty$, the involution may be represented by

$$\theta^2(b\theta + a) + \lambda(c\theta + b) = 0.$$

Now suppose the points of the involution to be points, $(\theta^2, \theta, 1)$, of the conic $xz - y^2 = 0$. Define the pole of a line in regard to points A, B, C as the point O such that AO and the line meet BC in points harmonic in regard to B and C, with a similar condition for C, A and for A, B. Then we may prove that, for all sets A, B, C of the involution $\theta^2(b\theta + a) + \lambda(c\theta + b) = 0$, the pole of the line joining the two double points, $\theta = 0$, $\theta = \infty$, is the same, being the point $(a, -3b, c)$.

The condition for an involution of sets of three points upon a conic may be approached differently. The following examples lead up to this.

Ex. 21. *Reciprocation of one conic into another when they have a common self-polar triad.* As has already been remarked (above,

p. 107), the equations of two conics which have a common self-polar triad, when the coordinates are taken in regard thereto, are of the forms

$$ax^2 + by^2 + cz^2 = 0, \quad a'x^2 + b'y^2 + c'z^2 = 0.$$

Now let $Ax^2 + By^2 + Cz^2 = 0$ be a further conic for which the same triad is self-polar. If we consider the locus of the poles, taken in regard to this last conic, of the tangents of one of the former conics, it will be another conic. In fact the pole of the line $ax\xi + by\eta + cz\zeta = 0$, in regard to $Ax^2 + \ldots = 0$, is $(A^{-1}a\xi, B^{-1}b\eta, C^{-1}c\zeta)$, and when (ξ, η, ζ) is such that $a\xi^2 + b\eta^2 + c\zeta^2 = 0$, this pole describes the conic

$$a^{-1}A^2x^2 + b^{-1}B^2y^2 + c^{-1}C^2z^2 = 0.$$

If we consider the envelope of the polars, also taken in regard to $Ax^2 + \ldots = 0$, of the points of the same conic, $ax^2 + \ldots = 0$, it is similarly seen to consist of the tangents of the conic $a^{-1}A^2x^2 + \ldots = 0$. This last is then called the polar reciprocal of $ax^2 + \ldots = 0$ in regard to $Ax^2 + \ldots = 0$. There are thus four conics $Ax^2 + \ldots = 0$ in regard to which the polar reciprocal of $ax^2 + \ldots = 0$ is the other given conic $a'x^2 + \ldots = 0$, namely those for which $A^2 = aa'$, $B^2 = bb'$, $C^2 = cc'$.

Conversely, if a conic S be reciprocated to a conic S', a self-polar triad of points for S becomes a self-polar triad of lines for S', as we easily see; thus, when S and S' have a common self-polar triad, this is also self-polar for the reciprocating conic.

It may be remarked that if we take the polar line of a point, P, or (ξ, η, ζ), in regard to the conic $Ax^2 + \ldots = 0$, so obtaining $Ax\xi + By\eta + Cz\zeta = 0$, and then take the pole of this line in regard to one of the three associated conics, say $-Ax^2 + By^2 + Cz^2 = 0$, we obtain the point $(-\xi, \eta, \zeta)$ or P', which can be obtained from P by joining the point $(1, 0, 0)$, or A, to P, by a line, AP, meeting BC in D, and taking P' on AD harmonic to P in regard to A and D.

Ex. 22. *The determination of the common self-polar triad of two conics in general.* The construction for the common self-polar triad of two conics has been given (above, p. 23) when their four common points are given, and these are distinct. When the equations of the conics are given, in general form, say $ax^2 + 2fyz + \ldots = 0$, $a'x^2 + 2f'yz + \ldots = 0$, the algebraic determination will begin by seeking a point, (x, y, z), whose polar line is the same for both conics. For this, we must have

$$\frac{ax + hy + gz}{a'x + h'y + g'z} = \frac{hx + by + fz}{h'x + b'y + f'z} = \frac{gx + fy + cz}{g'x + f'y + c'z};$$

these lead to three equations of the form

$$(a - \lambda a')x + (h - \lambda h')y + (g - \lambda g')z = 0,$$

which, if the two given conics be $S = 0$, $S' = 0$, express that the polar lines of the three points $(1, 0, 0)$, etc., taken in regard to the conic $S - \lambda S' = 0$, meet in a point. Thus the conic $S - \lambda S' = 0$, for the appropriate value of λ, is a pair of lines, through the common points of the given conics, which intersect in (x, y, z). By elimination of x, y, z we find that λ is a root of a cubic equation, say $\Delta(\lambda) = 0$, which arises naturally in determinant form. When the given conics have four distinct intersections, there are three line pairs through these, and, therefore, this cubic equation has three roots which are different. Denote them by $\lambda_1, \lambda_2, \lambda_3$, in this case. Then let l_1, m_1, n_1 be determined from two of the equations of the form

$$(a - \lambda_1 a')\, l_1 + (h - \lambda_1 h')\, m_1 + (g - \lambda_1 g')\, n_1 = 0,$$

the third of these equations being a consequence of these two, and, similarly, let l_2, m_2, n_2 be found from the equations of the same form in which λ_1 is replaced by λ_2 and l_1, m_1, n_1 by l_2, m_2, n_2, respectively. If we denote by S_{12} the expression $al_1l_2 + f(m_1n_2 + m_2n_1) + \dots$, a sum of six terms, which is symmetrical in regard to (l_1, m_1, n_1) and (l_2, m_2, n_2), and denote by S'_{12} the similar expression in which $a, f, \dots$ are replaced by $a', f', \dots$, the first set of three equations enables us to deduce $S_{12} - \lambda_1 S'_{12} = 0$, and the second set of three equations similarly enables us to deduce $S_{12} - \lambda_2 S'_{12} = 0$. As we are supposing λ_1 and λ_2 to be different we can infer that $S_{12} = 0$, $S'_{12} = 0$. In the same way we infer that $S_{23} = S'_{23} = S_{31} = S'_{31} = 0$. From these it follows that if, in S and S', we replace x, y, z, respectively, by $l_1\xi + l_2\eta + l_3\zeta$, $m_1\xi + m_2\eta + m_3\zeta$, $n_1\xi + n_2\eta + n_3\zeta$, then S has a form $P\xi^2 + Q\eta^2 + R\zeta^2$ and S' a form $P'\xi^2 + Q'\eta^2 + R'\zeta^2$; here, for instance, P is what S becomes when l_1, m_1, n_1 are written for x, y, z, with similar values for Q, R, P', Q', R', and, as is easy to see, $P = \lambda_1 P'$, $Q = \lambda_2 Q'$, $R = \lambda_3 R'$. As the equations from which l_1, m_1, n_1 are found are homogeneous in these, we may suppose them taken so that $P' = 1$, and, similarly, may suppose l_2, m_2, n_2 and l_3, m_3, n_3 so taken that $Q' = 1$ and $R' = 1$.

When the roots $\lambda_1, \lambda_2, \lambda_3$ of the cubic equation above are not all different, the previous theory, and, in particular, the equations such as $S_{12} = 0$, may cease to hold, and it may not be possible to choose ξ, η, ζ so that S and S' involve only squares of these. Without entering here into a question of the general theory of quadratic forms, we give below the forms, for all cases, to which two conics can be reduced (Ex. 25).

Ex. 23. *Fundamental invariants for two conics.* As the cubic equation for λ, which arises above, has the geometrical interpretation in regard to the line pairs which pass through the common points of the conics $S = 0$, $S' = 0$, the four coefficients in this equation have values which, save for a common factor, are independent of the base points in terms of which the coordinates are taken. If we denote the cubic, written at length, by $\Delta - \lambda\Theta + \lambda^2\Theta' - \lambda^3\Delta' = 0$, the expression Δ is that polynomial, homogeneously of the third degree in the coefficients of the conic S, whose vanishing is the condition for $S = 0$ to be a line pair (above, p. 102), while Δ' is the similar polynomial for S', the expression Θ is only of the second degree in the coefficients of S, but is of the first degree in the coefficients of S', being, explicitly, the sum of three pairs of terms such as $Aa' + 2Ff'$, where $A = bc - f^2$, $F = gh - af$, etc., which are the coefficients in the tangential equation of S, while Θ' is similarly related to S'. We proceed to find the geometrical significance of the equation $\Theta = 0$, or of $\Theta' = 0$. [Add.]

Ex. 24. *The algebraical condition for one conic to be outpolar to another, or to be triangularly circumscribed to another.* It was proved in Chap. I (Ex. 11), and will appear independently here, that if two conics S and Σ' be such that a triad of points of S be self-polar in regard to Σ', then there is an infinite number of other triads of points of S with the same property; the polar, in regard to Σ', of any point, P, of S, meets S in points, Q, R, such that P, Q, R is self-polar in regard to Σ'. And, when this is so, there are triads of tangents of Σ' which are self-polar in regard to S, also in infinite number. It was suggested that S should be spoken of as outpolar to Σ', and Σ' as inpolar to S. The property is one relating to the points of the outpolar conic, S, and to the tangents of the inpolar conic, Σ'; and its algebraic condition involves, most conveniently, the coefficients in the point equation of the outpolar conic, and the coefficients in the tangential equation of the inpolar conic. The necessary and sufficient condition is linear in both these sets of coefficients, being, in fact, the vanishing of the sum of the three pairs of terms such as $aA' + 2fF'$, which, above, we have called Θ'. As the expression is of the first degree in the coefficients of S, it follows that, if S_1, S_2, ... be conics all outpolar to Σ, so also is any conic $A_1S_1 + A_2S_2 + \ldots = 0$.

It was also proved in Chap. I (Ex. 7), and will appear here, that if two conics S and Σ' be such that a triad of points A, B, C exists on the former, whose joins, BC, CA, AB, touch the latter, then there is an infinite number of other such triads, the tangents drawn to Σ', from any point of S, meeting S again in two points whose join is a tangent of Σ'. The condition for two conics to be in this relation is again primarily one for the points of S, and the tangents of Σ'. This condition is in fact

$$\tfrac{1}{4}(aA' + 2fF' + \ldots)^2$$
$$= (bc - f^2)(B'C' - F'^2) + 2(gh - af)(G'H' - A'F') + \ldots,$$

where, on both sides of the equation, there is a sum of three such pairs of terms as are written. If we suppose that the point equation, and not the tangential equation, of Σ', is given, being $a'x^2 + 2f'yz + \ldots = 0$, we have $B'C' - F'^2 = a'\Delta'$, $G'H' - A'F' = f'\Delta'$, etc.; then writing, as usual, $A = bc - f^2$, $F = gh - af$, etc., the condition can also be written $\frac{1}{4}(\Theta')^2 = \Delta'\Theta$, the conic which is triangularly inscribed to the other being Σ', or S'.

It is to be noticed that if we take a conic by which S is reciprocated into Σ', a triad of points of S which is self-polar in regard to Σ' becomes a triad of tangents of Σ' which is self-polar in regard to S, so that the condition $\Theta' = 0$ involves two geometrical facts; but a triad of points of S whose joins touch Σ', becomes, when the reciprocating conic is properly chosen, the triad of these three joins. (Cf. Chap. I, Ex. 24.) This is brought out by writing the condition $\Theta'^2 = 4\Delta'\Theta$ symmetrically in regard to the point equation of S and the tangential equation of Σ', as we have done. It may also be remarked, in regard to the two theorems, that the points in which a tangent line of Σ' meets S are conjugate points in regard to the conic whose equation is $2F - S\Theta' = 0$, where $F = 0$ is the conic locus of points from which the tangents to S and Σ' form a harmonic pencil (above, Ex. 17).

To prove that the algebraic conditions above given are necessary and sufficient, is easy, if we remark that they are both expressible by the invariants referred to in Ex. 23; it is necessary then only to verify them for any conveniently chosen triad of points of reference for the coordinates, that is, for any two conveniently chosen forms to which the equations of the conics can be simultaneously reduced.

Thus, for the first condition, suppose that a triad of points, A, B, C, lying on S, is self-polar in regard to Σ'. We can then, referring coordinates to A, B, C, suppose $S = 2fyz + 2gzx + 2hxy$, and $\Sigma' = b'c'u^2 + c'a'v^2 + a'b'w^2$. For these two we evidently have $\Theta' = 0$, which is thus *necessary*. Conversely, suppose $\Theta' = 0$; take the polar, in regard to Σ', of any point, A, of S, and let this meet S in B and C. In regard to A, B, C we can then suppose, as before, that $S = 2fyz + 2gzx + 2hxy$. The tangential equation $\Sigma' = 0$ must be such that the pole of the line BC, in regard to Σ', which in general is the point whose coordinates are A', H', G' (being the point whose equation is $u'(A'u + H'v + G'w) + v'(H'u + \ldots) + w'(G'u + \ldots) = 0$, when (u', v', w') are the coordinates, $(1, 0, 0)$, of the line BC), must, in this case, be the point A, or $(1, 0, 0)$; thus $G' = 0$ and $H' = 0$. The general form of Θ' is however, here, $2fF' + 2gG' + 2hH'$; thus, as we are assuming $\Theta' = 0$, we must have $fF' = 0$. We can only have $f = 0$ if the conic S reduces to the line pair $2x(gz + hy) = 0$, which we exclude. Wherefore $F' = 0$, and Σ' has the form

$$A'u^2 + B'v^2 + C'w^2 = 0.$$

Therefore $\Theta' = 0$ is *sufficient* for the triad A, B, C to be self-polar in regard to Σ'.

In regard to this relation of two conics, we may remark, further, that we have shewn (Chap. I, Ex. 11) that when S is outpolar to Σ', there can be found, on S, sets of four points, A, B, C, D, such that the pair of lines AD, BC are conjugate in regard to Σ', as also are BD, CA and CD, AB. In general, if, from three points A, B, C, in regard to which the equation of Σ' is $A'u^2 + 2F'vw + \ldots = 0$, there be drawn lines AD, BD, CD respectively conjugate to BC, CA, AB, with respect to Σ', they will meet in a point, D, of coordinates x, y, z, given by $xF' = yG' = zH'$; if the points A, B, C be on S, which then has an equation of the form $2fyz + 2gzx + 2hxy = 0$, the condition that this point D should also be on S is $2fF' + 2gG' + 2hH' = 0$, which is exactly $\Theta' = 0$. The equation $\Sigma' = 0$ can be written in the form

$$\frac{1}{F'}(G'H' - A'F')u^2 + \frac{1}{G'}(H'F' - B'G')v^2 + \frac{1}{H'}(F'G' - C'H')w^2$$
$$- F'G'H'\left(\frac{u}{F'} + \frac{v}{G'} + \frac{w}{H'}\right)^2 = 0,$$

and $u = 0$, $v = 0$, $w = 0$, $(F')^{-1}u + (G')^{-1}v + (H')^{-1}w = 0$ are the respective equations of the points A, B, C, D. In general, if (x_1, y_1, z_1), (x_2, y_2, z_2), (x_3, y_3, z_3), (x_4, y_4, z_4) be any four points, and A_1, A_2, A_3, A_4 be any constants, the equation

$$\Sigma A_r(ux_r + vy_r + wz_r)^2 = 0,$$

containing four terms, for $r = 1, 2, 3, 4$, is easily seen to be the tangential equation of a conic in regard to which the line joining any two of the four points is conjugate to the line joining the other two. Dually, sets of four tangents of Σ' exist, whose point pair intersections are conjugate in regard to S. (Cf. p. 218.)

The particular cases of the relation referred to in Ex. 13 of Chap. I are easy to verify. In particular, a single point, (ξ, η, ζ), regarded tangentially as a coincident point pair, of equation $(u\xi + v\eta + w\zeta)^2 = 0$, is inpolar to S, if (ξ, η, ζ) lie thereon; this suggests immediately the form above given for Σ' in terms of the equations of four points of S, if we notice that, when two or more conics, $\Sigma_1' = 0$, $\Sigma_2' = 0, \ldots$ are all inpolar to S, so also is any conic $A_1\Sigma_1' + A_2\Sigma_2' + \ldots = 0$. We easily verify that the equation

$$(u\xi + v\eta + w\zeta)^2 = 0,$$

if $\xi = m_1n_2 - m_2n_1$, $\eta = n_1l_2 - n_2l_1$, $\zeta = l_1m_2 - l_2m_1$, is that formed, by the rule, as the tangential equation of the line pair

$$(l_1x + m_1y + n_1z)(l_2x + m_2y + n_2z) = 0,$$

consisting of any two lines meeting in (ξ, η, ζ).

If $\Sigma_1 = 0$, $\Sigma_2 = 0$, ..., $\Sigma_5 = 0$ be any five conics, a conic $S = 0$ can be found which is outpolar to all of them, this requiring five linear equations for the six coefficients of S. Dually, a conic can be found inpolar to any five given conics. As an application of this, we can prove that, if $S = 0$, $T = 0$, $U = 0$ be the point equations of any three conics, all the conics given by the equation $\theta^2 S + 2\theta T + U = 0$, for varying values of θ, are inpolar to another conic; for the tangential equation corresponding to this is of the fourth degree in θ, and we can find a conic outpolar to the five conics whose tangential equations are those obtained by equating to zero the coefficients of all the powers (θ^r, for $r = 4, 3, 2, 1, 0$) of θ occurring in this tangential equation. This outpolar conic will, we have seen, contain the point of intersection of every line pair contained, for a proper value of θ, in the system $\theta^2 S + 2\theta T + U = 0$. The condition for a conic of this form to be a line pair, being of the third degree in the coefficients, is of the sixth degree in θ. If we assume, once more illogically anticipating the point of view explained in the following Chapter IV, that an equation of the sixth degree has six roots among the system of symbols which we are employing, we can then infer that the six line pairs of the system of conics $\theta^2 S + 2\theta T + U = 0$ intersect in six points lying on a conic.

Coming now to the relation between conics of which one is triangularly circumscribed to the other, suppose that three points, A, B, C, of a conic, S, are such that the joins, BC, CA, AB, touch another conic Σ'. Taking coordinates relatively to these points, we may then suppose that

$$S = 2fyz + 2gzx + 2hxy, \quad \Sigma' = 2F'vw + 2G'wu + 2H'uv.$$

Then, the expression $aA' + 2fF' + \dots$ reduces to $2fF' + 2gG' + 2hH'$; and the expression

$$(bc - f^2)(B'C' - F'^2) + 2(gh - af)(G'H' - A'F') + \dots$$

reduces to $(fF' + gG' + hH')^2$. The condition $\Theta'^2 = 4\Delta'\Theta$ is thus *necessary*. Conversely, if this condition be assumed, and we draw, from an arbitrary point, A, of S, the two tangents to Σ', meeting S again in B and C, and refer the coordinates to A, B, C, we have $S = 2fyz + 2gzx + 2hxy$, $\Sigma' = A'u^2 + 2F'vw + 2G'wu + 2H'uv$; thus the condition leads to $ghA'F' = 0$. We suppose S not to reduce to two lines, and Σ' not to reduce to two points; wherefore none of g, h, F' is zero, and we infer $A' = 0$, which shews that BC touches Σ'; or the condition is *sufficient*. [Add.]

We have already seen (Chap. I, Ex. 24) that the triads of points of S whose joins touch Σ' are all self-polar in regard to another conic, Ω. When we take

$$S = 2fyz + 2gzx + 2hxy, \quad \text{and} \quad \Sigma' = 2F'vw + 2G'wu + 2H'uv,$$

and take two points of S of coordinates x_1, y_1, z_1 and x_2, y_2, z_2, the equation of the line joining these is

$$(x_1x_2)^{-1}fx + (y_1y_2)^{-1}gy + (z_1z_2)^{-1}hz = 0,$$

as we verify at once; the condition that this line should touch Σ', which is $f^{-1}F'x_1x_2 + g^{-1}G'y_1y_2 + h^{-1}H'z_1z_2 = 0$, is however also the condition that the points (x_1, y_1, z_1), (x_2, y_2, z_2) should be conjugate in regard to $f^{-1}F'x^2 + g^{-1}G'y^2 + h^{-1}H'z^2 = 0$. It is easily seen that, in regard to this conic, S and Σ' are polar reciprocals; this is then the conic Ω. If we take another of the four conics in regard to which S and Σ' are polar reciprocals, say Ω', a triad of points, A, B, C, of S, whose joins touch Σ', reciprocates, in regard to Ω', into a triad of tangents of Σ' whose intersections, say A', B', C', lie on S. The point A' is thus obtained from A by the sequence of two reciprocations, in regard to Ω' and Ω, and, as has been remarked, the line AA' passes through one of the triad of points self-polar in regard to both S and Σ', as also do BB' and CC'. The aggregate of the triads A, B, C may thus be arranged in sets of four, of which any two are in perspective.

If the conics S, Σ' be referred to their common self-polar triad, it is easy to choose a parameter for the points of S, such that the condition, that a chord of S should be a tangent of Σ', takes the form $(\theta^2\phi^2 + 1)a + \theta\phi b - (\theta^2 + \phi^2) = 0$, and to see (see Ex. 20, above) that the condition that two points, θ, ϕ, so connected should be two of a set of an involution of sets of three points is $a^2 = b + 1$. Introducing this value of b, and adjoining the factor $\theta - \phi$, we obtain, for the cubic equation satisfied by ϕ and the two values, θ_1, θ_2, associated therewith,

$$\sigma^3 - \sigma^2 a\phi(\phi^2 - a)(a\phi^2 - 1)^{-1} - \sigma a + \phi(\phi^2 - a)(a\phi^2 - 1)^{-1} = 0.$$

Thus, in accordance with the theory, the involution of sets of three points is given by $\lambda(a\phi^2 - 1) - \phi(\phi^2 - a) = 0$, for varying values of λ. Four associated sets of this involution are given by λ, $-\lambda$, λ^{-1}, $-\lambda^{-1}$, corresponding to the values ϕ, $-\phi$, ϕ^{-1}, $-\phi^{-1}$, as we easily see. The expression $\Theta'^2 - 4\Delta'\Theta$ can be written as the product of four (irrational) factors; it vanishes when the roots α, β, γ, of the cubic equation $\Delta - \lambda\Theta + \lambda^2\Theta' - \lambda^3\Delta' = 0$, are subject to

$$\alpha^{\frac{1}{2}} + \beta^{\frac{1}{2}} + \gamma^{\frac{1}{2}} = 0.$$

Ex. 25. *Enumeration of reduced forms for the equations of any two conics.*

When two conics intersect in four points which are not distinct, the preceding determination of the equations $ax^2 + by^2 + cz^2 = 0$, $a'x^2 + b'y^2 + c'z^2 = 0$, fails. When the conics touch in two points, they have an infinite number of common self-polar triads, and their equations can, in an infinite number of ways, be reduced to

$x^2+y^2+z^2=0$, $x^2+y^2+cz^2=0$. In this case they can be reciprocated into one another in an infinite number of ways.

Prove that when the conics have one point of contact, their equations can be taken to be $2xy+z^2=0$, $2xy+cz^2+y^2=0$. And further that they are, then, polar reciprocals of one another in regard to either of the two conics $2xy \pm c^{\frac{1}{2}}z^2+\frac{1}{2}y^2=0$.

Also, that when three of the points of intersection coincide at one point, their equations can be taken to be

$$2xy+z^2=0, \quad 2xy+z^2+2yz=0.$$

And that, then, they are polar reciprocals of one another in regard to $2xy+z^2+yz-\frac{1}{8}y^2=0$.

Finally, when the four intersections coincide, that their equations can be taken to be $2xy+z^2=0$, $2xy+z^2+y^2=0$. And that, then, they are polar reciprocals of one another in regard to

$$2xy+z^2+\tfrac{1}{2}y^2-\tfrac{1}{2}\sigma(my+2z)^2=0,$$

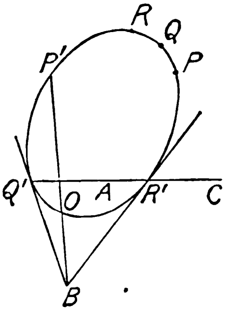
for any value of m, σ being 0 or 1. [Add.]

Ex. 26. *A particular involution of sets of three points. Apolar triads.*

It has been seen that an involution of sets of three points on a conic is obtained by the intersections of this conic with a set of conics all passing through a point, O, of the conic and through three other points, A, B, C, not lying on the conic. A special case which is of interest is when A, B, C are a self-polar triad in regard to the given conic. It can then be seen that if the parameters, θ, of two sets of the involution be such that, respectively,

$$a\theta^3+3b\theta^2+3c\theta+d=0 \quad \text{and} \quad a'\theta^3+3b'\theta^2+3c'\theta+d'=0,$$

then $ad'-3bc'+3cb'-da'=0$. This relation is clearly unaffected if we replace a, b, c, d, respectively, by $a+\lambda a'$, $b+\lambda b'$, $c+\lambda c'$, $d+\lambda d'$, whatever λ may be. It is also unaffected if we use, in place of θ, a parameter, ϕ, given by $(m\theta+n)/(r\theta+s)$; namely, if the cubic equations then become $A\phi^3+3B\phi^2+\ldots=0$, and $A'\phi^3+\ldots=0$, we have $AD'-3BC'+\ldots=0$; as may readily be verified. Every two sets of the involution are then apolar triads. Conversely, let P, Q, R and P', Q', R' be any two triads upon a conic; upon the line $Q'R'$ two points, A, C, can be taken which are conjugate to one another in regard to all conics through the four points P', P, Q, R; in particular A, C will then be conjugate in regard to the given conic. If B be the pole of $Q'R'$, in regard to the given conic, and BP' meet this conic again in O, it can be shewn that the six points P, Q, R, A, C, O lie



on a conic (above, p. 92). But, when P', Q', R' and P, Q, R are apolar, this conic also passes through B, as may be proved. The points A, B, C are a self-polar triad in regard to the given conic; and there are two conics through these, and through the point O, whose further intersections with the given conics are, respectively, the triad P', Q', R' and the triad P, Q, R; namely, the first of these is the degenerate conic consisting of the lines AC and BO; the second of these is the conic above remarked. Thus every conic through A, B, C, O meets the given conic in a triad of points apolar with P, Q, R, and with P', Q', R'.

If the given conic, referred to Q', R', B, have the equation $xz - y^2 = 0$, any conic through A, B, C has an equation of the form $x^2 - \lambda^2 z^2 = 2y(fz + hx)$; if this pass through O, or $(m^2, m, 1)$, we can replace $2f$ by $m^3 - \lambda^2 m^{-1} - 2hm^2$. The three other intersections of this conic with the given one are then determined by

$$\theta^3 + \theta^2 m + \theta m^2 + \lambda^2 m^{-1} - 2h\theta(\theta + m) = 0,$$

which, for every value of h, is apolar with the cubic $\theta^2 + \theta m = 0$, belonging to Q', R', P'. It is easy to see that A, C are conjugate in regard to all conics through P', P, Q, R.

If, for $f = ax^3 + 3bx^2y + 3cxy^2 + dy^3$, the Hessian form

$$H = f_{11}f_{22} - f_{12}^2, \quad \text{where } f_{11} = \partial^2 f/\partial x^2, \text{ etc.},$$

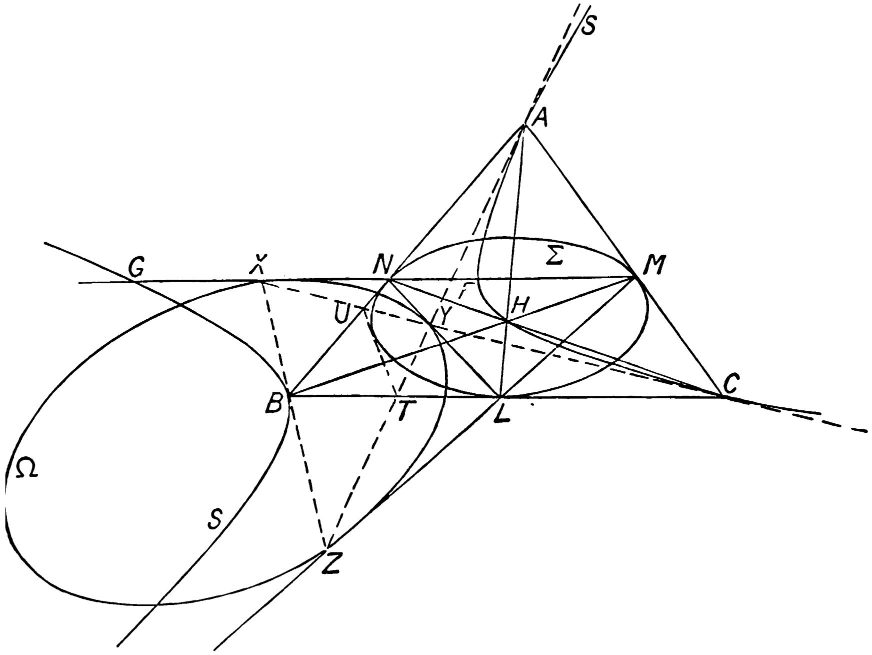
be denoted by $px^2 + qxy + ry^2$, we at once verify that $ar - bq + cp = 0$ and $br - cq + dp = 0$. This gives the result, previously mentioned (above, p. 124), that the cubic form $H(Ax + By)$, wherein A, B are arbitrary, is apolar with f. We have also mentioned (see above, p. 30) that if the tangents at three points, P, Q, R, of a conic, meet QR, RP, PQ in D, E, F, the line DEF meets the conic in the Hessian points, upon the conic, of the points P, Q, R. Wherefore, if P, Q, R and Q', R' be any points of a conic, the point, P', such that P', Q', R' are apolar with P, Q, R, may be constructed by drawing the conic touching QR, RP, PQ, $Q'R'$ and the line DEF; the tangents to this conic, other than $Q'R'$, drawn from Q' and R', meet in the point, P', of the given conic, which is required. A further construction for P' arises from what is said above; we have only to draw the conic through P, Q, R and B (the pole of $Q'R'$), which meets $Q'R'$ in points, A, C, conjugate in regard to the given conic; if this meet the given conic again in O, then P' is on BO.

The line DEF, spoken of above, may, as before (Chap. I, Ex. 9), be called the Hessian line of P, Q, R. The reader may verify, for example, that for the three points of a circle, of centre O, consisting of the absolute points I, J and any point, P, of the circle, the Hessian line is that through the middle point of O, P, at right angles to OP. Given three tangents of a conic, we may, dually, define the Hessian point of these. For example, in the case of a parabola, of focus S, the Hessian point of the three tangents consisting of SI, SJ and the absolute line IJ, is the point H, such that the directrix is at right angles to SH and passes through the middle point of S, H.

It may also be proved that if two conics, S and S', meet in A, B, C, D, the polar line, in regard to the conic S, of the Hessian point of the tangents of S' drawn at A, B, C, meets S in two points, which, with D, form, on S, a triad apolar with the triad A, B, C. Dually, if the common tangents of two conics, Σ and Σ', be a, b, c, d, and we take the Hessian line of the three points where Σ' touches a, b, c, this Hessian line meets Σ in two points which, taken with the point of contact of d with Σ, form a triad apolar with the points of contact of a, b, c with Σ. (Cf. Chap. I, Ex. 32.)

Ex 27. Three conics related in a particular way.

Suppose that a conic, Σ, touches three lines, BC, CA, AB, respectively at L, M, N; and that H is the Hessian point of the three tangents, being the point common to AL, BM, CN. Further, that



S is any conic, through A, B, C, which passes also through H. Then, for S, the triad L, M, N is self-polar. The tangents of S, at A and C, thus meet on NL, say, in Y, and if these tangents meet BC, BA, respectively, in T and U, the line TU touches Σ. For, taking various conics S, through A, B, C, H, the lines TU envelope a conic, and this is identified with Σ by remarking that particular conics S are the line pairs AB, NC; AL, CB; AC, BH, for which the line TU is, respectively, AB; BC; CA. The line TU is the Hessian line of A, B, C, for the conic S; the relation of the conics S, Σ is thus reciprocal.

The conic S meets MN in two points, F, G, which are harmonic in regard to M and N; thus the point triad A, F, G, of points of S, is self-polar in regard to Σ, and S is outpolar to Σ. If the tangents of S, at A, B, C, meet MN, NL, LM, (in pairs), respectively in X, Y, Z, the line triad YZ, ZX, XY is self-polar for all conics which touch BC, CA, AB and TU, in particular for Σ. Thus S is also inpolar to Σ.

Further, if we consider the locus of the poles, in regard to Σ, of the tangents of S, that is, the polar reciprocal of S in regard to Σ, whose tangents are the polars, in regard to Σ, of the corresponding points of S, we obtain a third conic, say, Ω. As the polar of XZ, in regard to Σ, is the point Y, and the polar of B, in regard to Σ, is NL, with a similar remark for ZY and XY, it appears that Ω touches MN, NL, LM, respectively at X, Y and Z. It will appear that Ω is equally the polar reciprocal of Σ in regard to S; and that any two of the three conics, S, Σ, Ω are related to one another in the same way as were S and Σ.

We see that the condition that a conic, S, through A, B, C, should contain the Hessian point of the lines BC, CA, AB, in regard to a conic Σ touching BC, CA, AB, is that S should be outpolar to Σ. With the symbols, if S be $2fyz + 2gzx + 2hxy = 0$, and Σ be, tangentially, $vw + wu + uv = 0$, which is not a restriction, the Hessian point referred to is $(1, 1, 1)$, and the condition that S should contain this is $f + g + h = 0$, which is the condition that S should be outpolar to Σ. Thus it follows that, if A', B', C' be any other triad of points of the conic S, for which $B'C'$, $C'A'$, $A'B'$ touch Σ, the Hessian point of these lines, in regard to Σ, also lies on S; and the Hessian line of A', B', C', in regard to S, also touches Σ; and the figure may be developed from A', B', C' as it was from A, B, C. In the figure we have considered, there are three triads of points; A, B, C; L, M, N, and X, Y, Z; the points of one triad lie on the joins of the points of another triad, while the joins of the points of the first triad contain the points of the third triad. Keeping the conics, S, Σ, Ω, fixed, such a set of three point triads can be initiated from any one of the nine points; and the triad, A', B', C', of points of S, belonging to such a set, will be apolar with A, B, C. This follows from what has preceded.

The conics S, Σ, being such that S is both outpolar to Σ, and triangularly circumscribed to Σ, are such that the two invariants

Θ, Θ' for these two conics (above described, Ex. 23) are both zero. For we have both $\Theta' = 0$ and $\Theta'^2 = 4\Delta'\Theta$. Referring S and Σ to their common self-polar triad, we find that these, and the conic Ω, may be taken to have equations $x^3 + y^2 + z^2 = 0$, $x^2 + \omega y^2 + \omega^2 z^2 = 0$, $x^2 + \omega^2 y^2 + \omega z^3 = 0$, where ω is such that $(2\omega + 1)^2 + 3 = 0$. Another form to which three such conics can be reduced is $x^2 + 2yz = 0$, $y^2 + 2zx = 0$, $z^2 + 2xy = 0$ (see the concluding problems on Analytical Conics in Wolstenholme's problems).

Another deduction of the three conics may be made by taking three points, A, B, C, of the conic S, then drawing, through the pole, Y, of AC, any line to meet BA, BC, respectively, in N and L, and then describing the unique proper conic, Σ, which touches BA, BC, respectively, at N and L, and also touches AC. If this conic touch AC at M, the conic Ω then arises as touching NL at Y, and touching MN and ML where these are met by the tangent at B of the conic S.

Particular figures in which three such conics arise may be referred to: (1) If O, P, Q, R be the feet of the four normals drawn to a conic, S, from any point, T, and, the point O being kept fixed, the point T be allowed to vary on the normal at O, the triads of lines, QR, RP, PQ, so obtained, are all tangents to a parabola, Σ, and the poles of these lines, in regard to S, describe a rectangular hyperbola, Ω. These three conics are related as above. Their respective equations, that of Σ being tangential, may be taken to be

$$a^{-1}x^2 + b^{-1}y^2 - z^2 = 0, \quad z_0 uv - b^{-1}y_0 uw - a^{-1}x_0 vw = 0,$$
$$xyz_0 + xzy_0 + yzx_0 = 0,$$

where $a^{-1}x_0{}^2 + b^{-1}y_0{}^2 - z_0{}^2 = 0$. (2) If a circle, S, be described to pass through the focus of a parabola, Σ, with its centre on the directrix of the parabola, there is associated with these a rectangular hyperbola, Ω. The equations may be taken to be

$$(x + az)^2 + y^2 - 4a^2z^2 = 0, \quad y^2 - 4axz = 0, \quad x^2 - y^2 - 3a^2z^2 - 2axz = 0,$$

the tangential equation of Ω being $-3l^2 + 4m^2 + a^{-2}n^2 + 2a^{-1}nl = 0$. In connexion with this set we may deduce the result that when a parabola touches the lines BC, CA, AB, in such a way that its directrix contains the centre of the circle A, B, C, the nine points circle of the triad which is formed by the intersections of the tangents of the circle drawn at A, B, C, touches this circle at the focus of the parabola.

Ex. 28. *The director circle of a conic touching three lines is cut at right angles by the circle for which the three lines form a self-polar triad.* Let a, b, c be the lines, Σ the conic touching them, and C the circle. As Σ is inpolar to C, therefore C is outpolar to Σ; thus, by Gaskin's theorem, C cuts the director circle of Σ at right angles.

Ex. 29. The circle in regard to which a triad of points is self-polar has its centre at the orthocentre of the triad. If two triads of points on a conic have the same orthocentre, there is a circle in regard to which both triads are self-polar. (Cf. Ex. 21, p. 45.)

Ex. 30. Prove that conics touching three lines whose director circles have a common point have a fourth common tangent.

Ex. 31. *A transformation of conics through four points into conics having double contact.* The equations

$$\xi^{-1}(xy - z^2) = \eta^{-1}y(x - y) = -\zeta^{-1}z(x - y)$$

lead to $$x^{-1}(\xi\eta - \zeta^2) = y^{-1}\eta(\xi - \eta) = -z^{-1}\zeta(\xi - \eta)$$

and transform conics, of equation $y^2 - z^2 + \lambda(z^2 - x^2) = 0$, passing through the four points $(1, \pm 1, \pm 1)$, into conics, of equation $(x - y)^2 + \lambda(z^2 - x^2) = 0$, all having double contact on $x - y = 0$.

Other Examples are found in the Additions at the end of the Volume.

CHAPTER IV

RESTRICTION OF THE ALGEBRAIC SYMBOLS. THE DISTINCTION OF REAL AND IMAGINARY ELEMENTS

Review of the development of the argument. In the first three chapters of this volume we have followed the plan, adopted in Chapter I of Volume I, of avoiding reference to the relative order of the points of a line, or to characteristics of the algebraic symbols which would follow from such order, save for the occasional anticipation, in some of the latter examples in Chapter III, involved in referring to the roots of an equation. Our discussion of the Real Geometry, in Chapter II of Volume I, led us to regard the figures of such a real geometry, when amplified by means of the postulated elements, as existing among those of the Abstract Geometry. Thus we came to recognise, upon a line of which three points, O, E, U, are given, the existence of an aggregate of points satisfying the conditions for an abstract order (Vol. I, pp. 121, 128); while, however, in the real geometry, two points determined a segment, *two* segments were determined in the abstract geometry by the assignment of two points; and, instead of the possibility of speaking of a point as lying between two others, we were led to speak of the separation of two points of a line by two others (*ibid.* pp. 118, 119). At the same time, the points of a line obtainable, from three given points of the line, by a finite number of repetitions of the process of forming the fourth harmonic point from three given points, were associated, relatively to the three fundamental points, with certain iterative symbols, analogous to the integers of ordinary arithmetic (*ibid.* pp. 86, 138); and it was found, on the basis of the conception of the separation of two points by two others, that the points obtainable by this harmonic process arise in every segment of the line (*ibid.* p. 132). It was suggested (*ibid.* p. 146) that a consequence of the assumption of the existence of an aggregate of points upon the line satisfying the condition (3) for an abstract order (*ibid.* p. 122), would be the introduction of algebraic symbols forming a natural extension of the iterative symbols, as the irrational numbers of arithmetic form an extension of the rational numbers; it would follow from the equable distribution of the points of the harmonic net, that points for which such extended symbols are appropriate would be equably distributed. The deduction of Pappus' theorem (*ibid.* p. 129) was for points satisfying the conditions for an abstract order, it being assumed that the lines involved contained all the points necessary to the satisfaction of these conditions. More fully, the geometrical scheme was built up by supposing certain points to be given, and other points, in infinite number, to be deduced from these by prescribed rules of construction; it was assumed that if the fundamental points were among those for which the conditions for an abstract order, on any lines containing them, were satisfied, the points derived therefrom by the prescribed conditions might equally be regarded as satisfying such conditions. This underlying assumption of the existence of what, relatively to the rules of construction, may be called a *closed* set of points, which is to be made more precise with the use of the algebraic symbols, was avoided, in the Abstract Geometry of Chapter I of Vol. I, by the frank assumption of Pappus' theorem.

We were not content, however, with only points satisfying the conditions for an abstract order. We recognised, also, the existence of points such as would arise if the algebraic symbols appropriate to the geometry were such that the equation $z^2 = c$ could always be satisfied by a symbol, z, of the system employed, whatever symbol of this system c might be. When, in particular, c is -1, this condition requires the existence of points not previously recognised (see Vol. I, p. 162). We shall, as is customary, use i to denote a symbol for which $i^2 = -1$. By the adjunction of this symbol, i, to the symbols previously introduced on the basis of the iterative symbols, it is then possible to obtain a solution of the equation $z^2 = c$ for every symbol c which is itself formed from i and the previous symbols. If we call the symbols consisting of the iterative symbols, and those derived from them as the irrational numbers of arithmetic are derived from the rational numbers, the *real* symbols, all the symbols arising in consequence of the fundamental geometrical constructions, and the possibility of Steiner's problem (Vol. I, p. 155), in virtue of the laws of combination of the symbols (Vol. I, p. 64), will evidently be of the form $x + iy$, where x and y are real symbols.

It is the case now that, if we introduce certain laws of order of succession, or, if the phraseology is allowed, certain conceptions of *magnitude*, the real symbols are, in manipulation, indistinguishable from the real numbers of arithmetic, and the symbols $x + iy$ are indistinguishable from the numbers of ordinary Analysis. To those who have considered the theoretical basis of Analysis, this conclusion will be evident. But this basis is often discussed with the help of conceptions derived from the consideration of the measurement of quantity, and with a metrical Euclidean plane[1]. Some brief further indication of the ideas involved may therefore be allowed.

---

[1] Cf. Gauss, *Werke*, III, 1866, p. 79. Ich werde die Beweisführung in einer der Geometrie der Lage entnommenen Einkleidung darstellen, weil jene dadurch die grösste Anschaulichkeit und Einfachheit gewinnt. Im Grunde gehört aber der

To some it will appear that it would have been better, as it would have been simpler, frankly to assume from the first that all points to be considered in the geometry are such as those for which the numbers of Analysis, $x + iy$, are appropriate. To the writer this attitude appears to beg one of the main, and most interesting, questions arising in discussing the foundations of geometry. It is admitted that, by help of the symbols, we can define a closed system of points and figures to which this closed system of symbols is appropriate. But this does not appear to preclude the existence of other points and figures susceptible of geometrical theory. It is true of course that in the present volumes we do not obtain any geometrical results for which corresponding results, identical in statement, do not hold in the realm of points representable by symbols $x + iy$. But this appears to be a consequence of the arbitrary limitation, adopted for practical reasons, involved in the assumption, first of Pappus' theorem, and then of the possibility of Steiner's construction, or, more generally, as in some examples in Chap. III, of the possibility of the solution of problems depending, when expressed algebraically, on equations of higher than the second order. Nor, even, is it the case that the rules for the order of succession of the real symbols, to which we presently proceed, are the only ones we might adopt. For instance, an interesting theory arises by considering a system of symbols representable in the form $a + bx + cx^2 + \ldots$, wherein $a, b, c, \ldots$ may be supposed to be real symbols, but x *not* one of these, and agreeing that such a symbol shall be held to follow another symbol of the same form, when, in the difference of these, $a - a' + (b - b')x + (c - c')x^2 + \ldots$, the first of the coefficients $a - a', b - b', c - c', \ldots$, which is not zero, is *positive*. [Add.]

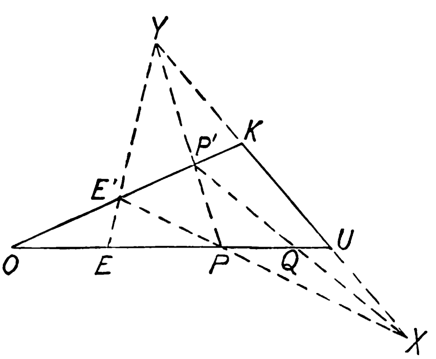
The distinction of positive and negative for the real symbols. The real symbol, a, of a point, $O + aU$, belonging to the ordered aggregate which we may suppose to exist upon a line, upon which three points of the aggregate, O, U, and E, of symbol $E = O + U$, are given, is said to be *positive* when the point lies in the segment OU which contains E. When the point belongs to the other segment OU, the symbol a is said to be negative. We saw that the points $O + aU$, $O - aU$ are harmonic conjugates in regard to O and U, and, therefore, separated by O and U (Vol. I, pp. 74, 119); thus, when a is a positive symbol, the symbol $-a$ is negative. In particular, as $0 = -0$, it is immaterial whether we regard the symbol of the point O as positive or negative; the point U is exceptional, as will appear, and our definition does not apply to it.

eigentliche Inhalt der ganzen Argumentation einem höhern von räumlichen unabhängigen Gebiete der allgemeinen abstracten Grössenlehre an, dessen Gegenstand die nach der Stetigkeit zusammenhängenden Grössencombinationen sind, einem Gebiete, welches zur Zeit noch wenig angebauet ist, und in welchem man sich auch nicht bewegen kann ohne eine von räumlichen Bildern entlehnte Sprache.

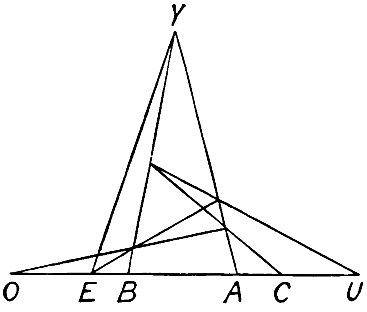
Whether c be a positive or negative real symbol, the symbol c^2 is positive; in virtue of $(-c)(-c) = c^2$ (Vol. I, p. 85), it is sufficient to prove this when c itself is positive. To pass from $P, = O + cU$, to $Q, = O + c^2U$, the construction given (Vol. I, p. 84) was as follows: draw, from O and U, respectively, two arbitrary lines OK, UK, meeting in K; take Y arbitrarily on UK; let EY meet OK in E', and $E'P$ meet KU in X; then, if PY meet OK in P', the point Q is the intersection of $P'X$ with OU. Conversely, if

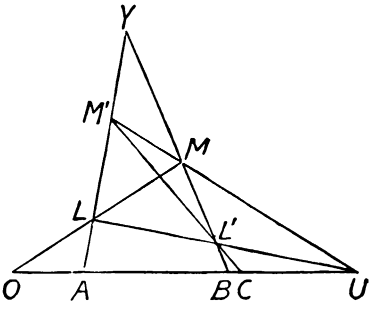
$$Q = O + aU,$$

and a be a positive real symbol, there is one positive real z for which $z^2 = a$, as well as a negative real $-z$. To obtain P from Q is, in fact, the problem considered in Vol. I, p. 157 (iii): we are to draw through the given points E', Q, Y, respectively in the segments $OE'K$, OQU, $UXYK$, three lines, $E'PX$, XQP', $YP'P$, whose intersections in pairs, respectively P', P and X, shall lie respectively in the specified segments.



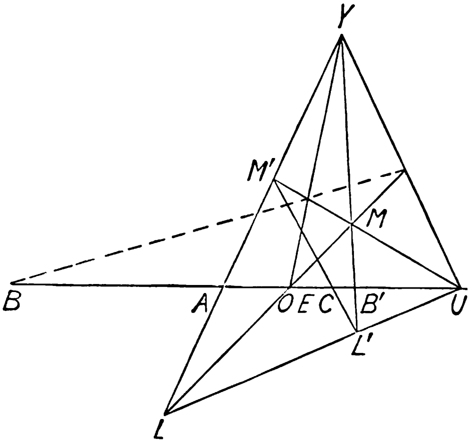
If a, b be both positive real symbols, the symbol $c, = a + b$, is also positive; if a, b be both negative, then c is also negative. In each case, the equation $a + b = 0$ requires that both $a = 0$ and $b = 0$. The product ab is, likewise, positive when a, b are both positive, or both negative.





Order of magnitude for the real symbols. The real symbols may then be put in order, which we may call the order of magnitude, by the rule that $a > b$ when $a - b$ is a positive symbol. If $A = O + aU$, $B = O + bU$, it can be proved that the geometrical condition for this is that the order U, B, A shall be the same as that of O, E, U. In this definition it is understood that neither A nor B is at U. It follows that if x be any real symbol, and $a > b$, then $a + x > b + x$; also if a, b, x, y be positive real symbols, and $a > b, x > y$, then $ax > by$. And so on.

With these definitions it is at once possible to pass to the notion of the upper (or lower) *bound*, of any indefinitely continued sequence of real symbols, when such exists; and to the notion of a continuous function, and the theory of such functions.



The roots of a polynomial. It requires then only an elaboration of these conceptions to shew that a polynomial

$$z^n + (a_1 + ib_1) z^{n-1} + \ldots + a_n + ib_n,$$

wherein $a_1, b_1, \ldots, a_n, b_n$ are real symbols, can be written as the product of n factors of the form $z + p + iq$, where p, q are real symbols.

Writing for z the form $x + iy$, and collecting the real symbols together, the polynomial takes the form $u + iv$, when u and v are polynomials in x and y with only real symbols as coefficients. A proof of the theorem may be constructed by proving that $u^2 + v^2$, which is a real continuous function of x and y, which is necessarily positive, has zero for its least value. In particular, when all of $b_1, b_2, \ldots, b_n$ are zero, if there is a root $x + iy$, with y not zero, there is also a root $x - iy$, so that, when n is odd, there is at least one root, x, which is real. [Add.]

The exponential and logarithmic functions. We also assume the existence of the so-called exponential function, exp (z), or e^z, which is unaltered when z is replaced by $z + 2\pi i$, and the functions

$$\cos z, = \tfrac{1}{2}(e^{iz} + e^{-iz}), \quad \sin z, = \frac{1}{2i}(e^{iz} - e^{-iz}),$$

$$\cosh z = \tfrac{1}{2}(e^{z} + e^{-z}), \quad \sinh z = \tfrac{1}{2}(e^{z} - e^{-z}).$$

When $e^z = \zeta$, we write $z = \log \zeta$, the function $\log \zeta$ being indeterminate by additive integer multiples of $2\pi i$. The fundamental properties of this function are also assumed.

A simple application to the double points of an involution. If O, U and A, B be two pairs of points, in line, there is a pair of points, P, Q, of the line, which are harmonic both in regard to O, U and in regard to A, B. If, beside O, U, there be given another point, E, of the line, which, in terms of the symbols of O, U, has the symbol $E = O + U$, then the symbols of A, B, and of P, Q, have definite expressions in terms of O and U. It is of importance to know when the expressions of P and Q, in terms of O and U, contain only real symbols.

Let the expressions of A and B be $O + aU$, $O + bU$, respectively; let p, q be two symbols such that $p^2 = a$ and $q^2 = b$; we clearly have

$$q(O + p^2U) + p(O + q^2U) = (p + q)(O + pqU),$$
$$-q(O + p^2U) + p(O + q^2U) = (p - q)(O - pqU);$$

comparing these, remembering that points of symbols $A \pm mB$ are harmonic in regard to A and B, we see that the points $O + pqU$, $O - pqU$ are the points desired, harmonic both in regard to O, U, and in regard to A, B.

Now, when a, b are real, and, therefore, ab is real, the symbol pq, which is such that $(pq)^2 = ab$, is real only when ab is positive, that is, only when a, b are both positive, or both negative. Thus, when O, U, E and A, B are regarded as real, *the points P, Q,* which are harmonic both in regard to O, U and A, B, *are real provided A and B are not separated by O and U, but not otherwise.*

If, however, relatively to O, U, and E, the points A, B are such that $a = x + iy$, and $b = x - iy$, where x, y are real, then ab, which is $x^2 + y^2$, is real and positive; in this case, then, P, Q are real. Two such points, A, B, are commonly said to be *conjugate imaginaries* in regard to O, U and E.

As the results are of frequent application, we may regard the matter from another point of view. Let us refer both O, U and A, B to two other points of the line, say, X and Y, which we suppose to be given, together with another point of the line whose symbol is $X + Y$; suppose then that $O = X + \xi Y$, $U = X + \eta Y$, where ξ, η are the roots of the equation $ax^2 + 2hx + b = 0$, and also that $A = X + \alpha Y$, $B = X + \beta Y$, where α, β are the roots of the equation $a'x^2 + 2h'x + b' = 0$. The general pair of points, of the involution determined by the two pairs O, U and X, Y, is then $X + mY$, $X + nY$, where m, n are the roots of the equation

$$ax^2 + 2hx + b + \lambda(a'x^2 + 2h'x + b') = 0,$$

for a proper value of λ. If the symbols ξ, η be either real, or conjugate imaginaries, so that $\xi + \eta$ and $\xi\eta$ are real, we may suppose a, h, b to be real, the case when ξ, η are real being that in which $h^2 - ab$ is positive. Conversely, when a, h, b are real, ξ and η are either real or conjugate imaginaries. Similarly for α and β. We limit ourselves now to the consideration of the case when a, h, b, a', h', b' are all real. The points P, Q, which are harmonic both in regard to

O, U and to A, B, are the double points of the involution determined by these two pairs. These arise, then, for the values of λ which make the last written quadratic a perfect square, namely when $(a+\lambda a')(b+\lambda b')=(h+\lambda h')^2$; the values of λ satisfying this will either be real, or be conjugate imaginaries. If these values be λ_1 and λ_2, the last written quadratic will arise by squaring

$$(a+\lambda_1 a')x+h+\lambda_1 h', \text{ or } (a+\lambda_2 a')x+h+\lambda_2 h',$$

and the symbols of P, Q will be

$$(a+\lambda_1 a')X-(h+\lambda_1 h')Y, \quad (a+\lambda_2 a')X-(h+\lambda_2 h')Y;$$

these points P, Q will then be real in regard to X, Y and $X+Y$, if, and only if, λ_1 and λ_2 be real, for which the condition is that

$$(2hh'-ab'-a'b)^2-4(h^2-ab)(h'^2-a'b')$$

should be positive. If we put

$$M=-a^{-2}(h^2-ab), \quad M'=-(a')^{-2}(h'^2-a'b'),$$

this expression is equal to $a^2a'^2$ multiplied into

$$[(a^{-1}h-(a')^{-1}h')^2+M-M']^2+4M'(a^{-1}h-(a')^{-1}h')^2.$$

We see thus that the expression is positive if either M or M' be positive; that is, if either h^2-ab or $h'^2-a'b'$ be negative; that is, if one, or both, of the two pairs O, U and A, B, be conjugate imaginaries in regard to X, Y and $X+Y$. But, when M, M' are both negative, so that ξ, η, α, β are all real, or O, U and A, B are all real in regard to X, Y and $X+Y$, the expression is equal to $a^2a'^2$ multiplied into $(\xi-\alpha)(\xi-\beta)(\eta-\alpha)(\eta-\beta)$; it is, therefore, only positive when O, U are not separated by A and B.

We may interpret ξ, η and α, β as values of the parameter, θ, on the conic expressed by $x=\theta^2$, $y=\theta$, $z=1$, speaking of points given by real values of θ as real points. Then the double points of the involution given by the two pairs of points of the conic, O, U and A, B, are the points of contact of the tangents to the conic which can be drawn from the point in which the chords OU and AB intersect. The previous remarks, therefore, give the result that, from any point of a line which does not cut the conic in two real points, there can be drawn two real tangents of the conic. Two real tangents can also be drawn from a point which is such that, from it, two lines can be drawn whose respective pairs of intersections with the conic are both real and do not separate one another, regarded as points of the aggregate of real points of the conic which is given by the real values of θ. But from a point from which two lines can be drawn intersecting the conic each in a pair of real points, those of one pair separating those of the other pair, no real tangents can be drawn to the conic.

We may interpret the result somewhat differently, regarding O, U

as the double points of one involution, and A, B as the double points of another involution; then P, Q are the pair of points common to both involutions. These are then real when at least one of the involutions has for its double points a pair of conjugate imaginary points. Regarding the points, as before, as lying on the conic $xz - y^2 = 0$, the result shews that, if T and T' be two points, not lying on the conic, one of which, at least, is such that no real tangents can be drawn from it to the conic, then the line TT' meets the conic in two real points. For, the involution of which the double points are the points of contact of tangents from T to the conic, consists of pairs of points of the conic lying on lines through T.

Another application is as follows: With reference to two absolute points, I and J, we have defined the axes of a conic, whose centre is Y (the pole of the line IJ), as the lines joining Y to the points, P, Q, of the line IJ, which are harmonic, both in regard to I, J, and in regard to the two points, X and Z, in which the conic meets the line IJ. Then, when, with respect to points regarded as real on the line IJ, the points I and J are conjugate imaginaries, the axes of the conic are real, provided the centre, Y, is real, and the points X, Z, where the conic meets the line IJ, are either real or are conjugate imaginaries.

Remark. In what precedes we have dealt with the reality of P, Q in two ways, first considering A, B relatively to O, U, and afterwards considering both O, U and A, B relatively to two other points X, Y. The distinction is not immaterial; if O, U be imaginary in regard to X and Y, a point which is real in regard to X and Y may be imaginary in regard to O and U. For instance, if $\lambda^2 + \mu^2 = 1$, and $O = X + (p + iq)Y$, $U = X + (p - iq)Y$, then the point given by $O + (\lambda + i\mu)U$ is the same as that given by

$$X + [p + \mu^{-1}(1 - \lambda)q]\,Y.$$

General statement of the meaning of real and imaginary points in a plane. As a basis for geometry in a plane, we suppose that four points are given, say A, B, C and D. These are regarded as real. By the intersections of the joining lines of pairs of these points, three other points are obtained. By the intersections of the joining lines of the pairs of all the points now obtained, other points are found, and the method may be indefinitely repeated. The derivation may be arranged as a series of applications of the process of finding the fourth harmonic point of three given points of a line, or of the process of finding the fourth harmonic line of three lines which meet in a point. The points and lines so obtained are unlimited in number. Further, with a proper definition of the meaning of the statement, it appears that the points so derived occur everywhere in the plane. This generalises the theorem for the points of a harmonic net upon a line (Vol. I, p. 131). The symbols of the points A, B, C being fixed relatively to one another by the condition that the symbol of the point D is $A + B + C$, the points so derived are in fact all those expressed by symbols of the form $lA \pm mB \pm nC$, where l, m, n are iterative symbols. This has not been formally proved, but seems sufficiently clear from what was said, Vol. I, p. 86 (see also Moebius, *Ges. Werke*, Leipzig, 1885, Vol. I, p. 247). Thus, as in the case of points of a line, in virtue of the notion of an abstract order (Vol. I, p. 128), these points form a net sufficient to identify a multitude of points of the plane, all expressed by symbols $pA + qB + rC$, where p, q, r are real symbols in the sense which has been explained. It is these points, and no others, which we speak of as the points of the plane which are real with respect to A, B, C and D. All other points of the plane, of symbols $xA + yB + zC$, for which one at least of $x^{-1}y$, $x^{-1}z$, $y^{-1}z$, $y^{-1}x$, $z^{-1}x$, $z^{-1}y$ is a complex symbol $(p + iq)$, the others of these being real, we speak of as imaginary or complex points, relatively to A, B, C and D.

This statement is capable of much more minute analysis. For the purposes we have in view here, it is necessary to trace the connexion between the algebraic symbols employed and the numbers of Analysis; it is to this end that the Moebius net is introduced.

Some applications of the definition. Imaginary points and lines. A line which has two real points, say $pA + qB + rC$ and $lA + mB + nC$, has an infinite number of other points which are real, with symbols $(p + \sigma l) A + (q + \sigma m) B + (r + \sigma n) C$, where σ is any real symbol. Similarly, if two lines which meet in a real point, P, have each a further real point, respectively Q and R, then an infinite number of lines can be drawn through P having each an infinite number of real points; they are those, namely, which contain real points of the line QR. A line which has two real points has an equation of the form $ax + by + cz = 0$, where a, b, c are real symbols. Conversely, a line with such an equation contains an infinite number of real points, and may be called a *real line*. Through the common point of two real lines, which is necessarily real, may be drawn an infinite number of real lines. A real line contains, however, an infinite number of imaginary points; and, through a real point can be drawn an infinite number of imaginary lines.

Conversely, an imaginary line contains one, but only one, real point; and, through an imaginary point there passes one, and only one, real line. For, to an imaginary point,

$$(l + ip) A + (m + iq) B + (n + ir) C,$$

where l, m, n, p, q, r are real but $l^{-1}p$, $m^{-1}q$, $n^{-1}r$ not all equal, there corresponds a *conjugate* imaginary point,

$$(l - ip)A + (m - iq)B + (n - ir)C;$$

and, similarly, to an imaginary line there corresponds another, the conjugate imaginary line. The join of an imaginary point to its conjugate is a real line through the first point; the intersection of an imaginary line with its conjugate is a real point of the first line. Conversely, a line given by the equation

$$(l + ip)x + (m + iq)y + (n + ir)z = 0,$$

where l, m, n, p, q, r are all real, but $l^{-1}p$, $m^{-1}q$, $n^{-1}r$ are not all equal (since otherwise this would be a real line), contains only the real point for which both the equations $lx + my + nz = 0$, $px + qy + rz = 0$ are satisfied; through this point the conjugate imaginary line passes. Similarly, for an imaginary point.

The reader will compare this theory with that given in Vol. I (p. 166), of aggregates of real elements having the mutual relations of imaginary elements. Consider any imaginary point. We can, conveniently, suppose its symbol to be $3^{\frac{1}{2}}L + iP$, where

$$3^{\frac{1}{2}}L = lA + mB + nC, \quad P = pA + qB + Cr,$$

its conjugate being $3^{\frac{1}{2}}L - iP$. The values $i/3^{\frac{1}{2}}$ and $-i/3^{\frac{1}{2}}$ are the roots of the equation $3x^2 + 1 = 0$. The quadratic $3x^2 + 1$ is the Hessian form of the cubic $(x - s)[(x - s)^2 - (1 + 3sx)^2]$, as is easy to verify, the symbol s being arbitrary. The roots of this cubic are s, $(s - 1)/(1 + 3s)$ and $(s + 1)/(1 - 3s)$; if we use $\vartheta(s)$ to denote $(s - 1)/(1 + 3s)$, and $\vartheta^2(s)$ to denote $\vartheta[\vartheta(s)]$, these roots are s, $\vartheta(s)$, $\vartheta^2(s)$; we easily see that $\vartheta^3(s)$, or $\vartheta[\vartheta^2(s)]$, is equal to s. Thus (see Vol. I, p. 173), the theory referred to would represent the given imaginary point, whose symbol is $3^{\frac{1}{2}}L + iP$, by a set of three points taken, in a definite order, on the real line containing the given point, namely the three points whose symbols are $L + sP$, $L + \vartheta(s)P$, $L + \vartheta^2(s)P$. The conjugate imaginary point, whose symbol is $3^{\frac{1}{2}}L - iP$, would then be represented by the triad, $L + sP$, $L + \vartheta^2(s)P$, $L + \vartheta(s)P$, consisting of the same points in a different order. And, s being arbitrary, the same imaginary point would be represented by an infinite number of equivalent triads.

Real and imaginary conics. More care is necessary in defining a real conic than in defining a real line, since a conic can be expressed by an equation in which all the coefficients are real and still not have any real point. For instance, the conic whose equation, relatively to the given real points of the plane, is $x^2 + y^2 + z^2 = 0$, contains no point whose coordinates are all real. A conic can also have two real points, and no other real points; or, can have four real points, and no other real points. Consider, for example, the conic expressed by the equation

$$z^2 + zx(l+i) + zy(m+i) - xy[h^2 - lm + k + i(2h - l - m)] = 0,$$

where l, m, h, k are real symbols, i having the usual significance ($i^2 = -1$). This conic contains the two points (1, 0, 0) and (0, 1, 0), which we regard as real. Any other point of real coordinates lying on this conic must be such as to satisfy both the equations

$$z^2 + lzx + mzy - xy(h^2 - lm + k) = 0,\quad zx + zy - xy(2h - l - m) = 0\,;$$

these, however, by elimination of z, require the equation

$$[(h-l)x - (h-m)y]^2 + k(x+y)^2 = 0,$$

and this can be satisfied by no real values of x and y if k be positive (other than $x = 0$, $y = 0$, which, by recurring to the original equations, does not lead to a point of the conic). When k is negative, there are two values of $x^{-1}y$ which satisfy this equation, each of which leads to a value of $x^{-1}z$. Thus the conic has two, or four, real points, according as k is positive or negative.

In general, the real points of a conic expressed by an equation $(a + ia')x^2 + \ldots = 0$, whose coefficients are not real, are the points common to two conics, each with real coefficients, $ax^2 + \ldots = 0$, $a'x^2 + \ldots = 0$. These common points have coordinates which depend upon the roots of an equation of the fourth degree, wherein the coefficients are real; of such an equation, as we have remarked, the real roots are in number, none, two, or four. Thus, a conic whose coefficients are not real possesses none, or two, or four real points, unless it possesses an infinite number (as when it degenerates into two lines of which one is real and the other is not real).

A conic whose equation has real coefficients may have no real point, as we have seen. If, however, such a conic have one real point, and be not a line pair meeting at this point, it has an infinite number of real points; for any real line drawn through the real point meets the conic in another real point. A conic which is a line pair, consisting of two conjugate imaginary lines, contains one real point, the intersection of these, and no other.

Thus we see that we may conveniently speak of a conic which is not a line pair, as real, regarded as a locus of points, when it is expressed by an equation with real coefficients, and possesses one real point. Such a conic has a real tangent at every real point, and is thus real, also, regarded as an envelope. When we speak of a conic as imaginary, it will be desirable to specify whether its equation has real coefficients or not.

It is obvious that a conic which has five real points is a real conic; it may be defined, in the original way, by two related pencils of lines whose centres are at two of these points. But, a real conic possesses imaginary points, and such points may be among five points which are utilised to define such related pencils of lines. It is unnecessary to enter into an examination of the possibilities.

The interior and exterior points of a real conic. In regard to a real conic, supposed not to be a line pair, we may speak of any real point of the plane which does not lie on the conic, as being either *interior*, or *exterior*, to the conic. For the polar line of a real point, say, P, in regard to a conic expressed by an equation with real coefficients, is a real line, and will meet the conic either in two real points, or in two conjugate imaginary points; in the latter case the two tangents that can be drawn to the conic from the point P are conjugate imaginary lines, and we speak of the point P as *interior* to the conic. It was shewn above (p. 160) that every real line drawn through such an interior point meets the conic in two real points. A point, from which two real tangents can be drawn to the real conic, is spoken of as an *exterior* point; from such a point can be drawn some lines which meet the conic in two conjugate imaginary points, and others which meet it in two real points. It can be proved that, if we take two interior points, and consider the two segments of the line which joins these, which are determined by the two real points in which this line meets the conic, then all the real points of one of these segments are interior points. The real points of a plane are thus divided into two categories by means of the real points of a real conic which is not a line pair.

The behaviour for an imaginary conic which is determined by a real equation is different. The tangents drawn to such a conic from any real point are conjugate imaginary, so that, in one sense, any point might be called an interior point; but every real line meets the conic in two conjugate imaginary points.

The reality of the common points, and of the common self-polar triad, of two conics. We consider two conics which are both expressed by equations with real coefficients; one, or both, of the conics may be real. As has been remarked, the determination of the common points of two such conics may be reduced to the solution of an equation of the fourth degree, with real coefficients. To any root of such an equation which is not real there corresponds another root which is the conjugate imaginary of the former; therefore, it may be shewn, to any one of the four common points of the two conics which is not real, there corresponds another common point, conjugate imaginary to the former; and, the line joining these two common points is real. There is, therefore, always, at least one line pair, of two real lines, passing through the four common points of two such conics. If the four common points of the two conics are all real, and different, there are six lines, each joining two of these points, which are all real; in this case the common self-polar triad, of points and lines, constructed from these joins, consists of three real points and three real lines. If the common points of the two conics consist of the two real, and different, points A, B, with the two conjugate imaginary points C and C', the lines AB, CC' are both real, the lines AC, AC' are conjugate imaginaries, and the lines BC, BC' are conjugate imaginaries. The point, P, of intersection of AB and CC' is, therefore, real; the point, Q, of intersection of AC and BC' is conjugate imaginary to the intersection, R, of the lines AC', BC, which are, respectively, conjugate imaginary to AC and BC'; thus the line QR is real, and the common self-polar triad, P, Q, R, consists of one real point and one real line, together with two conjugate imaginary points, and two conjugate imaginary lines. Lastly, if the intersections of the two conics consist of two conjugate imaginary points A, A' and two conjugate imaginary points C, C', the lines AA', CC' are real, and meet in a real point, P; the lines AC, $A'C'$ are conjugate imaginary and meet in a real point, Q, and the lines AC', $A'C$ are conjugate imaginary and meet in a real point, R. The common self-polar triad is thus wholly real. This last case arises, for example, when one of the conics is real, and the other, though having a real equation, is imaginary. Incidentally, we thus give a proof that the cubic equation expressed by

$$\begin{vmatrix} a-\lambda a', & h-\lambda h', & g-\lambda g' \\ h-\lambda h', & b-\lambda b', & f-\lambda f' \\ g-\lambda g', & f-\lambda f', & c-\lambda c' \end{vmatrix} = 0,$$

upon which, as we have seen (Chap. III, Ex. 22), the determination of the common self-polar triad of the two conics $ax^2 + \ldots = 0$, $a'x^2 + \ldots = 0$ depends, has real roots when one at least of the two quadric forms occurring on the left in the equations of the conics, is such that it preserves a constant sign for all real values of x, y, z— it being understood that all the coefficients $a, \ldots, a', \ldots,$ are real.

The tangential equation of a conic, whose point equation is real, has also real coefficients. We can therefore state the preceding results also in terms of the reality of the common tangents. But the dependence of the reality of the common tangents upon the reality of the common points is a matter also for enquiry.

We have disregarded the possibilities of coincidence of the four common points of the two conics in what has been said; the omission may easily be supplied. [Add.]

Ex. A conic passes through three points, A, B, C, and has the points D, D' as conjugate points, and the points E, E' as conjugate points. Find two other (real) points of the conic. In particular, when E, E' are on the line DD', and separate these.

CHAPTER V

PROPERTIES RELATIVE TO AN ABSOLUTE CONIC. THE NOTION OF DISTANCE. NON-EUCLIDEAN GEOMETRY

The interval of two points of a line relatively to two given points of the line. If M, N, P, Q, be four points of a line, and the symbols of these points be such that $aP = M + xN$, $bQ = M + yN$, then the symbol yx^{-1} is such that: (1), it is unaltered by replacing any one or more of the symbols P, Q, M, N, respectively, by pP, qQ, mM, nN, where p, q, m, n are any symbols of the system employed, of which the commutativity in multiplication is, of course, assumed; (2), it has the same value as for any other four points, M', N', P', Q', which form a range related to M, N, P, Q; with a slight change of notation this is the same statement as that a range of points, M, N, $M+N$, $M+\lambda N$, is related to a range of points represented by M', N', $M'+N'$, $M'+\lambda N'$. A proof has been given, Vol. I, p. 154; (3), the symbol yx^{-1} is equal to the symbol formed by the analogous rule from the equations which express M, N in terms of P and Q, that is, the equations

$$-a^{-1}(x-y)M = yP - xba^{-1}Q, \quad a^{-1}y(x-y)N = yP - yba^{-1}Q.$$

The symbol can then be represented by $(P, Q;\ M, N)$, or by $(M, N;\ P, Q)$. What is of the greatest importance to us here is the fact that, if P, Q, R be any three points of the line MN, we have

$$(P, Q;\ M, N) \,.\, (Q, R;\ M, N) = (P, R;\ M, N).$$

Now, and in all that follows, we suppose that the algebraic symbols employed are those arrived at in the preceding chapter, which have the same properties in computation as the complex numbers of ordinary Analysis, with which they may thus be identified. If then $\phi(\xi)$ be any function for which $\phi(\xi\eta) = \phi(\xi) + \phi(\eta)$, and ξ denote $(P, Q;\ M, N)$, η denote $(Q, R;\ M, N)$, and ζ denote $(P, R;\ M, N)$, we shall have $\phi(\zeta) = \phi(\xi) + \phi(\eta)$. We apply this to the case when $\phi(\xi) = (2i)^{-1}\log(\xi)$.

Let the expression

$$\frac{1}{2i}\log[(P, Q;\ M, N)]$$

be called the *interval* from P to Q with respect to M and N. The interval from P to R is thus the sum of the interval from P to Q and that from Q to R, subject however to the ambiguity inherent in the definition. As $(Q, P;\ M, N)$ is the inverse of $(P, Q;\ M, N)$, the interval from Q to P is the negative of the interval from P to Q. But further, in virtue of the property of the logarithm, the interval, in default of further specification, is subject to the addition of an arbitrary integral multiple of π. We may agree that when P and Q coincide, in which case $(P, Q;\ M, N) = 1$, the interval vanishes, and, then, that when the interval is π, the two points again coincide. We may, however, apply the definition to cases in which the interval is not real, as will be seen. If the interval be denoted by θ, we have $(P, Q;\ M, N) = e^{2i\theta}$, and, when P, Q, M, N are all real points, it is $i\theta$ which is real. When $\theta = \frac{1}{2}\pi$, we have $(P, Q;\ M, N) = -1$; then P and Q are harmonic in regard to M and N.

Angular interval in regard to two absolute points. We have considered, in Chapter III, some of the consequences of supposing two points, I, J, of the plane, to be given, and taken as absolute points. With two such points, we may employ the considerations just given, to define the interval from one line, OP, to another line, OQ; namely, if these lines, respectively, meet the line IJ in P' and Q', we may take for this interval the value $(2i)^{-1} \log [(P', Q';\ I, J)]$. This depends only on the points, P' and Q', where the lines meet the line IJ, and not on the position of the intersection, O, of the lines. Suppose in particular, when the points of the plane are referred to three points, C, A, B, which we regard as real, that $I = A + iB$, $J = A - iB$, while P', Q' are given by

$$P' = \cos\alpha \,.\, A + \sin\alpha \,.\, B \quad \text{and} \quad Q' = \cos(\alpha+\theta) \,.\, A + \sin(\alpha+\theta) \,.\, B\,;$$

the lines CI, CJ, CP', CQ' can then be expressed by the respective equations $y = ix$, $y = -ix$, $y = \tan\alpha \,.\, x$, $y = \tan(\alpha+\theta) \,.\, x$. These relations give

$$2e^{i\alpha} P' = I + e^{2i\alpha} J, \quad 2e^{i(\alpha+\theta)} Q' = I + e^{2i(\alpha+\theta)} J$$

and hence $$(P', Q';\ I, J) = e^{2i\theta}.$$

This relation, approached from a metrical point of view, was, it seems, first used by Laguerre (*Nouv. Annal.* xii, 1853, p. 57; *Oeuvres* (1905) II, p. 12). As will be seen, it may be regarded as the foundation of all that follows in this Chapter. (Cp. p. 195.)

It is clear that, if O be any point of a conic containing I and J, of which P and Q are two fixed points, the interval from OP to OQ, in regard to I and J, is the same for all positions of O on the conic. In particular, when PQ passes through the pole of IJ, in regard to this conic, this interval is $\frac{1}{2}\pi$.

Interval in regard to an absolute conic. The postulation of two absolute points thus furnishes a ready means of defining the interval from one line to another. It does not however, except by a limiting process, furnish a means of defining the interval between two points, unless they lie on the line determined by the absolute points. The two absolute points may, however, be thought of as a degenerate conic envelope. This may suggest that we take a fixed undegenerate conic, given in the plane, as a basis for reference. If we do this, two points, say M and N, are determined on any line, PQ, which does not touch the conic, namely the points of intersection of PQ with this absolute conic; and then the interval from P to Q may be defined, as above, in respect to M and N. But this conic also determines two lines through an arbitrary point, O, of the plane, not lying on the conic, namely the tangents from O to this absolute conic; and then the angular interval between any two lines which intersect in O may be defined, as above, by means of these tangents. We have thus a method of defining both the interval from one point to another, and the interval from one line to another, in harmony with the duality otherwise existing in the geometry of the plane. When the absolute conic, regarded tangentially, becomes a point pair, we thence obtain what has, on other grounds, been chosen as the measure of an angle; we could, similarly, obtain a measure of the interval between two points, if we supposed the existence of two absolute lines in the plane, as a degenerate form of the absolute conic. From this general point of view, the ordinary metric relations, usually employed at least since the time of the Greeks, appear as an unsymmetric and incomplete scheme. Moreover, *distance*, as usually understood, which we shall shew to be deducible by a limiting process from what has been said, so far from being an obvious notion, characterising the space of experience, appears as an artificial, if useful, application of the algebraic symbols.

The idea of length is, presumably, suggested by our experience of what are called rigid bodies. We may refer, at once, here, to the notion which replaces this in the present point of view. Let P, Q, M, N be four points in line, of respective coordinates (x, y, z), (x', y', z'), (ξ, η, ζ), (ξ', η', ζ'). Let P_1, Q_1, M_1, N_1 be other four points, the coordinates of P_1 being definite linear functions of the coordinates of P, say

$$x_1 = ax + by + cz, \quad y_1 = lx + my + nz, \quad z_1 = px + qy + rz,$$

the coordinates of Q_1 being the *same* linear functions of the coordinates of Q, those of M_1 the *same* linear functions of the coordinates of M, and those of N_1 the same linear functions of the coordinates of N. It may then be shewn without difficulty that P_1, Q_1, M_1, N_1 are in line, and are a range which is related to the range P, Q, M, N. The linear transformation employed is, in fact, the representation of the correspondence between two related planes (here coinciding) which was considered in Vol. I, p. 149.

Of such linear transformations, depending on eight parameters (the ratios of the coefficients a, b, c, l, m, ...), there is a set, wherein the eight parameters are such functions of three parameters that any point of an arbitrarily chosen conic gives rise to another point of the same conic; as we shall see in more detail later. Any two transformations of this set, carried out in succession, lead from a point of this conic to another point of this conic, and so, in combination, constitute a transformation of the same set.

If the conic be the absolute conic by which we measure the interval between two points P and Q, as has been explained, M and N being points of the conic, the interval between the transformed points, P_1 and Q_1, has, clearly, from what has been said, the same measure as the interval PQ.

The change, by a linear transformation leaving the absolute conic unaltered, from the interval PQ to the interval P_1Q_1, is the operation which, from our present point of view, replaces what, in the metrical geometry, is described as the movement of PQ into the position P_1Q_1.

The reader may shew that the general linear transformation changing any point of the conic $x^2+y^2+z^2=0$ into another point of this conic, is given by

$$\begin{aligned}
x_1 &= \tfrac{1}{2}(D^2+A^2-B^2-C^2)x + (AB-CD)y + (CA+BD)z,\\
y_1 &= (AB+CD)x + \tfrac{1}{2}(D^2+B^2-C^2-A^2)y + (BC-AD)z,\\
z_1 &= (CA-BD)x + (BC+AD)y + \tfrac{1}{2}(D^2+C^2-A^2-B^2)z,
\end{aligned}$$

where A, B, C, D are arbitrary.

We now consider the matter more in detail: Let the absolute conic be given, with respect to real points of reference for the coordinates, by an equation with real coefficients; it may, thus, be either a real conic or an imaginary conic. We can suppose the points of reference, still being real, to be so chosen that this equation is of the form $z^2+\kappa(x^2+y^2)=0$, it being supposed that this conic is not degenerate. The coefficient, κ, is then real; it is negative for a real conic, but positive for an imaginary conic.

The proof of this form may be given, as follows; First, a homogeneous quadratic form in *two* variables, x, y, with real coefficients, can be reduced, by a real linear change of coordinates, to a sum of squares, with real coefficients. For, let the form be $ax^2+2hxy+by^2$. If both a and b be zero, this is $\frac{1}{2}h\,[(x+y)^2-(x-y)^2]$, which consists of two squares. If not, suppose a not to be zero; then the form is $a(x+a^{-1}hy)^2+(b-a^{-1}h^2)y^2$, which again consists of two squares. Second, consider the form in *three* variables, consisting of three pairs of terms such as $ax^2 + 2fyz$. If one of the three coefficients a, b, c, say the coefficient a, be not zero, the form is

$$a(x + a^{-1}hy + a^{-1}gz)^2 + (b - a^{-1}h^2)y^2$$
$$+ (c - a^{-1}g^2)z^2 + 2(f - a^{-1}gh)yz;$$

here the three terms after the first are a quadratic form in y and z only, with real coefficients, and can be written as a sum of two (or fewer) squares, with real coefficients. If, however, all of a, b, c be zero, but none of f, g, h be zero, the original form in x, y, z is

$$2fgh(f^{-1}x + \tfrac{1}{2}g^{-1}y + \tfrac{1}{2}h^{-1}z)^2 - 2f^{-1}ghx^2 - \tfrac{1}{2}fgh(g^{-1}y - h^{-1}z)^2,$$

which consists of three squares. If all of a, b, c be zero, and one, or two, of f, g, h be zero, the form reduces to a product of two real linear forms, PQ, which is $\frac{1}{4}(P + Q)^2 - \frac{1}{4}(P - Q)^2$. In any case, therefore, the form is reducible, in many ways, to $pX^2 + qY^2 + rZ^2$, where p, q, r are real, and X, Y, Z are real linear functions of x, y, z. Assuming that the form, when equated to zero, does not represent a line pair, no one of p, q, r is zero. And, in the equation so obtained, we may suppose that all of p, q, r are positive, or only one is positive. When r is positive, and p, q are also positive, by taking $X_1 = X(p/\kappa)^{\frac{1}{2}}$, $Y_1 = Y(q/\kappa)^{\frac{1}{2}}$, $Z_1 = Zr^{\frac{1}{2}}$, where κ is an arbitrary real positive number, we obtain the equation $Z_1^2 + \kappa(X_1^2 + Y_1^2) = 0$. When r is positive, and p, q are both negative, we can put

$$X_1 = X(-p)^{\frac{1}{2}}/(-\kappa)^{\frac{1}{2}}, \quad Y_1 = Y(-q)^{\frac{1}{2}}/(-\kappa)^{\frac{1}{2}}, \quad Z_1 = Zr^{\frac{1}{2}},$$

where κ is an arbitrary real negative number, and so obtain the equation $Z_1^2 + \kappa(X_1^2 + Y_1^2) = 0$.

Case of an imaginary conic as Absolute. Let (x_0, y_0, z_0) and (x, y, z) be any two points not lying on the absolute conic. Let f denote the expression $z^2 + \kappa(x^2 + y^2)$, and f_0 what this becomes when x_0, y_0, z_0 are put for x, y, z, respectively; also let ψ denote the expression $zz_0 + \kappa(xx_0 + yy_0)$. For the case of an imaginary conic, κ is positive, and f, f_0 are positive; and $ff_0 - \psi^2$, which is equal to

$$\kappa\left[\kappa(xy_0 - x_0y)^2 + (zx_0 - z_0x)^2 + (zy_0 - z_0y)^2\right],$$

is also positive. Let M, N denote the points in which the line joining the point (x_0, y_0, z_0) to the point (x, y, z) meets the conic. We can suppose that, for a positive real value of θ, one of these points has the coordinates

$$x_0f_0^{-\frac{1}{2}} - e^{i\theta}xf^{-\frac{1}{2}}, \quad y_0f_0^{-\frac{1}{2}} - e^{i\theta}yf^{-\frac{1}{2}}, \quad z_0f_0^{-\frac{1}{2}} - e^{i\theta}zf^{-\frac{1}{2}},$$

where the square roots, $f_0^{-\frac{1}{2}}, f^{-\frac{1}{2}}$, have their real positive values; for the substitution of these coordinates in the equation of the conic gives the condition

$$1 - 2e^{i\theta}\psi f_0^{-\frac{1}{2}}f^{-\frac{1}{2}} + e^{2i\theta} = 0,$$

namely $$\cos\theta = \psi f_0^{-\frac{1}{2}} f^{-\frac{1}{2}},$$

of which the value is less than unity. If then, relatively to the points of reference for the coordinates, A, B, C, we define the symbols, O and P, of the points (x_0, y_0, z_0) and (x, y, z), respectively, by means of

$$O = f_0^{-\frac{1}{2}}(x_0 A + y_0 B + z_0 C), \quad P = f^{-\frac{1}{2}}(xA + yB + zC),$$

we may write, for the symbols of the points M and N.

$$M = O - e^{-i\theta}P, \quad N = O - e^{i\theta}P,$$

where $\cos\theta = \psi f_0^{-\frac{1}{2}} f^{-\frac{1}{2}}$, $\sin\theta = (ff_0 - \psi^2)^{\frac{1}{2}} f_0^{-\frac{1}{2}} f^{-\frac{1}{2}}$,

and the symbol, $(O, P;\ M, N)$, defined above (p. 166), is, then, given by

$$(O, P;\ M, N) = e^{2i\theta}.$$

Now let the point where the line OP meets the polar line of O in regard to the absolute conic be denoted by U. The coordinates (ξ, η, ζ) of this point are given by $\xi = xf_0 - x_0\psi$, $\eta = yf_0 - y_0\psi$, $\zeta = zf_0 - z_0\psi$; for these belong to a point on the line joining (x_0, y_0, z_0) to (x, y, z), and are such that $\zeta z_0 + \kappa(\xi x_0 + \eta y_0) = 0$. With these values we have $\zeta^2 + \kappa(\xi^2 + \eta^2)$ equal to $f_0(ff_0 - \psi^2)$, which is positive. If we denote the positive square root of this by μ, we have three equations, for x, y, z, of the following form

$$xf^{-\frac{1}{2}} = \psi f_0^{-\frac{1}{2}} f^{-\frac{1}{2}} . x_0 f_0^{-\frac{1}{2}} + (ff_0 - \psi^2)^{\frac{1}{2}} f_0^{-\frac{1}{2}} f^{-\frac{1}{2}} . \xi\mu^{-1}.$$

We may therefore write, using for the point U the symbol $U = \mu^{-1}(\xi A + \eta B + \zeta C)$,

$$P = \cos\theta . O + \sin\theta . U.$$

Conversely, this equation may, if preferred, be used as giving the definition of θ. If we regard O and U as fixed, it gives a real position of P upon the line OU for every real value of θ, all such positions being obtained by restricting θ to the range from 0 to π. In particular, when $\theta = 0$, the point P is at O; and when $\theta = \frac{1}{2}\pi$, the point P is at U, the conjugate point to O in regard to the absolute conic.

By a precisely similar argument any other point Q, of the line OU, can be expressed, in terms of P and the point, P', conjugate to P upon this line, by the equation

$$Q = \cos\phi . P + \sin\phi . P'.$$

As the original formula was equivalent to $(O, P;\ M, N) = e^{2i\theta}$, so this formula is equivalent to $(P, Q;\ M, N) = e^{2i\phi}$. Thus we have $(O, Q;\ M, N) = e^{2i(\theta+\phi)}$, so that, also

$$Q = \cos(\theta + \phi) . O + \sin(\theta + \phi) . U.$$

This, however, is

$$\cos\phi\,(\cos\theta\,.\,O+\sin\theta\,.\,U)+\sin\phi\,(-\sin\theta\,.\,O+\cos\theta\,.\,U)\,;$$

thus we see that

$$P'=\cos(\theta+\tfrac{1}{2}\pi)\,.\,O+\sin(\theta+\tfrac{1}{2}\pi)\,.\,U,$$

and, when P is given, in terms of O and U, by θ, then P', the conjugate of P, in regard to the conic, upon the line OU, is given by $\theta+\frac{1}{2}\pi$. This fact can, of course, be directly verified, the coordinates of P' being, as we easily see,

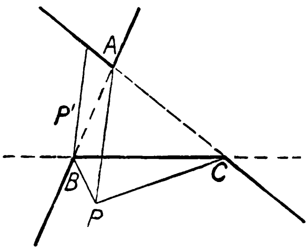
$$-x_0\,(ff_0-\psi^2)+\xi\psi,\quad -y_0\,(ff_0-\psi^2)+\eta\psi,\quad -z_0\,(ff_0-\psi^2)+\zeta\psi.$$

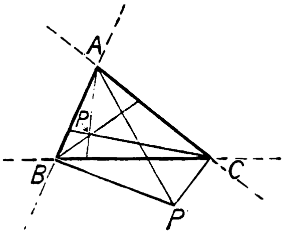
In words, the interval, in regard to the conic, from a point P to any point on its polar line, is $\frac{1}{2}\pi$.

In a precisely similar way, the interval from a line OA to a line OB may be defined with reference to the tangents, OM', ON', drawn from O to the absolute conic. If the points A, B be on the polar of O, the interval is, by definition, equal to the interval from the point A to the point B. In particular when OB is conjugate to OA, in regard to the absolute conic, the interval between these lines is $\frac{1}{2}\pi$.

Application to a triangle. We may illustrate these definitions by applying them to the intervals between any three given points, not lying in line, and the intervals between the lines which join these points. But some preliminary remarks will be useful, in view of the ambiguity we have noticed, in the definition of the interval between two given elements.

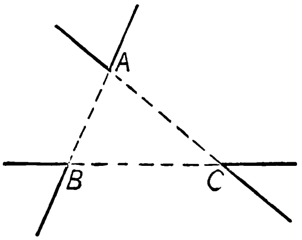
Any two points determine *two* segments, in one or other of which any other real point, of the line determined by the two given points, must lie. If then we have three points, A, B, C, which are not in line, and speak of the segments BC, CA, AB, there are eight ways in which this may be understood. We desire, however, to associate with each of the segments, say, with BC, which may be regarded as an aggregate of points, a certain aggregate of lines, all passing through the point, A, not on the line BC, so that every one of the lines shall contain one of the points of the segment. Limiting ourselves to *real* points and lines, relatively to A, B, C, if we speak of this aggregate of lines as an *angle*, we may say that there are, for each of the points such as A, two angles. We have then in all eight possibilities, of three pairs, each pair being constituted by a segment and its corresponding angle. These eight possibilities fall, however, into two sets, each of four possibilities. In any one of the first set of four possibilities, the three segments, say, BC, CA, AB, and the associated angles, say, A, B, C, have, in regard to real points, the two following properties: (1) Any line of the plane either contains no point of any of the three segments, or contains a point of each of two of the segments; (2) If any point P of the plane be joined to A, B and C, and we consider the intersections of the joining lines PA, PB, PC, respectively, with the lines BC, CA, AB, either, one, of these intersections, or all, lie in the segments of these lines which

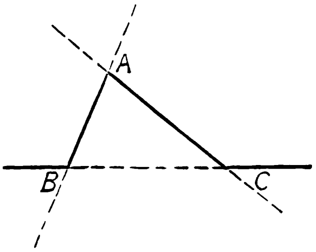




define the possibility considered. If the two segments of the line BC be denoted by a and a', and the two respectively associated angles at A by A and A', with a similar notation for B and C, and one of the four possibilities spoken of consist of A, a; B, b; C, c, then another of these consists of A, a; B', b'; C', c', and the other two are respectively A', a'; B, b; C', c' and A', a'; B', b'; C, c.

The other four possibilities consist of the associations, A', a'; B, b; C, c and A', a'; B', b'; C', c', together with A, a; B', b'; C, c





and A, a; B, b; C', c'. For these also a statement can be made as to the intersections of an arbitrary line with the segments considered, and the lines joining an arbitrary point, to A, B, C, which belong to the angles associated therewith. But this statement will be different from that which holds for the first four possibilities. It appears unnecessary to enter into a detailed analysis of the statement made (cf. Vol. I, p. 100).

In what follows we confine ourselves to one of the first four possibilities. It is immaterial which one; but we could, if desired, describe that one by supposing an additional line given in the plane, whose intersections with the lines BC, CA, AB would enable us to distinguish between the two segments of the line. If we denote the intervals BC, CA, AB chosen, measured relatively to the absolute conic, respectively by a, b, c, the other supplementary segments

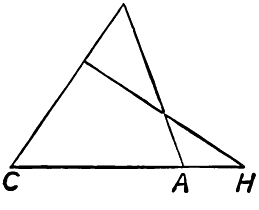
BC, *CA*, *AB* may be taken to be, respectively $\pi - a$, $\pi - b$, $\pi - c$, as we have seen. Similarly the interval between *AB* and *AC*, associated with a, being denoted by A, the supplementary interval between these lines will be $\pi - A$; the intervals adopted at B and C will likewise be denoted by B and C. So far, as we have seen, this statement is ambiguous. But if we agree that a shall be positive and between 0 and $\frac{1}{2}\pi$, when *the point*, B', of the line *BC*, *which is conjugate to B*, in regard to the absolute conic, *does not lie in the segment BC* which is denoted by a, then a will be without ambiguity. In this case, the point, C', of the line *BC*, which is conjugate to C, in regard to the absolute conic, will also not lie in the chosen segment *BC*; for, as B, B' and C, C' are pairs of an involution whose double points are the imaginary intersections of the line *BC* with the imaginary absolute conic, the points B, B' are separated by the pair C, C'. (Above, p. 158.) Similarly we agree that A shall be positive and between 0 and $\frac{1}{2}\pi$, when the line through A which is conjugate to *AB* does not lie in the angle called A, in which case, for a similar reason, the line through A conjugate to *AC* will not lie in the chosen angle A. And we make the like agreement for b, c, B and C.

We can, for the sake of algebraic symmetry, suppose, for the present, without loss of generality, that the equation of the absolute conic is $x^2 + y^2 + z^2 = 0$. If then, for example, (x, y, z) and (x', y', z') be the coordinates of the points A and B, respectively, the interval c, of A, B, will be such (p. 171, above) that

$$\cos c = \pm \frac{xx' + yy' + zz'}{(fx)^{\frac{1}{2}} (fx')^{\frac{1}{2}}},$$

$$\sin c = \frac{[(yz' - y'z)^2 + (zx' - z'x)^2 + (xy' - x'y)^2]^{\frac{1}{2}}}{(fx)^{\frac{1}{2}} (fx')^{\frac{1}{2}}},$$

where fx denotes $x^2 + y^2 + z^2$, and, for each of the square roots, the positive real value is to be taken. In $\cos c$, the numerator vanishes and changes sign when (x', y', z') passes over the point, of the line joining this to (x, y, z), which is conjugate to (x, y, z). We can, therefore, agree to attach to the coordinates of (x', y', z') such a sign that the numerator in $\cos c$ is positive when c, as defined above, is less than $\frac{1}{2}\pi$, and then omit the ambiguous sign $\pm$ in the above formula for $\cos c$.



We now take, first, the particular case in which the lines *AB*, *AC* are conjugate to one another in regard to the absolute conic. We denote the coordinates of the points A, B, C, respectively, by (x, y, z), (x', y', z'),

(x'', y'', z''), and denote by Δ the absolute, positive, value of the determinant

$$\begin{vmatrix} x, & y, & z \\ x', & y', & z' \\ x'', & y'', & z'' \end{vmatrix},$$

the minors in this determinant, each with its proper sign, being denoted, respectively, by

$$\begin{matrix} u, & v, & w, \\ u', & v', & w', \\ u'', & v'', & w''; \end{matrix}$$

any minor of the determinant formed by these last elements is equal to the complementary minor of the original determinant, multiplied by the value of this determinant itself, as is well known. We have the identity

$$(yz' - y'z)^2 + (zx' - z'x)^2 + (xy' - x'y)^2$$
$$= (x^2 + y^2 + z^2)(x'^2 + y'^2 + z'^2) - (xx' + yy' + zz')^2;$$

from this, or independently, we have

$$\Sigma (yz' - y'z)(yz'' - y''z) = \Sigma x^2 . \Sigma x'x'' - \Sigma xx' . \Sigma xx'',$$

which, still using fx for $f(x)$, we denote by

$$-f(u', u'') = fx . f(x', x'') - f(x, x')f(x, x'') \text{ ......(i).}$$

We similarly have, if fu mean $f(u)$,

$$-\Delta^2 f(x', x'') = fu . f(u', u'') - f(u, u')f(u, u'') \text{ ...(ii).}$$

Also, as $ux + vy + wz = 0$ is the equation of the line BC, and so on, we have, as equivalent to the condition that AB and AC are conjugate, the equation

$$f(u', u'') = 0 \text{ ....(iii).}$$

We shall write P, P', P'', U, U', U'', respectively, for the real positive numbers $(fx)^{\frac{1}{2}}, (fx')^{\frac{1}{2}}, (fx'')^{\frac{1}{2}}, (fu)^{\frac{1}{2}}, (fu')^{\frac{1}{2}}, (fu'')^{\frac{1}{2}}$.

For the interval c we have, then,

$$\cos c = f(x, x')/PP', \quad \sin c = U''/PP',$$

the $f(x, x')$ being taken positive, or negative, according as $c < \frac{1}{2}\pi$, or $c > \frac{1}{2}\pi$. For the angle C we have, similarly,

$$\cos C = \pm f(u, u')/UU', \quad \sin C = \Delta P''/UU';$$

but, the pole of the line CA is on the line AB, and is the point thereon which is conjugate to A; the line joining C to this point is the line through C which is conjugate to CA. Thus C is greater or less than $\frac{1}{2}\pi$, according as c is greater or less than $\frac{1}{2}\pi$. Also, from equations (ii), (iii), we have $-\Delta^2 f(x, x') = f(u'')f(u, u')$, which shews that $f(u, u')$ and $f(x, x')$ are of opposite sign. Wherefore we have

$$\cos C = -f(u, u')/UU'.$$

We can now shew that, of the three intervals a, b, c, either all are less than $\frac{1}{2}\pi$, or, just one of them is less than $\frac{1}{2}\pi$. For, let the polar line of the point B meet the line CA in H, so that H will be the pole of the line AB, and will be the point of the line CA which is conjugate to A. By our definition of the triangle considered, if this line, the polar line of B, do not contain a point of either of the segments BA, BC, then H will not be in the segment AC; so that, if each of the intervals a, c is less than $\frac{1}{2}\pi$, then b is, also, less than $\frac{1}{2}\pi$. But, if this line contain a point of each of the segments BA, BC, then, also, H is not in AC; so that, if each of a, c is greater than $\frac{1}{2}\pi$, then, also, b is less than $\frac{1}{2}\pi$. When the polar line of B contains a point of only one of the segments BA, BC, we reach the same conclusion.

But equations (i), (iii) give $f(x', x'')f(x) = f(x, x')f(x, x'')$, which is the same as

$$\frac{f(x', x'')}{P'P''} = \frac{f(x, x')}{PP'} \cdot \frac{f(x, x'')}{PP''};$$

if then we suppose, when x, y, z have been chosen, that the signs of x', y', z' and of x'', y'', z'' are so taken that, not only

$$\cos c = f(x, x')/PP',$$

as has already been agreed, but also $\cos b = f(x, x'')/PP''$, we can infer, remembering that, as has just been seen, one or all of a, b, c are less than $\frac{1}{2}\pi$, that

$$\cos a = \cos b \cos c \quad \text{..................} (1),$$

and also $\cos a = f(x', x'')/P'P''$. Then, from the equation

$$\Delta^2 f(x) = f(u')f(u'') - [f(u', u'')]^2,$$

by (iii), we have

$$\frac{\Delta P''}{UU'} = \frac{U''}{PP'} \bigg/ \frac{U}{P'P''},$$

and hence $$\sin C = \sin c/\sin a \quad \text{..................} (2).$$

Also, from equations (ii), (iii), we have

$$f(x', x'') = \frac{f(u, u')f(u, u'')}{\Delta^2}, \quad f(x, x'') = -\frac{fu' \cdot f(u, u'')}{\Delta^2},$$

so that $$-\frac{f(u, u')}{fu'} = \frac{f(x', x'')}{f(x, x'')},$$

which is $$-\frac{f(u, u')}{UU'} = \frac{U'}{f(x, x'')} \bigg/ \frac{U}{f(x', x'')},$$

namely $$\cos C = \tan b/\tan a \quad \text{..................} (3).$$

From the formulae (1), (2), (3), we deduce at once

$$\sin B = \sin b/\sin a, \quad \cos B = \tan c/\tan a, \quad \cos a = \cot B \cot C$$

together with

$$\cos B/\cos b = \sin C, \quad \cos C/\cos c = \sin B, \quad \tan B = \tan b/\sin c,$$
$$\tan C = \tan c/\sin b.$$

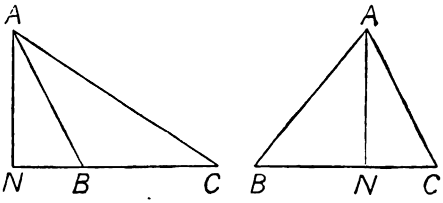
The sum of the angular intervals for a triangle. An immediate consequence of these formulae is that the angular intervals B, C have a sum which is greater than $\frac{1}{2}\pi$. For we have

$$\cos(B + C) = \cos B \cos C - \sin B \sin C = \sin B \sin C (\cos b \cos c - 1),$$

and $\cos b \cos c - 1$ is in all cases negative. Thus $\cos(B + C) < 0$, and therefore $B + C > \frac{1}{2}\pi$. Wherefore $A + B + C > \pi$.

And this last result is true for any triangle A, B, C, whether AB, AC be conjugate lines or not. For, let the lines drawn through A, B, C, each conjugate to the respectively opposite side, meet in the point P (Chap. I, Ex. 10). By our definition of the triangle, one at least of the lines AP, BP, CP contains a point of the opposite segment; for example, suppose that AP contains the point N of the segment BC. We can then apply the above argument to each of the triangles A, N, B and A, N, C. If the angular intervals BAN, NAC be called, respectively, ϕ and ψ, we have $\phi + B > \frac{1}{2}\pi$, $\psi + C > \frac{1}{2}\pi$, $\phi + \psi = A$, and hence $A + B + C > \pi$. This is an important result.

Formulae for a general triangle. Let the line through A which is conjugate to the line BC meet this in N, which is not necessarily a point of the segment BC. Denote by p the interval AN, and by ϕ, ψ, respectively, the angular intervals BAN, NAC, with the conventions introduced before in dealing with the right-angled triangle.



We have

$$\sin p = \sin c \sin B = \sin b \sin C;$$

so that we have

$$\frac{\sin A}{\sin a} = \frac{\sin B}{\sin b} = \frac{\sin C}{\sin c} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1),$$

the first of these being introduced by a construction similar to that here described.

Further, using NC for $-CN$, and BN for $-NB$, with a similar convention for ϕ and ψ, when necessary, we have

$$\cos a = \cos(BN + NC) = \cos BN \cos NC - \sin BN \sin NC,$$
$$\cos b \cos c = \cos BN \cos NC \cos^2 p;$$

hence

$$\cos a - \cos b \cos c = \cos BN \cos NC \sin^2 p - \sin BN \sin NC;$$

we have, however,

$$\sin b \sin c \cos A = \sin b \sin c \cos(\phi + \psi)$$
$$= \sin b \sin c (\cos\phi \cos\psi - \sin\phi \sin\psi),$$

while $$\frac{\cos\phi}{\cos BN} = \sin B = \frac{\sin p}{\sin c}, \quad \frac{\cos\psi}{\cos NC} = \sin C = \frac{\sin p}{\sin b},$$

and $$\sin\phi = \frac{\sin BN}{\sin c}, \quad \sin\psi = \frac{\sin NC}{\sin b};$$

hence

$$\sin b \sin c \cos A = \cos BN \cos NC \sin^2 p - \sin BN \sin NC.$$

Thus we infer

$$\cos a = \cos b \cos c + \sin b \sin c \cos A \;\ldots\ldots\ldots\ldots(2).$$

By a similar proof we have

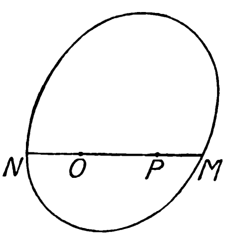
$$\cos A = -\cos B \cos C + \sin B \sin C \cos a \;\ldots\ldots\ldots(3).$$

From these formulae it follows, also, that $\cos a - \cos(b + c)$, being equal to $2 \sin b \sin c \cos^2 \frac{1}{2}A$, is necessarily positive. Wherefore, if $\sigma = \frac{1}{2}(a + b + c)$, we see that each of the products $\sin\sigma \sin(\sigma - a)$, $\sin\sigma \sin(\sigma - b)$, $\sin\sigma \sin(\sigma - c)$ is positive; and from these we can deduce that $a + b + c < 2\pi$ and $b + c > a$ (Euclid, Book XI, Props. 21, 22). The latter of these two results is deducible from the former by considering the triangle whose angles are A, $\pi - B$, $\pi - C$; and the former is deducible from the previously obtained result, $A + B + C > \pi$, by considering the triangle whose vertices are the poles of the sides of the given triangle. [Add.]

It should perhaps be remarked that though the formulae here obtained are identical with those usually given for the metrical trigonometry of the sphere, there is an important distinction between that case and this. For on the plane two points coincide if the interval between them is π, while two lines have only one point of intersection. What are two diametrically opposite points of the surface of a sphere are here replaced by a single point. The equivalent, in the present theory, of the geometry of the surface of a sphere, arises below (p. 196).

The case of a real conic as Absolute. When we take as absolute conic of reference a *real*, undegenerate, conic, of which we may suppose the equation to be $fx = 0$, where $fx = -x^2 - y^2 + z^2$, it is necessary, when we are discussing only the real points of the plane, to distinguish between points which are interior points of this conic, and those which are exterior. The former are characterised by the twofold property (above, p. 164) that every real line through an interior point meets the conic in two real points, while the tangents to the conic from the point are imaginary. For an exterior point, O, the tangents to the conic from O are real; some real lines drawn from O meet the conic in two real points, others in two imaginary points, and a line of the former sort is separated by the two real tangents from a line of the second sort.

It seems unnecessary to enter into great detail. We consider only real points which are interior to the conic; and our main object is to shew that the results obtained are those which were found by Lobatschewsky and Bolyai in their (metrical) so-called non-Euclidean geometry. Bibliographical references are given at the end of the volume (Note III).



Let the line joining two interior points, O, P, meet the conic in M and N, so chosen that N, O, P, M are in order; then the expressions of the symbols of O and P in terms of those of M and N will be of the forms $O = M + hN$, $P = M + kN$, where, if the point whose symbol is $M + N$ be an interior point of the conic, the real symbols h, k will be positive and $h > k$. Thus $(O, P;\, M, N)$, or $h^{-1}k$, is real and positive and less than 1, and we may take for $\log [(O, P;\, M, N)]$ a value -2σ, where σ is real and positive. Thus the interval θ as previously defined, by $(2i)^{-1} \log [(O, P;\, M, N)]$, is given by $\theta = i\sigma$. If, for fixed positions of N, O, M, the point P vary, from N, through O, to M, the value of σ varies from $-\infty$, through 0, to $+\infty$; and $\cos\theta$, $\sin\theta$ are, respectively, $\cosh\sigma$ and $i \sinh\sigma$. The conic, $-x^2 - y^2 + z^2 = 0$, meets the lines $x = 0$, $y = 0$ each in real points, but does not meet the line $z = 0$ in real points; thus the points $(1, 0, 0)$ and $(0, 1, 0)$ are exterior points, but the point $(0, 0, 1)$ is an interior point; for this point the expression $-x^2 - y^2 + z^2$ is positive; this expression is therefore constantly positive for all interior points. Similarly, if $u, = yz' - y'z$, $v, = zx' - z'x$, $w, = xy' - x'y$, be the coordinates of a line, the expression $-u^2 - v^2 + w^2$, which vanishes when the line touches the conic, has one sign for all lines which meet the conic in two real points, and the opposite sign for lines not meeting the conic in real points; the expression is negative for the line $x = 0$, and is thus negative for all lines which meet the conic in two real points. Again, if (x, y, z) and (x', y', z') be two interior points, and the signs of x, y, z, as of x', y', z', be properly taken, the expression $-xx' - yy' + zz'$ has a definite sign; for the polar of an interior point contains only exterior points; the expression is thus positive for any two interior points. We see thus that it is appropriate to replace the formulae

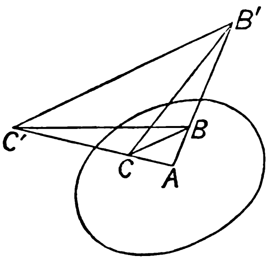
$$\cos\theta = (-xx' - yy' + zz')(fx \, . \, fx')^{-\frac{1}{2}}, \quad \sin\theta = (fu)^{\frac{1}{2}}(fx \, . \, fx')^{-\frac{1}{2}},$$

by the formulae

$$\cosh\sigma = (-xx' - yy' + zz')(fx \, . \, fx')^{-\frac{1}{2}}, \quad \sinh\sigma = (-fu)^{\frac{1}{2}}(fx \, . \, fx')^{-\frac{1}{2}},$$

replacing $(fu)^{\frac{1}{2}}$ by $i(-fu)^{\frac{1}{2}}$. All the square roots, as well as $\cosh\sigma$ and $\sinh\sigma$, are now to be taken positively. These formulae can, if desired, be continued, to give the interval between an interior point, O, and an exterior point, P; the interval σ will then be of the form $\frac{1}{2}i\pi + \lambda$, where λ is real.

The interval between two lines which intersect at an interior point of the conic is to be taken with respect to the two imaginary tangents drawn to the conic from this point. Thus, as in the case of the imaginary conic considered above, the functions that enter are the trigonometrical functions, cos and sin, two lines which are at an interval π being coincident. In particular, as before, two conjugate lines are at an interval $\frac{1}{2}\pi$.



If we consider three points, A, B, C, all interior to the conic, such that AB and AC are conjugate lines, the polar line of A lies entirely exterior to the conic; and, if this meet AB and AC, respectively, in B' and C', these are the poles of AC and AB, respectively. The line, CB', through C, conjugate to CA, thus meets AB, at B', outside the conic and, therefore, the angular interval between CA and CB is less than $\frac{1}{2}\pi$. The same is true of the interval between BA and BC. Recalling, then, what was seen above, for the case when the absolute conic was imaginary, if we use a, b, c for the values of the interval σ belonging, respectively, to BC, CA, AB and B, C for the angle intervals ABC and ACB, the formulae for the triangle ABC are obtainable from those above given for an imaginary conic by merely replacing $\cos a$, $\sin a$, $\cos b$, $\sin b$, $\cos c$, $\sin c$ by $\cosh a$, $\sinh a$, $\cosh b$, $\sinh b$, $\cosh c$, $\sinh c$, respectively. In particular,

$$\cos(B + C), = \sin B \sin C (\cosh b \cosh c - 1),$$

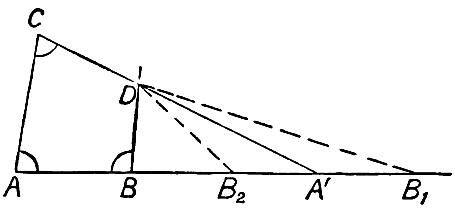
is necessarily positive. Thus we have $B + C < \frac{1}{2}\pi$, the angle between AB and AC being $\frac{1}{2}\pi$.

From this, as before, for any triangle A, B, C for which A, B, C are interior to the conic, we infer that $A + B + C < \pi$.

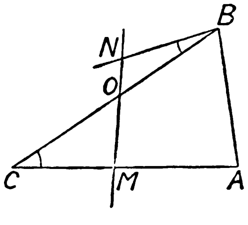
The angle interval, θ, between two lines $ux + vy + wz = 0$, $u'x + v'y + w'z = 0$, which intersect at a point (x, y, z), is such that $\sin\theta$ is of the form $\Delta(fx)^{\frac{1}{2}}(fu \,.\, fu')^{-\frac{1}{2}}$; this interval is then zero for two lines which intersect on the absolute conic. It is thus possible, in this case, to have a triangle for which every one of the three angle intervals is zero, if we allow the vertices to be on the conic.

The sum of the angles of a triangle and a quadrangle of three right angles. If we recall (see above, Chap. IV, p. 158) that two pairs of real conjugate points, on the same line, separate one another, or do not separate one another, according as the line meets the absolute conic in imaginary, or in real, points, we can prove the important theorem for the sum of the angles of a triangle with a single assumption of congruence; we give indications of how this may be done.

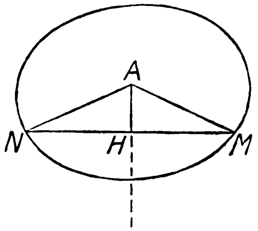
Let A, B, D, C be four points such that AB, CD both pass through the pole, A', of AC, while, also, AC, BD both pass through the pole of AB. The angles at A, B, C are then all equal to $\frac{1}{2}\pi$. Let B_1 be the pole of BD; this point, which is on BA', is separated from B by A and A' if AA' meet the absolute conic in imaginary points. In this case, the angular interval between DB and DB_1 is $\frac{1}{2}\pi$, and, therefore, the angular interval between DB and DC, which is the fourth angle of the quadrangle $ABDC$, is greater than $\frac{1}{2}\pi$. When however the line AA' meets the absolute conic in real points, the pole of BD is not separated from B by A and A'; in this case, let this pole be denoted by B_2, instead of B_1. The angle BDB_2 being $\frac{1}{2}\pi$, the fourth angle, BDC, of the quadrangle $ABDC$, is now *less* than $\frac{1}{2}\pi$.



Bearing in mind the important result thus obtained for a quadrangle of which three angles are right angles, let A, B, C be any triangle with a right angle at A; and, for convenience, suppose the segments AB, AC are both less than $\frac{1}{2}\pi$. Let O be the point of the segment CB such that the intervals CO and OB are equal. From B draw a line BN making the angle CBN equal to the angle ACB. From O draw a line to the pole of AC, meeting this, at right angles, in M, and meeting BN in N. For the triangles CMO and BNO we assume, then, (cf. (3), p. 178), that ON is at right angles to NB. As the angles at A, M, N are right angles, we can by the preceding result, applied to the quadrangle $AMNB$, make an inference as to the angle at B, of this quadrangle; and this angle at B is equal to the sum of the angles ABC, ACB, of the triangle ABC. [Add.]



Comparison with the Lobatschewsky-Bolyai geometry resumed. Now consider a line meeting the real absolute conic in the points M and N, and any point, A, interior to the conic, not lying on this line. We have seen that the σ, (cf. p. 179), between A and any real point of the conic is to be regarded as infinite, and that the interval between A and a point exterior to the conic, if considered at all, is to be regarded as imaginary. In accordance with our usual preconception of the position of a point as being determined by its distance from accessible points, it may seem natural to regard points which are exterior to the conic as not existent, or as at least inaccessible. If we do this, we shall regard all the lines through A which have intersections with the line MN as being limited by the lines AM and AN; and then we may speak of AM, AN as the *two* parallels to MN which can be drawn through A; their intersections with the line MN are at an infinite interval from A, and an infinite number of lines can be drawn through A which do not intersect MN (at any point interior to the conic). Let the line drawn through A conjugate to MN intersect this in H, a point easily seen to be in the segment MN which is interior to the conic; let θ, ϕ denote, respectively, the angular intervals HAM and HAN, and let p be the value of the interval above denoted by σ, for AH. As the angles AMH, ANH are both zero, we infer, from the formulae



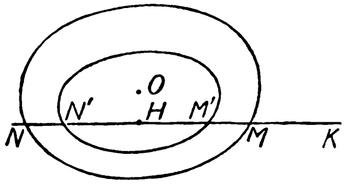
$$\sin\theta = \cos AMH \operatorname{sech} p,$$
$$\sin\phi = \cos ANH \operatorname{sech} p,$$

which we have obtained, that θ and ϕ are equal, both being $\sin^{-1}(\operatorname{sech} p)$. This would then be what, in the Lobatschewsky geometry, is called the *angle of parallelism*.

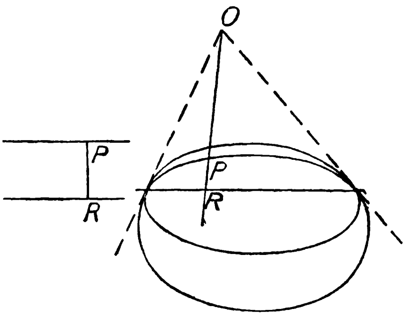
Further, if O be any fixed point interior to the absolute conic, and P a variable interior point such that the interval OP is constant, then P describes a conic having two contacts with the absolute conic, namely at the (imaginary) points where this conic is met by the polar line of O. This conic has the equation

$$(zz' - xx' - yy')^2 = (z^2 - x^2 - y^2)(z'^2 - x'^2 - y'^2)\cosh^2\sigma,$$

where (x', y', z') are the coordinates of O, and σ is the constant interval OP. This conic is that called by Lobatschewsky a *circle*, of which (x', y', z') is the centre. If any chord, $M'N'$, of this circle meet the absolute conic in M and N, and H, K be the two points which are the double points of the involution determined by the pairs M, N and M', N', the one of these points which is interior to the absolute conic being H, it is easy to see that the intervals $N'H$ and HM' are equal, and that the line drawn through H conjugate to $M'N'$ passes through O. In words, the lines, drawn

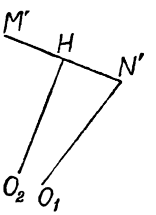


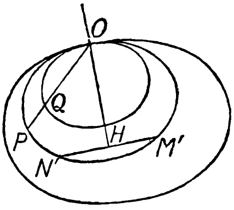
through the middle points of the chords of a circle at right angles to these chords, all pass through the centre of the circle.



If through every point R, interior to the absolute conic, of a line which meets the conic in two real points, a line be drawn at right angles to this line, and thereon a point, P, be taken so that the interval RP is always the same (the point P being, in a sense to be explained, always on the same side of the given line) then the locus of P is that called by Lobatschewsky an *equidistant curve*. In fact, if O, the pole of the given line, be a point exterior to the given conic, the locus of a point P such that the interval OP is constant, is precisely such an equidistant curve.

The corresponding locus, of P, may be considered when O is a point of the absolute conic. This will then be a conic whose four intersections with the absolute conic all coincide at one point. This is the *horocycle* of Lobatschewsky. The lines bisecting at right angles the chords of the horocycle are all parallel, that is, they all pass through a point (O) of the absolute conic. This fact enables us to construct a horocycle passing through a point N'; for draw through this a definite line $N'O_1$; then draw any line $N'HM'$, the point H being such that the angle $HN'O_1$ is the angle of parallelism for a line through N' which is to be parallel to the line, HO_2, drawn through H at right angles to $N'H$, namely $\cosh N'H$ is equal to $\operatorname{cosec}(O_1N'H)$ (see above). The point M' is then such that $M'H = HN'$. If $N'O_1$ remain the same, the angle $O_1N'H$ being allowed to vary, the locus of M' is a horocycle. (This construction is given by Lobatschewsky, *Geometrische Untersuchungen zur Theorie der Parallellinien*, Reprint, Berlin, 1887, § 31, p. 37.) If two horocycles have the same centre, O, and a variable line through O meet these, respectively, in P and Q, the interval PQ is constant; or, two concentric horocycles cut equal segments on two parallel lines passing through their common centre (Lobatschewsky, *loc. cit.* § 33, p. 39).





Case of degenerate conic as Absolute. In the case of a conic represented in point coordinates by $z^2 + \kappa (x^2 + y^2) = 0$, or in line coordinates by $\kappa w^2 + u^2 + v^2 = 0$, say, respectively, $fx = 0$ and $Fu = 0$, the interval, p, between two points (x, y, z), (x', y', z') is, save for sign, such that

$$(fx \, . \, fx')^{\frac{1}{2}} \cos p = zz' + \kappa (xx' + yy'),$$

$$(fx \, . \, fx')^{\frac{1}{2}} \sin p = \{\kappa [\kappa (xy' - x'y)^2 + (xz' - x'z)^2 + (yz' - y'z)^2]\}^{\frac{1}{2}},$$

and the angle, θ, between two lines

$$ux + vy + wz = 0, \quad u'x + v'y + w'z = 0,$$

save for sign, is such that

$$(Fu \, . \, Fu')^{\frac{1}{2}} \cos \theta = \kappa ww' + uu' + vv',$$

$$(Fu \, . \, Fu')^{\frac{1}{2}} \sin \theta = \{\kappa (uw' - u'w)^2 + \kappa (vw' - v'w)^2 + (uv' - u'v)^2\}^{\frac{1}{2}}.$$

Consider what these become, supposing κ to be positive, when, first, κ approaches to zero, and, second, with the usual phraseology, κ becomes indefinitely great. In the former case the absolute conic becomes the point pair given by $z = 0$, $x \pm iy = 0$, or by $u^2 + v^2 = 0$. In this case the interval p becomes zero, but in such a way that $p \, . \, \kappa^{-\frac{1}{2}}$ approaches to the limit, d, which is given by

$$d = \{(xz' - x'z)^2 + (yz' - y'z)^2\}^{\frac{1}{2}} / zz' \, ;$$

the interval, θ, however, remains finite, being, save for sign, such that

$$\cos \theta = (uu' + vv')/mm', \quad \sin \theta = (uv' - u'v)/mm',$$

where $m^2 = u^2 + v^2$, $m'^2 = u'^2 + v'^2$. When κ becomes infinitely great the absolute conic becomes the line pair given by $x \pm iy = 0$. The interval p becomes such that

$$\cos p = (xx' + yy')/nn', \quad \sin p = (xy' - x'y)/nn',$$

where $n^2 = x^2 + y^2$, $n'^2 = x'^2 + y'^2$; and the interval θ becomes zero, but in such a way that $\theta \, . \, \kappa^{\frac{1}{2}}$ approaches to the limit ϕ given by

$$\phi = [(uw' - u'w)^2 + (vw' - v'w)^2]^{\frac{1}{2}} / ww'.$$

Consider the former case, obtained by supposing κ to vanish. If we regard the line $z = 0$ as consisting of those inaccessible points which we ordinarily speak of as being at infinity, this case may be held to include the familiar metrical geometry of the Greeks, on the basis of which measuring instruments at present in use are constructed. This usual metrical geometry evidently assumes that when two points are given, the segment which joins them is without ambiguity, being that segment of the line joining them which does not contain a point of the line $z = 0$. It will be natural enough to make that convention; for the degenerate conic of reference may be regarded as arising from an imaginary conic, $(\kappa > 0)$, and such conic contains no real point of any line considered; or may be regarded as arising from a real conic, $(\kappa < 0)$; and we have considered, in that case, only points lying within the conic. When that convention is made, only triangles being considered whose segments contain no point of the line $z=0$, by putting $\alpha=\kappa^{\frac{1}{2}}a$, $\beta=\kappa^{\frac{1}{2}}b$, $\gamma=\kappa^{\frac{1}{2}}c$, we may deduce from the formulae, previously given (above, pp. 177, 178), using α', β', γ' in place of A, B, C,

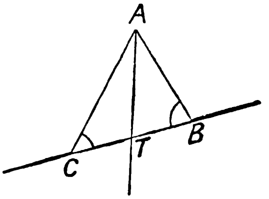
$$\sin\alpha'/\sin\alpha=\sin\beta'/\sin\beta, \quad \cos\alpha=\cos\beta\cos\gamma+\sin\beta\sin\gamma\cos\alpha',$$

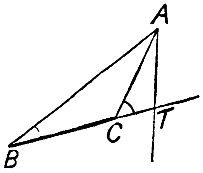
$$\cos\alpha'=-\cos\beta'\cos\gamma'+\sin\beta'\sin\gamma'\cos\alpha,$$

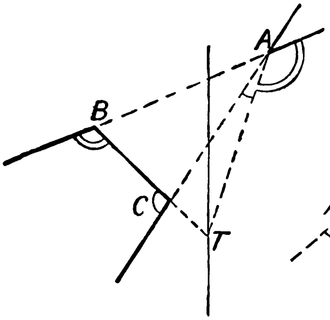
the respective results

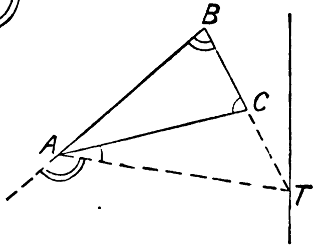
$$a^{-1}.\sin\alpha'=b^{-1}.\sin\beta', \quad a^2=b^2+c^2-2bc\cos\alpha', \quad \cos\alpha'=-\cos(\beta'+\gamma').$$

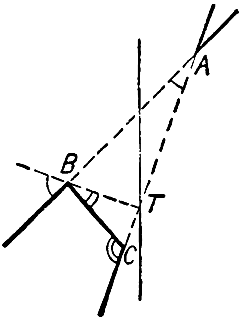
These may also be deduced independently. The last of these follows from $\alpha'+\beta'+\gamma'=\pi$, which can be proved, as by Euclid, from the fact that two lines BA, CA, which meet $z=0$ in the same point A, are at equal angular intervals, ABT, ACT, with a line BC meeting them in B and C, respectively. As before, this assumes that the segment BC contains no point of $z=0$; the point T is the point of the line $z=0$, on the line BC, on the *other* segment BC.

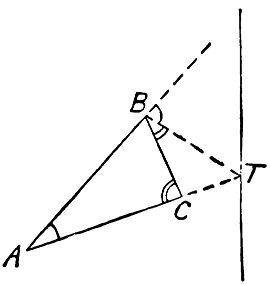












It follows from this* that if we consider an (improper) triangle of which the segments AB, AC contain points of $z=0$, but the segment BC contains no such point, and A, B, C denote the angular intervals BAC, CBA, ACB, then $A+\pi-B+\pi-C=\pi$, or $B+C=\pi+A$. In particular when $A=\frac{1}{2}\pi$, that is, when the points of intersection of AB and AC with $z=0$ are harmonic in regard to the absolute points, I, J, lying on $z=0$, we have $A+B+C=2\pi$.

It appears sufficiently clear from this that any statement of the ordinary Euclidean geometry, even one which has reference to measurement, continues to hold when the so-called line at infinity is replaced by any line of the plane, and the so-called circular points at infinity are replaced by any two conjugate imaginary points lying thereon†. [Add.]

The arbitrariness and comparison of the several methods of measurement. When intervals, between points and between lines, are measured by means of an imaginary conic, the figure considered is sometimes said to lie in an *elliptic* plane; when the conic is real, in an *hyperbolic* plane; and, when the conic of reference is a point pair, in a *parabolic*, or Euclidean plane. The phraseology is convenient; but it is apt to be misconceived. *The plane and the geometry* (though not the symbols, or numbers, associated with intervals) *are the same in all the three cases.* Statements in regard to the intervals are to be considered as abbreviated statements in regard to particular combinations of the algebraic symbols merely; and we have sought to shew that the symbolism is not a necessary, though it is sometimes a convenient, support of the geometrical theory. No deduction of a really geometrical kind can be legitimately based on statements of which any particular conception of distance forms an indispensable part; such statements are equivalent

---

* In this deduction the fundamental fact that the angles ACT, ABT (in the first two diagrams) are equal, follows from the formulae for $\cos\theta$, $\sin\theta$ on page 184, two lines meeting on $z=0$ having equal ratios u'/v'. The last four diagrams illustrate the proof of $\alpha'+\beta'+\gamma'=\pi$ in the various cases, similarly marked angles being equal.

† But a difference is necessary in the definition of movement when we pass to the case in which the Absolute conic becomes a point-pair. The linear transformation of the plane leaving an undegenerate conic unaltered is uniquely determined by its effect upon the range of points on the conic; but the pair of points $z=0$, $x^2+y^2=0$ is unaltered by every transformation $x_1=mx$, $y_1=my$, $z_1=z$. For the former case the self-transformation of the conic involves that the distance of two points is unaltered (cf. p. 169); for the latter case it is necessary to introduce this condition. Thereby, as may be shewn directly (p. 184), the formulae for a movement takes the forms (still involving three arbitrary constants)

$$x_1=px-qy+r,\quad y_1=qx+py+s,\quad z_1=z,$$

where $p^2+q^2=1$. These may be obtained from the formulae of p. 169, if therein we first put $z\kappa^{-\frac{1}{2}}$, $z_1\kappa^{-\frac{1}{2}}$ in place of z, z_1, so that the formulae may relate to the self-transformation of $z^2+\kappa(x^2+y^2)=0$, then divide the coefficients on the right by $\frac{1}{2}(D^2+C^2-A^2-B^2)$, then put $m\kappa^{\frac{1}{2}}$, $n\kappa^{\frac{1}{2}}$ in place of A, B, and then, regarding the ratios of C, D, m, n as definite, put $\kappa=0$.

only to statements in regard to the behaviour of particular measuring instruments, which must rest on physical hypotheses.

In illustration of this general remark, we may, if we please, apply two of the systems of measurement simultaneously. Thus, let A, B, C be any three points, and consider a triangle formed with these, in the sense explained above when discussing the reference to an imaginary conic. Let the segment intervals, BC, CA, AB, with reference to a certain imaginary absolute conic, be denoted, respectively, by α, β, γ, and the angle intervals, BAC, CAB, ABC, corresponding thereto, be denoted, respectively, by α', β', γ'. If we take any three points as reference points for coordinates, and two points I, J which, relatively to these reference points, are given by $z=0$, $x \pm iy = 0$, we can also measure the segments and angles, as explained above, with reference to the point pair I, J; let them be denoted then, respectively, by a, b, c, A, B, C. Then *both* the equations

$$\cos\alpha = \cos\beta\cos\gamma + \sin\beta\sin\gamma\cos\alpha',$$

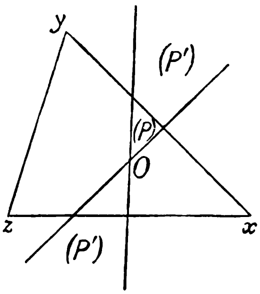
and

$$a^2 = b^2 + c^2 - 2bc\cos A,$$

are true.

An interesting application of this liberty, which has some importance of its own, may be made. This expresses the interval, measured with reference to the imaginary conic $x^2+y^2+z^2=0$, between two lines, by means of an integral which is to be evaluated with measurements of distance and angle that are made relatively to the point pair, I, J, given by $z=0$, $x \pm iy = 0$. Represent x/z, y/z, respectively, by X and Y; an element of area, with the Euclidean reference, is, we may assume, on the basis of familiar notions, given by $dXdY$, or by $rdrd\theta$, where r is the Euclidean distance from a point, and θ the Euclidean angle from a fixed line. If two lines, intersecting in O, be given, of equations $ux+vy+wz=0$, $u'x+v'y+w'z=0$, these may be regarded as defining a region, (P) and (P'), over which the integral

$$\iint \frac{dXdY}{(1+X^2+Y^2)^{\frac{3}{2}}}$$



may be taken (every element $dXdY$ being positive). It will be found that the *integral is* then *equal to twice the interval between the lines*, measured in regard to the conic $x^2+y^2+z^2=0$. Of this statement we may give indications of a straightforward proof. Let d denote the Euclidean distance from the origin z, or $(0, 0, 1)$, to the intersection, O, of the lines, r denote the Euclidean distance from O to a point, P, of the region of integration, and θ the Euclidean angle between the line zO, and the line OP. The integral is then

$$\int_{\phi}^{\phi'} d\theta \int_0^{\infty} rdr\{(1+d^2+r^2+2dr\cos\theta)^{-\frac{3}{2}}+(1+d^2+r^2-2dr\cos\theta)^{-\frac{3}{2}}\},$$

where ϕ is the angle between the line zO and one of the given lines, ϕ' the angle between zO and the other given line. This form of the integral is obtained by pairing together points, P and P', on a line through O, in regard to which the harmonic conjugate of O is on the line $z=0$; the factor $r\cos\theta$, arising for P, corresponds to a factor $r\cos(\theta+\pi)$, or $(-r)\cos\theta$, arising for P'. To carry out the integration, we may notice that

$$\int xdx\,[(x-a)^2+b^2]^{-\frac{3}{2}} = [ax-(a^2+b^2)]\,b^{-2}\,[(x-a)^2+b^2]^{-\frac{1}{2}},$$

and utilise the identity

$$\cos^{-1}\frac{u'V-v'U}{s'\Delta} - \cos^{-1}\frac{uV-vU}{s\Delta} = \cos^{-1}\frac{uu'+vv'+ww'}{ss'},$$

where

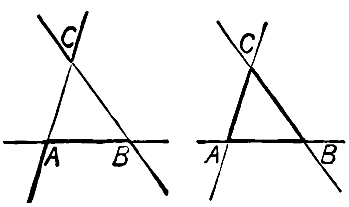
$$U=vw'-v'w,\quad V=wu'-w'u,\quad s^2=u^2+v^2+w^2,$$
$$s'^2=u'^2+v'^2+w'^2,\qquad \Delta^2=U^2+V^2.$$

The integral will then be found to become

$$2\cos^{-1}[(uu'+vv'+ww')/ss'].$$

On the basis of this result, we may speak of the *extent*, relatively to the imaginary conic, of a region of the plane, meaning thereby the value of the integral, evaluated, with the parabolic measurements, as here, over this region. In this sense, any two lines enclose a finite extent, equal to $2A$, where A is the interval between the lines, measured by the imaginary conic. The two lines enclose two regions, which are complementary; the sum of the extents of these two regions is that of the whole plane, which is thus finite. The angular interval, in regard to the imaginary conic, for the other region, is $\pi-A$, and the extent of this is $2\pi-2A$. Thus 2π is the extent of the whole plane.

Thus also the extent of a triangle, in terms of the angular intervals of it, with reference to the imaginary conic, is $A+B+C-\pi$. For, if the extent of the triangle be denoted by Δ, the whole plane is made up of four regions whose respective extents are $2A-\Delta$, $2B-\Delta$, $2C-\Delta$, and Δ; putting the sum of these equal to 2π, we find



$$\Delta = A+B+C-\pi.$$

Conversely, we may avoid the use of the integral, by defining the extent of a triangle as being $A+B+C-\pi$, allowing this to apply also to the triangle whose angular intervals are C, $\pi-A$, $\pi-B$, and assuming that the extent of a composite region is the sum of the extents of its component regions. For the extent between the lines CA, CB we should thus obtain

$$[A+B+C-\pi]+[C+\pi-A+\pi-B-\pi], \text{ or } 2C.$$

Ex. 1. Shew that the extent of a *circle*, relatively to the imaginary conic, that is of the conic whose equation is

$$(xx'+yy'+zz')^2=(x^2+y^2+z^2)(x'^2+y'^2+z'^2)\cos^2 r,$$

is $2\pi(1-\cos r)$.

Ex. 2. If σ be the interval, relatively to the imaginary conic, between two points, prove that the integral $\int d\sigma$, extended along the circle, has the value $2\pi\sin r$. (Cf. p. 200.)

The remarks in the present section are largely anticipatory; it will be understood that they are intended to be suggestive, and are not complete.

Plane metrical geometry by projection from a quadric surface. Spherical geometry. In Chap. III we have considered the theory of the circle, or of geometry with two absolute points of reference. In the present chapter we have considered the theory with reference to an absolute conic. These are in pursuance of the plan we have adopted, of devoting the present volume to geometry in one plane. We shall see in detail, in a subsequent volume, that a plane in which two absolute points are given is more properly to be regarded as the projection of a surface, called a quadric, existing in space of three dimensions, which has the property of being met in two points by an arbitrary line. The centre of projection lies on this surface. Similarly, a plane in which an absolute conic is given is naturally suggested by the projection of the points of a quadric, from a centre of projection not lying on the quadric. It appears, therefore, to be necessary to make some remarks here in regard to a quadric surface; as we are to deal with geometry in three dimensions in the next volume, these remarks will be brief, and incomplete.

We have already, in Volume I, p. 82, constructed, from four points A, B, C, D which do not lie in a plane, a point whose symbol, in terms of the symbols of these points, is

$$P=\lambda A+\mu B+\lambda\mu C+D;$$

if we denote this by $P=xA+yB+zC+tD$, we have $xy=zt$; conversely, any point whose *coordinates*, x, y, z, t, relatively to A, B, C, D, satisfy this equation, is such a point as P, for suitable values of λ and μ. It is the aggregate, or locus, of all such points which we speak of here as a quadric surface. For our purpose it will be convenient to use ξ, η instead of x, y, subject to $x=\xi+i\eta$, $y=\xi-i\eta$, so that the equation takes the form $\xi^2+\eta^2=zt$. We can shew that the surface contains an infinite number of lines, which break up into two systems, there being one line of each system through every point of the surface. Every line of either system, in fact, meets every line of the other system, but two lines of the same system do not intersect. For, first, whatever θ may be, every point (ξ, η, z, t) which is such that $\xi+i\eta=\theta t$, $\xi-i\eta=\theta^{-1}z$, is evidently such that $\xi^2+\eta^2=zt$, and is, therefore, a point of the surface; such a point has the symbol $\theta tA+\theta^{-1}zB+zC+tD$, and is a point of the line joining the points whose symbols are $\theta^{-1}B+C$, $\theta A+D$; the two equations taken together thus represent this line. By taking different values of θ, we thence obtain a system of lines. If $(\xi_0, \eta_0, z_0, t_0)$ be any point of the surface, the equal values, $(\xi_0+i\eta_0)\,t_0^{-1}$, $z_0(\xi_0-i\eta_0)^{-1}$, give a value of θ for which the line contains this point. It is easy, moreover, to verify that two lines of this system, for the respective values θ, ϕ of the parameter, given by $\xi+i\eta=\theta t$, $\xi-i\eta=\theta^{-1}z$ and $\xi+i\eta=\phi t$, $\xi-i\eta=\phi^{-1}z$, do not meet.

Similarly, the surface contains another system of lines, of which one is given by $\xi-i\eta=\phi t$, $\xi+i\eta=\phi^{-1}z$, one of which passes through every point of the surface. No two of these intersect. But this line meets that, of the former system, given by $\xi+i\eta=\theta t$, $\xi-i\eta=\theta^{-1}z$, in the point given by $\xi+i\eta=\theta$, $\xi-i\eta=\phi$, $z=\theta\phi$, $t=1$.

It is easy to prove that any line of the threefold space contains two points of the quadric, unless it consist wholly of points belonging thereto; for the substitution in $xy=zt$ of values $x_1+\sigma x_2$, $y_1+\sigma y_2$, $z_1+\sigma z_2$, $t_1+\sigma t_2$, respectively for x, y, z, t, leads to a quadric equation for σ. Further, that the points of an arbitrary plane, which lie on the quadric, are the points of a conic; for, let any line of this plane meet the quadric in the two points P and R, of coordinates (x_1, y_1, z_1, t_1) and (x_3, y_3, z_3, t_3); and let Q (x_2, y_2, z_2, t_2) be another point of this plane, not on the line PR: if, then, in $xy=zt$, we replace x, y, z, t, respectively, by $x_1+\theta x_2+\phi x_3$, and similar expressions, we find that ϕ is expressible in terms of θ; by choosing Q suitably, this leads to a symbol, for any point of the quadric lying in the plane, of the form $P+m\theta Q+n\theta^2R$. This shews that all such points lie on a conic. In particular, the plane containing the two lines of the quadric which meet in any point, P, of the surface, contains no other points of the quadric than the points of these two lines. This plane is called the tangent plane of the quadric at P. The lines are called the generating lines, or generators, of the surface, at P.

Any equation which is linear (and homogeneous) in the coordinates, ξ, η, z, t, of a point, expresses that this point lies on a definite plane; this equation may then be called the equation of the plane. If the equation be $-ct+2f\eta+2g\xi+hz=0$, the point $(\xi+i\eta)A+(\xi-i\eta)B+zC+tD$, being, in virtue of this equation, the same as

$$c(\xi+i\eta)A+c(\xi-i\eta)B+czC+(2f\eta+2g\xi+hz)D,$$

or $$\xi(cA+cB+2gD)+\eta(icA-icB+2fD)+z(cC+hD),$$

is a point of the plane containing the three points whose symbols are, respectively,

$$c(A+B)+2gD,\quad ic(A-B)+2fD,\quad cC+hD;$$

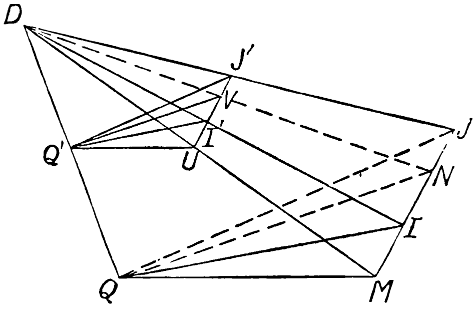
by proper choice of c, f, g, h, this is any plane whatever.

In particular, the three equations $\xi=0$, $\eta=0$, $z=0$ represent, respectively, three planes. And these intersect in the point of coordinates $(0, 0, 0, 1)$, that is, the point D. This is a point of the quadric, since these coordinates satisfy the equation $\xi^2+\eta^2=zt$. The line which joins this point, D, to any point, of coordinates (ξ, η, z, t), meets the plane whose equation is $t=0$, in the point $(\xi, \eta, z, 0)$. This point is the projection, from D, of the point (ξ, η, z, t). Any point of the quadric, other than D itself, can thus be made to correspond, by projection, to a point of the plane $t=0$. But the line which is expressed by the two equations $\xi+i\eta=0$, $z=0$, is wholly on the quadric; and this line passes through D; every point of the quadric lying on the line is, therefore, projected from D into the same point of the plane $t=0$. So, likewise, is every point of the quadric lying on the line expressed by the two equations $\xi-i\eta=0$, $z=0$. Every point of the plane $t=0$, other than the two points so obtained, is the projection of a definite point of the quadric. These two exceptional points of the plane $t=0$ are, necessarily, themselves points of the quadric; if we denote them by I and J, we may regard the point D of the quadric as projecting into the line IJ.

In this projection, the points of the quadric which lie on any plane passing through D project into the points of a line, in the plane $t=0$, and conversely. A plane not passing through D is intersected by the generators of the surface at D (whose equations are $\xi+i\eta=0$, $z=0$ and $\xi-i\eta=0$, $z=0$) in two points, say, I' and J'; the points of the quadric lying on such a plane project, therefore, into the points of a curve, in the plane $t=0$, which passes through the points I and J. If the plane in question be that given by the equation $-ct+2f\eta+2g\xi+hz=0$, we see, eliminating t by means of $\xi^2+\eta^2=zt$, that the equation of this curve is $-c(\xi^2+\eta^2)+2f\eta z+2g\xi z+hz^2=0$. The curve is that we have, in Chap. III, called a circle, relatively to the points I, J. In particular, when the plane contains the point D, we have $c=0$, and the circle degenerates into the line, in the plane $t=0$, given by $z=0$, together with another line.

Thus the geometry in a plane, relative to two absolute points, which we have considered in Chap. III, may be regarded as the geometry dealing with the points of a quadric surface. A circle in the plane is thereby replaced by a plane section of the quadric surface.

Consider, from this point of view, the measurement of angle between two lines in the plane $t=0$, relatively to the points I, J. Let the lines intersect in Q, and meet the line IJ, respectively, in the points M, N. The measurement, we have explained (above, p. 167), is by means of the range M, N, I, J. The four lines QM, QN, QI, QJ, of the plane $t=0$, are projected from D by means of four planes which intersect in the line DQ. Any plane, not containing the line DQ, is met by these four planes in a flat pencil of four lines which is related to the pencil $Q(M, N, I, J)$, in the sense explained in Vol. I; in particular we may take the tangent plane of the quadric at D, which is met by these four planes in the pencil $D(M, N, I, J)$. Let DQ meet the quadric surface in Q' (beside D); there is, at Q', one generator which meets the generator DI, say in I', and another generator which meets the generator DJ, say in J'. It is easy to verify that the tangent line of any plane section of the quadric, at any point, lies in the tangent plane of the surface at that point. The planes DQM, DQN give rise to two conics lying on the quadric surface, which have the points Q' and D for common points; the tangent at Q' of the former conic meets the tangent of this at D, in a point, say, U, which is on the line DM in which the plane DQM meets the tangent plane, DIJ, at D; similarly, the tangent at Q' of the latter conic meets the tangent of this at D, in a point V lying on DN. These points U, V are in the tangent plane of the quadric at Q'. Thus the pencil $Q'(U, V, I', J')$ is related to the pencil $Q(M, N, I, J)$. Two tangent planes can be drawn to the quadric surface from an arbitrary line, as we may see by taking the two points where the line meets the quadric, and considering the intersections of the generators of the surface at one of these points with the generators of the surface at the other of these two points. In our figure, as $I'D$, $I'Q'$ are generators, and $J'D$, $J'Q'$ are generators, the planes $DI'Q'$ and $DJ'Q'$ are the tangent planes of the surface which can be drawn through the line DQ; thus the axial pencil of planes which has



been spoken of, consists of the two planes through DQ containing the lines QM and QN, together with the two tangent planes to the surface from the line DQ. It is by considering the two former planes, with respect to the two latter, that the angle between the lines QM, QN is measured.

It can be shewn that if, through any point E, a line be drawn to meet the quadric surface in R and S, and the point F be taken thereon harmonic to E in regard to R and S, then the locus of F, for all such lines drawn through E, is a plane. This plane, say e, is called the polar plane of E in regard to the quadric. For the quadric $\xi^2+\eta^2=zt$, its equation is $2(\xi\xi'+\eta\eta')=zt'+z't$, where (ξ', η', z', t') are the coordinates of E. If the polar plane of one point, E, contain a point, F, then the polar plane of F contains the point E; two such points, E, F, are said to be conjugate in regard to the quadric. To any arbitrary plane there is one point, called its pole, of which the plane is the polar plane; if the pole of one plane lie on another plane, the pole of this other lies on the former; two such planes are said to be conjugate. To any plane drawn through a given line, there corresponds another plane passing through the line, conjugate to the former plane; the pairs of planes so obtainable form an axial pencil in involution, of which the double elements are the two tangent planes to the quadric which can be drawn through the given line.

With this, we can state in another way the condition adopted in Chap. III for the lines QM, QN to be at right angles to one another in regard to I and J, which was that M and N should be harmonic conjugates in regard to I and J. It requires that the planes DUQ', DVQ' should be harmonic in regard to the tangent planes, $DI'Q'$, $DJ'Q'$, drawn to the quadric from the line DQ. Thus, from what is said above, the condition is that the planes DQM and DQN should be conjugate to one another in regard to the quadric.

Now suppose we take two circles in the plane $t=0$, intersecting in the point Q, and in another point, R, in addition to I and J. We may consider the pencil of four lines, consisting of QI, QJ and the two tangents of these circles at Q. Let DQ and DR meet the quadric again, beside D, in Q' and R', respectively. The pencil of four lines, spoken of, passing through Q, is, we have seen, related to a pencil of four lines through Q', lying in the tangent plane of the quadric at Q'; these lines are the generators of the quadric at Q' (corresponding to QI, QJ), and the tangents at Q' of the two plane sections of the quadric which, as we have seen, project, from D, into the two given circles of the plane $t=0$. Through these four lines, in the tangent plane at Q', we can draw four planes all passing through the line $Q'R'$, so determining an axial pencil of planes related to the plane pencil in question. Of these planes, one will be a plane containing one of the generators at Q' and, also, that generator at R' which intersects this; this plane will be a tangent plane to the quadric drawn through the line $Q'R'$; another of the four planes will be that containing the other generator at Q', of the quadric, together with the generator at R' which intersects this, this being the other tangent plane to the quadric drawn from the line $Q'R'$. The other two planes of the axial pencil through $Q'R'$ are the planes of the two sections of the quadric which project, from D, into the two given circles. In accordance with what is said at the beginning of this chapter, the angle between the tangents at Q, of the two given circles, may be measured by the plane pencil, of centre Q, by taking these tangents with respect to QI and QJ. By what we have now said, it may also be measured by taking the plane sections of the quadric, through the line $Q'R'$, which project from D into the given circles, and considering these planes with respect to the two tangent planes of the quadric which can be drawn from the line $Q'R'$. Incidentally, it appears that the circles cut at the same angle at both their common points, Q and R. In particular, the circles cut at right angles if the two plane sections of the quadric, which project from D into these circles, are in planes which are conjugate to one another in regard to the quadric.

In these discussions, the lines and circles whose inclinations have been considered lie in the plane $t = 0$, which is in fact a tangent plane of the quadric, namely at the point $(0, 0, 1, 0)$. It is true, however, that a plane section of the quadric projects, from a point D of the quadric, into a circle upon any plane whatever, if the two absolute points for this plane are taken to be the points in which the generators of the quadric, at D, meet this plane.

Let us now replace the coordinates z and t by coordinates ζ, τ by means of $z = \tau + \zeta$, $t = \tau - \zeta$; the equation of the quadric then takes the form $\xi^2 + \eta^2 + \zeta^2 = \tau^2$. There is in the plane $\tau = 0$ a conic, lying on the quadric, given by $\xi^2 + \eta^2 + \zeta^2 = 0$. This conic meets an arbitrary plane, ϖ, of the threefold space in two points. Let us agree to take for the two absolute points of this plane, ϖ, in the sense discussed at length in Chap. III, these two points of this quadric. For a tangent plane of the quadric, say, at Q', these two points, lying on the quadric and on this plane, are the two points in which the plane $\tau = 0$ is met by the generators of the quadric at Q'. The effect is, then, that the angle between the tangent lines of the two plane sections of the quadric, at a point Q' where these sections intersect, as we have been led to consider it, is in fact obtainable by the rule, applied to the tangent plane of the quadric at Q', which we originally (p. 167) adopted for geometry in a plane; but, at the same time, the suggestion clearly arises of considering the interval between two points, of the plane $\tau = 0$, by a reference to a fixed conic lying in this plane.

Metrical geometry in regard to an absolute conic. We proceed now to consider this measurement in regard to a fixed conic from the point of view we have reached by introducing the quadric surface.

Denote the point $\xi = 0$, $\eta = 0$, $\zeta = 0$, which does not lie on the quadric, whose equation is $\xi^2 + \eta^2 + \zeta^2 = \tau^2$, by O. It is easily seen that the plane $\tau = 0$ is the polar plane of O in regard to the quadric. Any point, say, Q', of the quadric, may be projected from O on to the plane $\tau = 0$, giving a point, say, Q_1. All points, Q', of the quadric which lie on a plane passing through O, give rise, then, to points, Q_1, lying on a line of the plane $\tau = 0$. Consider two plane sections of the quadric whose planes pass through O; the common points, say Q' and R', of these two sections of the quadric, will then lie in line with O. We have seen that the angle between the tangent lines, at Q', of these sections, obtained by considering these lines with respect to the generators of the quadric at Q', may be obtained also by considering the planes of the two sections with respect to the two tangent planes of the quadric which can be drawn through the line $Q'R'$. Now consider the four lines in which these planes meet the plane $\tau = 0$; as $OQ'R'Q_1$ are in line, these four lines meet in the point Q_1 of the plane $\tau = 0$. Two of these lines, corresponding to the tangent planes of the quadric drawn through $Q'R'$, are the intersections with $\tau = 0$ of the planes joining O to the generators of the quadric at Q'; the other two of the four lines are the intersections with $\tau = 0$ of the planes of the two given sections. We can shew that the two former lines are the tangent lines, from Q_1, to the conic of the plane $\tau = 0$ given by $\xi^2 + \eta^2 + \zeta^2 = 0$. For let one of the generators at Q', of the quadric, meet the plane $\tau = 0$, say, in H; this point is on the section of the quadric by the plane $\tau = 0$, that is, on the conic $\xi^2 + \eta^2 + \zeta^2 = 0$. The plane $\tau = 0$ being the polar plane of O, it is easy to see that the tangent plane of the quadric at H passes through O; this tangent plane contains the generator $Q'H$. Thus the plane joining O to this generator meets $\tau = 0$ in a line which touches the conic $\xi^2 + \eta^2 + \zeta^2 = 0$ at H, as was said. We are thus led from the measurement of the angle, at Q', between two lines, meeting at this point, lying in the tangent plane at Q', by means of two absolute points of this plane, to the measurement of the angle, at Q_1, between two lines, meeting at this point, lying in the plane $\tau = 0$, by means of the tangent lines drawn from this point to the conic $\xi^2 + \eta^2 + \zeta^2 = 0$.

Next consider any two points of the quadric, say, Q' and K'. Let them be projected from O into the two points, Q_1 and K_1, of the plane $\tau = 0$. Suppose that we measure the interval between the points Q' and K', as points of the quadric surface, by the angle between the lines OQ' and OK', taken in respect to the two absolute points of the plane $Q'OK'$, these being, as before, the points where this plane meets the conic $\tau = 0$, $\xi^2 + \eta^2 + \zeta^2 = 0$. We are thus led to measure the interval between the points, Q_1 and K_1, of the plane $\tau = 0$, by considering these with respect to the two points in which their joining line meets the absolute conic of their plane.

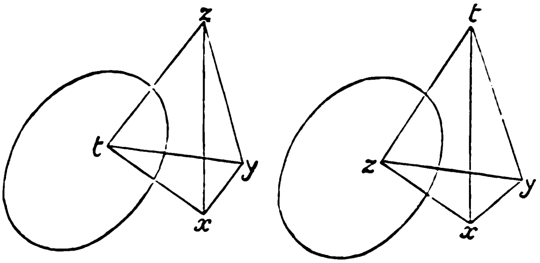
Thus, finally, the plane metrical geometry we have explained in this chapter, relatively to a fixed absolute conic, which gives an interval between two lines, and an interval between two points, is seen to be obtainable by projection of a geometry upon the quadric surface, the centre of projection, O, not being on the quadric. Lines of the plane are replaced by sections of the quadric, whose planes pass through the centre of projection, O. The interval between two points on the quadric surface is understood to be the interval between the lines joining these to O, taken with respect to the absolute points of the plane containing these joining lines; the interval between two lines of the plane is replaced by the interval between two lines lying in a tangent plane of the quadric surface, again taken with respect to the absolute points of this plane.

But this reduction of the metrical plane geometry, with respect to an absolute conic, to metrical geometry on a quadric surface, with respect, in the case of every plane concerned, to two absolute points in that plane, calls for a further important remark. While any point, Q', of the quadric, gives rise, by projection from O, to a single point, Q_1, of the plane, this last gives rise, conversely, not only to Q', but also to the second point, R', in which the line OQ_1 meets the quadric. Thus, whereas two points of the plane coincide when the interval between them, in regard to the absolute conic, is π (or any odd multiple of π), the corresponding points of the quadric surface do not then coincide, but are two points in line with O. Two points of the quadric surface coincide only when the interval between them is 0, or 2π, or an even multiple of π. The geometry of the points of a plane, in this book, is in fact that of lines, extended in both directions, passing through a point outside the plane. In the geometry on the quadric surface, which we may call *spherical* geometry, any such line gives rise to *two* points. In the plane two lines have one point in common; on the quadric surface, two plane sections are curves having *two* points in common. With proper conventions, the metrical formulae we have found for a triangle, when the measurements are with respect to an imaginary conic, continue to hold on the quadric given by the equation $\xi^2 + \eta^2 + \zeta^2 = \tau^2$, in which the coordinates ξ, η, ζ, τ are real; the arcs between two points being taken on planes through the point $(0, 0, 0, 1)$, and measured, as explained, with respect to the two points in which the planes meet the conic $\xi^2+\eta^2+\zeta^2=0$, $\tau=0$; while the angles between two such arcs are measured, on the tangent plane of the quadric, at the point of intersection of the arcs, with respect to the two points in which this plane meets the same conic.

But there are many cases in which the distinction between the plane geometry and the spherical geometry is of importance. As a single example we may refer to the following: On the quadric $\xi^2+\eta^2+\zeta^2=\tau^2$, consider the four points, A, B, C, D, of coordinates, respectively, $(-a, b, c, 1)$, $(a, -b, c, 1)$, $(a, b, -c, 1)$, $(-a, -b, -c, 1)$, where a, b, c are arbitrary real symbols such that $a^2+b^2+c^2=1$. These can be joined in pairs by six arcs, lying on the quadric in planes which pass through the point $(0, 0, 0, 1)$, forming four triangles ABC, BCD, CAD, ABD, in such a way that if the angles of the first of these be called A, B, C, those of the others are, respectively, C, B, A; A, C, B and B, A, C; the four triangles, which together exhaust the whole surface of the quadric, are in fact equal to one another, in angles and in arcs. The three angles A, B, C are such that $A+B+C=2\pi$. When, however, this figure is projected from O, the point $(0, 0, 0, 1)$, on to the plane $\tau=0$, while we get, from A, B, C, the triangle A_1, B_1, C_1, for which the angles are such that $A_1+B_1+C_1=2\pi$, the point D_1, arising from D, is an interior point of this, namely is such that every line through it meets two of the segments B_1C_1, C_1A_1, A_1B_1. (See below, p. 207.)

Representation of the original plane upon another plane. In the preceding section we have passed from a point, Q, of the plane, by projection from a point D, lying on a quadric surface, to a point, Q', of this surface. And then, by projection from a point, O, not lying on the quadric, to another point Q_1, lying on another plane (that denoted by $\tau=0$). If, with O and D given, we consider the reverse process of passing from Q_1 to Q, the point Q_1 will give rise, by projection from O, to two points of the quadric surface, say, Q' and R', and each of these will give, by projection from D, a single point of the original plane; so that we get two points, Q and R, corresponding to Q_1. But the results of the process will be found to be interesting, nevertheless. In particular, it will appear that the *distance* used by Riemann in his celebrated Dissertation of 1854, *Ueber die Hypothesen welche der Geometrie zu Grunde liegen* (Werke, 1876, p. 254), which at first sight appears to require that a system of metrical coordinates has been established beforehand, is in fact identical with the interval with respect to a conic which we have considered in the present chapter. Further, the origin of one particular representation of Lobatschewsky's Geometry (used, for example, by Poincaré, in his remarkable papers on Automorphic Functions, *Acta Math.* I, 1882, p. 7) will be made clear.

The absolute conic being supposed to be given by one of the two equations $z^2+x^2+y^2=0$, $z^2-x^2-y^2=0$, and, in the latter case, limiting ourselves to real values of x, y, z for which $z^2-x^2-y^2$ is positive, as in the earlier part of this chapter, let us associate, with each point, (x, y, z), of the plane the positive square root, $(z^2+x^2+y^2)^{\frac{1}{2}}$, or $(z^2-x^2-y^2)^{\frac{1}{2}}$. If we denote this square root by t, this comes to considering the point (x, y, z, t), of the quadric surface expressed, respectively, in the two cases, by the first or second of the equations $x^2+y^2+z^2=t^2$, $z^2-x^2-y^2=t^2$. This point, (x, y, z, t), is one of the two points in which the quadric is met by the line joining the point (x, y, z), of the plane, to the point $(0, 0, 0, 1)$. For the former quadric surface, this point is an interior point, in the sense that every line through it meets the quadric in two real points. For the latter quadric, the point $(0, 0, 0, 1)$ is an exterior point, only those lines through it which contain points for which $z^2-x^2-y^2>0$ meeting it in real points.



In the case of points of the quadric $x^2+y^2+z^2=t^2$, if we define ξ, η, respectively, by $\xi=2x/(z+t)$, $\eta=2y/(z+t)$, we may take, for the homogeneous coordinates, x, y, z, t, of a point of the quadric, respectively,

$$x=\xi,\quad y=\eta,\quad z=1-\tfrac{1}{4}(\xi^2+\eta^2),\quad t=1+\tfrac{1}{4}(\xi^2+\eta^2);$$

if we take $\lambda=\frac{1}{2}(\xi+i\eta)$, $\mu=\frac{1}{2}(\xi-i\eta)$, these are the same as

$$x=\lambda+\mu,\quad y=-i(\lambda-\mu),\quad z=1-\lambda\mu,\quad t=1+\lambda\mu.$$

Noticing that

$$\xi=x+t\,.\,0,\quad \eta=y+t\,.\,0,\quad 2=z+t\,.\,1,\quad 0=t+t(-1),$$

we may, if we wish, regard $(\xi, \eta, 2, 0)$ as the coordinates of a point, in the original plane of x, y, z, obtained by projecting the point, (x, y, z, t), of the quadric, from the point $(0, 0, 1, -1)$; this is a point of the quadric, being one of the points in which it is met by the line given by the two equations $x=0$, $y=0$. It is clear that, while any pair (ξ, η) gives rise only to one point (x, y, z), this point, being the same as $(-x, -y, -z)$, gives rise, conversely, beside (ξ, η), to the pair

$$\xi'=\frac{-2x}{-z+t},\quad \eta'=\frac{-2y}{-z+t},$$

which are $\xi' = -4\xi/(\xi^2+\eta^2)$, $\eta' = -4\eta/(\xi^2+\eta^2)$. Interpreting $(\xi, \eta, 2)$ as rectangular coordinates, so that the equation $\xi^2+\eta^2=4$ represents a circle, when (ξ, η) is within this circle, then (ξ', η') is without it, being such that $(-\xi', -\eta')$ and (ξ, η) are inverse points in regard to this circle (see pp. 67, 109, above). While, therefore, the complete plane (ξ, η) corresponds to all the points of the quadric $x^2+y^2+z^2=t^2$, the complete plane (x, y, z) is represented by restricting ourselves, for example, to the interior of the circle $\xi^2+\eta^2=4$ (together with, say, the points of the circumference of this circle for which η is positive).

With these formulae, any line of the original plane, with the equation $ux+vy+wz=0$, becomes, in terms of ξ and η, the locus represented by the equation

$$u\xi + v\eta + w\left[1 - \tfrac{1}{4}(\xi^2+\eta^2)\right] = 0,$$

which, if $(\xi, \eta, 2)$ be coordinates, represents a circle cutting at right angles the fixed (imaginary) circle whose equation is $1+\frac{1}{4}(\xi^2+\eta^2)=0$. Any such circle meets the real circle given by the equation $\xi^2+\eta^2-4=0$ at the ends of a diameter of this, and is, negatively, self-inverse in regard to this circle. Two such circles have two intersections of which only one is interior to the circle

$$\xi^2+\eta^2-4=0.$$

Further, if (x', y', z') be any other point of the original plane, and we introduce corresponding symbols, ξ', η', and λ', μ', the interval, θ, between the points (x, y, z) and (x', y', z'), relatively to the conic $x^2+y^2+z^2=0$, which, as we have seen, is given by

$$\cos\theta = \frac{xx'+yy'+zz'}{tt'},$$

is equally such that

$$\sin^2\tfrac{1}{2}\theta = \frac{(\lambda'-\lambda)(\mu'-\mu)}{(1+\lambda\mu)(1+\lambda'\mu')},$$

as we at once verify. In terms of ξ, η and ξ', η', this leads to

$$\sin\tfrac{1}{2}\theta = D/PP',$$

where

$$D^2 = \tfrac{1}{4}\left[(\xi'-\xi)^2+(\eta'-\eta)^2\right],\quad P^2 = 1+\tfrac{1}{4}(\xi^2+\eta^2),\quad P'^2 = 1+\tfrac{1}{4}(\xi'^2+\eta'^2).$$

If we suppose $\lambda'-\lambda$, $\mu'-\mu$ to be both small, and replace θ by ds, we thence obtain, for the determination of the interval between the points (ξ, η) and $(\xi+d\xi, \eta+d\eta)$, the form [Add.]

$$ds^2 = \frac{d\xi^2+d\eta^2}{\left[1+\frac{1}{4}(\xi^2+\eta^2)\right]^2}.$$

This may, of course, be obtained directly from the value of ds^2 for the interval between the points (x, y, z) $(x+dx, y+dy, z+dz)$; this latter is found at once to be

$$ds^2 = \frac{(ydz - zdy)^2 + (zdx - xdz)^2 + (xdy - ydx)^2}{(x^2+y^2+z^2)^2}$$

$$= \frac{dx^2 + dy^2 + dz^2 - dt^2}{t^2}, \; = \left[d\left(\frac{x}{t}\right)\right]^2 + \left[d\left(\frac{y}{t}\right)\right]^2 + \left[d\left(\frac{z}{t}\right)\right]^2.$$

The value obtained for ds, in terms of ξ, η, is precisely that found by Riemann (*loc. cit.* p. 264) for the element of length appropriate to a manifoldness which, in his sense, is of constant curvature, given by the absolute coordinates ξ, η. His result is for a metrical manifoldness of any number, n, of absolute coordinates. But it may be shewn, reversing the procedure here followed, that any such manifoldness is in correspondence with a manifoldness to which $(n+1)$ homogeneous coordinates are appropriate; and that his measure of length is then obtained by considering the interval between two points with respect to an enveloping cone of this, as in the preceding work, where $x^2+y^2+z^2=0$ is the equation of the cone formed by the lines drawn from $(0, 0, 0, 1)$ to touch the quadric $x^2+y^2+z^2=t^2$. The intermediate parameters λ, μ, which are convenient, but not necessary, are not available in the general case.

If in the formula for $\sin^2\frac{1}{2}\theta$, in terms of λ, μ, λ', μ', we replace λ, μ, respectively, by $-\mu^{-1}$, $-\lambda^{-1}$, and make the corresponding replacements for λ', μ', the form remains the same. This also happens in the changes by which λ and $-\mu^{-1}$ become $(A\lambda+B)/(C\lambda+D)$ and $(-A\mu^{-1}+B)/(-C\mu^{-1}+D)$, wherein A, B, C, D are arbitrary constants. This last change corresponds to a linear transformation of the coordinates x, y, z which is such that the conic $x^2+y^2+z^2=0$ remains unchanged. (See p. 169.) The former change, in terms of ξ, η, is of the form $\xi' = -4\xi/(\xi^2+\eta^2)$, $\eta' = -4\eta/(\xi^2+\eta^2)$, which has been noticed above. The expression for $\sin^2\frac{1}{2}\theta$ is thus unaltered by a transformation obtained by combining these two transformations.

Further, it is easy to compute that, if we measure the angle between two circles, of equations

$$u\xi + v\eta + w\left[1 - \tfrac{1}{4}(\xi^2+\eta^2)\right] = 0, \quad u'\xi + v'\eta + w'\left[1 - \tfrac{1}{4}(\xi^2+\eta^2)\right] = 0,$$

by taking the tangents at one of their common points, (ξ_0, η_0), with respect to the two lines whose equations are $\xi - \xi_0 \pm i(\eta - \eta_0) = 0$, as explained above, then this angle between the circles is equal to the angular interval between the lines, of the plane (x, y, z), which correspond to these circles, this last interval being taken relatively to the conic $x^2+y^2+z^2=0$. That this must be so is obvious geometrically, as in the preceding section.

And, it may be verified, by the formulae $X=\xi[1-\frac{1}{4}(\xi^2+\eta^2)]^{-1}$, $Y=\eta[1-\frac{1}{4}(\xi^2+\eta^2)]^{-1}$, that the integral introduced above (p. 187), to measure the extent of a region, becomes, in terms of ξ, η,

$$\iint\frac{d\xi\,d\eta}{[1+\frac{1}{4}(\xi^2+\eta^2)]^2}.$$

This is unaltered by the substitutions

$$\xi'=-4\xi/(\xi^2+\eta^2),\quad \eta'=-4\eta/(\xi^2+\eta^2).$$

When applied to a region which does not lie wholly within the circle $\xi^2+\eta^2=4$, it is to be taken only over that part of the region which does lie within this circle.

The case when the equation of the quadric surface is of the form $z^2-x^2-y^2=t^2$ is similar to the preceding. It is convenient, however, in this case, to make a substitution of the form

$$x=\lambda+\mu,\quad y=1-\lambda\mu,\quad z=1+\lambda\mu,\quad t=-i(\lambda-\mu);$$

if we take $\lambda=\frac{1}{2}(\xi+i\eta)$, $\mu=\frac{1}{2}(\xi-i\eta)$, this gives $\xi=2x/(y+z)$, $\eta=2t/(y+z)$, and $x=\xi$, $y=1-\frac{1}{4}(\xi^2+\eta^2)$, $z=1+\frac{1}{4}(\xi^2+\eta^2)$, $t=\eta$.

By these formulae, any point of the original plane (x, y, z), with the associated positive value of t, is made to correspond to a point of the plane in which $(\xi, \eta, 2)$ are coordinates, only the points of this latter plane for which η is positive being considered. The separating line $\eta=0$ plays, however, a different part from that played by the circle $\xi^2+\eta^2=4$ in the former case: the line $\eta=0$ consists of points each corresponding only to one point of the quadric, and is a natural boundary; the circle $\xi^2+\eta^2=4$ was generated as a locus of pairs of points, and was a conventional boundary, convenient but not unique. Further, the formulae give $z^2-x^2-y^2=\eta^2$; thus points of the original plane (x, y, z) which are outside the conic $z^2-x^2-y^2=0$, as they would correspond to a negative value of η^2, are not represented by real points of the plane $(\xi, \eta, 2)$; the curves of the plane $(\xi, \eta, 2)$ corresponding to two lines of the plane (x, y, z), which do not intersect within the conic $z^2-x^2-y^2=0$, will be curves with no real intersection. In fact a line whose equation is $ux+vy+wz=0$ is represented in the plane $(\xi, \eta, 2)$ by the locus whose equation is

$$u\xi+v[1-\tfrac{1}{4}(\xi^2+\eta^2)]+w[1+\tfrac{1}{4}(\xi^2+\eta^2)]=0;$$

this is a circle whose centre is on the line $\eta=0$, of which, as we have said, we consider only the points for which η is positive. All such circles arise, if all lines of the original plane be considered, and conversely. When two such circles intersect in two points, only one will be such that η is positive; this will correspond to an intersection of two lines, in the original plane, at a point interior to the conic $z^2-x^2-y^2=0$; when two such circles meet (and therefore touch) at a point for which $\eta=0$, they correspond to lines of the original plane which meet on the absolute conic, and may, therefore, be said to be parallel. It is easy to see that, through an arbitrary point, of the plane $(\xi, \eta, 2)$, for which η is positive, there can be drawn two circles, with centres on the line $\eta = 0$, each of which shall touch (on $\eta = 0$) a given circle whose centre is on $\eta = 0$. Particular (degenerate) circles of the system are the lines, of equations of the form $\xi =$ constant, which are at right angles to the line $\eta = 0$; these correspond to the lines of the original plane which meet at the point $(0, 1, -1)$ of the conic $z^2 - x^2 - y^2 = 0$. It is easy to compute that the angle between any two circles of the system, estimated as before by considering the tangents at the intersection, (ξ_0, η_0), of the circles, with respect to the two lines

$$\xi - \xi_0 \pm i(\eta - \eta_0) = 0,$$

is equal to the angular interval between the lines of the original plane which they represent, estimated with respect to the conic $z^2 - x^2 - y^2 = 0$. For the case of this conic, instead of the original interval, θ, between two points, we introduced an interval σ such that $\theta = i\sigma$. It can be shewn that, for the plane $(\xi, \eta, 2)$, this is such that

$$\sinh^2 \tfrac{1}{2}\sigma = \frac{(\lambda' - \lambda)(\mu' - \mu)}{-(\lambda - \mu)(\lambda' - \mu')}, \quad = \frac{(\xi' - \xi)^2 + (\eta' - \eta)^2}{4\eta\eta'},$$

becoming infinite when one of the points is on $\eta = 0$. When $\xi' = \xi + d\xi$, $\eta' = \eta + d\eta$, this gives [Add.]

$$d\sigma = \frac{(d\xi^2 + d\eta^2)^{\frac{1}{2}}}{\eta};$$

and, by the ordinary methods of the Calculus of Variations, it will be found that the curve for which the integral

$$\int (d\xi^2 + d\eta^2)^{\frac{1}{2}}/\eta,$$

taken between two fixed points, has a stationary value, is the circle through these points whose centre is on the line $\eta = 0$. We can interpret the interval σ, between two points P, P', by drawing, through these, the circle whose centre is on $\eta = 0$, and considering the points P, P' with respect to the two points, say M and N, in which this circle meets the line $\eta = 0$. For the pencil which these four points subtend at any point of the circle we then have, supposing that N, P, P', M are in order upon the portion of the circle considered, for which η is positive, the equation (p. 166)

$$(P, P'; M, N) = e^{-\sigma}.$$

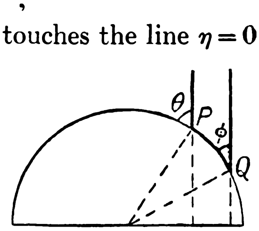
The curve, called by Lobatschewsky a circle, of centre (x', y', z'), whose equation is (above, p. 182)

$$(zz' - xx' - yy')^2 - \lambda^2(z^2 - x^2 - y^2) = 0,$$

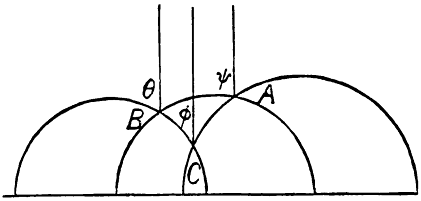
where λ is supposed real and positive, is represented, in the part of the $(\xi, \eta, 2)$ plane for which η is positive, by the circle whose equation is

$$(\xi - \xi')^2 + (\eta - \lambda)^2 = \lambda^2 - \eta'^2;$$

this circle has its centre at $\xi = \xi'$, $\eta = \lambda$. It touches the line $\eta = 0$ and becomes a horocycle if $\eta' = 0$, that is, if (x', y', z') lie on $z^2 - x^2 - y^2 = 0$.

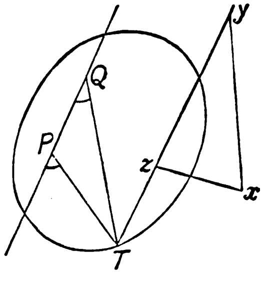


By means of any two points P, Q, a region is defined, bounded by the lines through P, Q with equations of the form $\xi = \text{constant}$, and by the circle through P, Q whose centre is on $\eta = 0$, but lying entirely outside this circle. If θ, ϕ be the angles between this circle and the two lines spoken of, respectively at P and Q, this being measured in the Euclidean way, by means of lines $\xi - \xi_0 \pm i(\eta - \eta_0) = 0$, it is easy to shew, if $\theta - \phi$ be positive, that the integral $\iint \eta^{-2}\, d\xi\, d\eta$, extended over this region, has the value $\theta - \phi$. Suppose now that we have three circles, with centres on $\eta = 0$, whose intersections in pairs are A, B, C. Any two of these points, say A and B, determine such a region as we have just considered, which we may denote momentarily by (A, B). The points A, B, C determine a triangle, whereof the joins are arcs of these circles; and, to limit ourselves to one case, this triangle may be supposed to be obtained by the addition of the two regions (B, C) and (C, A) and the subsequent subtraction of the region (B, A). With appropriate angles θ, ϕ, ψ (explained by the annexed diagram), the integral $\iint \eta^{-2} d\xi d\eta$, taken over the triangle, is then equal to



$$[\theta - \phi] + [(\pi - C + \phi) - (A + \psi)] - [(B + \theta) - \psi]$$

which is $\pi - A - B - C$, where A, B, C are the measures of the angles of the triangle. We have, above (p. 180), given a proof that this expression is necessarily positive.



The forms for x, y, z in terms of ξ, η, suggest, putting $X = x/z$, $Y = y/z$, that we consider the transformation

$$X = \xi[1 + \tfrac{1}{4}(\xi^2 + \eta^2)]^{-1},$$
$$Y = [1 - \tfrac{1}{4}(\xi^2 + \eta^2)]\,[1 + \tfrac{1}{4}(\xi^2 + \eta^2)]^{-1};$$

it is found that, then, the above integral, $\iint \eta^{-2} d\xi d\eta$, becomes

$$\iint (1 - X^2 - Y^2)^{-\frac{3}{2}}\, dX dY.$$

Thus we infer that if, in the original plane (x, y, z), the point

$(0, 1, -1)$ be T, and P, Q be two points of any line, interior to the absolute conic, so that TPQ is a triangle for which the angular interval between TP and TQ is zero, then this integral, extended over the triangle TPQ, is equal to the difference of the angular intervals between PQ and, respectively, PT and QT.

Comparison of the two cases considered. The distinction between the two cases considered above, of an imaginary conic of reference, and a real conic, has arisen by respecting the distinction between real and imaginary points. If, in the former case, we put $t_1 = -it$, and, in the latter case, put $z_1 = -iz$, as well as λ', μ' in place of λ, μ, the formulae are

$$x = \lambda + \mu, \quad y = -i(\lambda - \mu), \quad z = 1 - \lambda\mu, \qquad t_1 = -i(1 + \lambda\mu),$$
$$x = \lambda' + \mu', \quad y = 1 - \lambda'\mu', \quad z_1 = -i(1 + \lambda'\mu'), \quad t = -i(\lambda' - \mu'),$$

and the equations of the quadric surface, in these two cases, are $x^2 + y^2 + z^2 + t_1^2 = 0$ and $x^2 + y^2 + z_1^2 + t^2 = 0$, respectively. If we now replace z_1, t_1, respectively, by z and t, the comparison of the formulae leads to

$$\lambda' = -i\frac{1+\lambda}{1-\lambda}, \quad \mu' = i\frac{1-\mu}{1+\mu}.$$

Corresponding to the twenty-four orders in which the four coordinates x, y, z, t may be taken, there follow twenty-four such ways in which we may replace x, y, z, t by functions of two parameters λ, μ, so as to satisfy, identically, the equation of the quadric surface. These twenty-four sets of formulae can all be obtained from any one of them by replacing λ and μ by proper linear (fractional) functions, respectively of λ and μ, or of μ and λ. It is not difficult to see that these twenty-four pairs of replacements are combinations of the three pairs

$$(\alpha),\ \lambda' = \lambda^{-1},\ \mu' = -\mu; \quad (\beta),\ \lambda' = i\mu,\ \mu' = -i\lambda;$$
$$(\gamma),\ \lambda' = (1-\mu)(1+\mu)^{-1}, \quad \mu' = (1-\lambda)(1+\lambda)^{-1};$$

for instance the replacement above is $\alpha\beta\gamma$, obtained by first carrying out γ, then β, and then α. Neglecting the distinction between real and imaginary, we thus have, by putting $\lambda = \frac{1}{2}(\xi + i\eta)$, $\mu = \frac{1}{2}(\xi - i\eta)$, twenty-four such representations of the original plane (x, y, z), upon a plane (ξ, η).

Examples of the preceding considerations. *Ex.* 1. *Delambre's formulae in spherical trigonometry.* Let the absolute conic, which we suppose to be an imaginary conic, when referred to three real points X, Y, Z, have the equation

$$ax^2 + 2fyz + \ldots = 0,$$

containing six terms, of which the coefficients, $a, f, \ldots$, are real. No one of a, b, c is zero, and no one of $bc - f^2$, $ca - g^2$, $ab - h^2$, for the (imaginary) conic does not contain any of the points X, Y, Z, nor touch any of the lines YZ, ZX, XY. As usual, let $A = bc - f^2$, and $F = gh - af$, etc., and $\Delta = abc + 2fgh - af^2 - bg^2 - ch^2$. The left side of the equation being

$$a\left(x + \frac{h}{a}y + \frac{g}{a}z\right)^2 + \frac{C}{a}\left(y - \frac{F}{C}z\right)^2 + \frac{\Delta}{C}z^2,$$

it follows that a, C, Δ, and, therefore, similarly, all of b, c, A, B, may be taken to be positive (and not zero). We can then define intervals, YZ, ZX, XY, which we denote, respectively, by α, β, γ, and also angular intervals between the pairs of these lines, which we denote by α', β', γ', the first being that between XY and XZ, and so on, by the equations (following from pp. 175, 176)

$$\cos\alpha = \frac{f}{(bc)^{\frac{1}{2}}}, \quad \cos\beta = \frac{g}{(ca)^{\frac{1}{2}}}, \quad \cos\gamma = \frac{h}{(ab)^{\frac{1}{2}}},$$

$$\sin\alpha = \left(\frac{A}{bc}\right)^{\frac{1}{2}}, \quad \sin\beta = \left(\frac{B}{ca}\right)^{\frac{1}{2}}, \quad \sin\gamma = \left(\frac{C}{ab}\right)^{\frac{1}{2}},$$

$$\cos\alpha' = \frac{-F}{(BC)^{\frac{1}{2}}}, \quad \cos\beta' = \frac{-G}{(CA)^{\frac{1}{2}}}, \quad \cos\gamma' = \frac{-H}{(AB)^{\frac{1}{2}}},$$

$$\sin\alpha' = \left(\frac{a\Delta}{BC}\right)^{\frac{1}{2}}, \quad \sin\beta' = \left(\frac{b\Delta}{CA}\right)^{\frac{1}{2}}, \quad \sin\gamma' = \left(\frac{c\Delta}{AB}\right)^{\frac{1}{2}};$$

and it is then easy to see, comparing the relations previously obtained (above, p. 177), that these belong to a triangle of which X, Y, Z are the vertices. It is understood that, for example, $(bc)^{\frac{1}{2}}$ means $b^{\frac{1}{2}} . c^{\frac{1}{2}}$, both the factors being real, and so in each case. The signs of the square roots are to be determined consistently with the formulae referred to.

Now, if ϵ be $+1$ or -1, and σ be $+1$ or -1, we have, identically,

$$\frac{A\left[(BC)^{\frac{1}{2}} + \epsilon F\right]}{\Delta\left[(bc)^{\frac{1}{2}} - \sigma f\right]} = \frac{a\left[(bc)^{\frac{1}{2}} + \sigma f\right]}{(BC)^{\frac{1}{2}} - \epsilon F};$$

hence, as $AF = GH - f\Delta$, or directly, we see that the function

$$\left\{1 + \epsilon\frac{G}{(CA)^{\frac{1}{2}}}\frac{H}{(AB)^{\frac{1}{2}}} - \sigma\epsilon\left(1 - \frac{G^2}{CA}\right)^{\frac{1}{2}}\left(1 - \frac{H^2}{AB}\right)^{\frac{1}{2}}\right\} \div \left\{1 + \epsilon\frac{F}{(BC)^{\frac{1}{2}}}\right\}$$

is equal to the function obtained from this by replacing A, B, C, F, G, H, respectively, by a, b, c, f, g, h, and interchanging ϵ and σ. Wherefore

$$\{1 + \epsilon\cos\beta'\cos\gamma' - \sigma\epsilon\sin\beta'\sin\gamma'\} \div \{1 - \epsilon\cos\alpha'\}$$

is equal to

$$\{1 + \sigma\cos\beta\cos\gamma - \sigma\epsilon\sin\beta\sin\gamma\} \div \{1 + \sigma\cos\alpha\}.$$

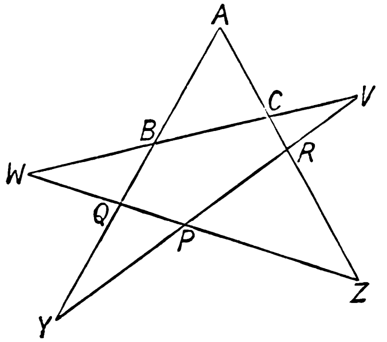
For instance, when $\epsilon = \sigma = 1$, we have

$$\left\{\frac{\cos\frac{1}{2}(\beta'+\gamma')}{\sin\frac{1}{2}\alpha'}\right\}^2 = \left\{\frac{\cos\frac{1}{2}(\beta+\gamma)}{\cos\frac{1}{2}\alpha}\right\}^2,$$

and similarly in the other cases.

Ex. 2. *Napier's analogies.* Let A, B, C be a triangle, in which AB, AC are conjugate lines, in regard to an imaginary conic of reference, so that the angular interval BAC is $\frac{1}{2}\pi$. Let the polar of B meet AB, AC, BC, respectively, in Y, R and V, and the polar of C meet AC, AB, BC, respectively, in Z, Q and W, while these polars meet in P, which is thus the pole of BC.

It can then be shewn that, as at A, the pairs of lines meeting in Y, Z, V, W are, in each of these four cases, conjugate to one another; and that, in the pentagon $PRCBQ$, each vertex is the pole of the opposite side.



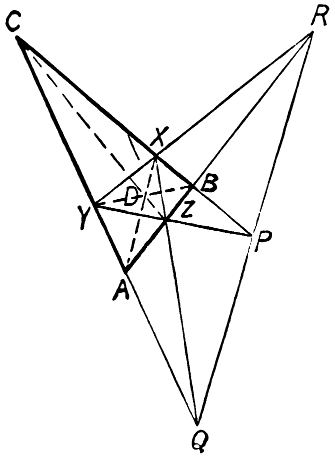
Each of the four triangles CRV, BQW, PQY, PRZ has its elements, three segments and three angles, expressible in a simple way in terms of those of the original triangle A, B, C. Obtain these expressions. Hence shew, in particular, that the relation $\sin RV = \sin CR \sin (VCR)$, which holds for the triangle CRV (see above, p. 176), involves, for the triangle ABC, the relation

$$\cos B = \cos b \sin C;$$

similarly, shew that the relation $\sin BW = \sin BQ \sin (BQW)$ involves, for ABC, the relation

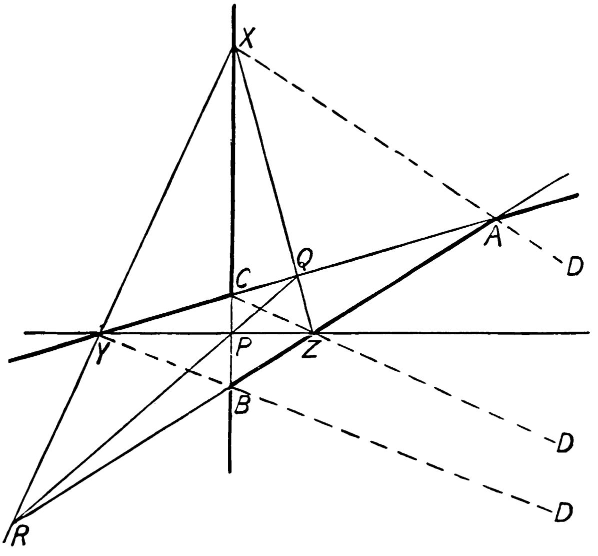
$$\cos a = \cos b \cos c;$$

and so on. (John Napier, *Mirifici logarithmorum canonis descriptio*, Edinburgh, 1614, *Lib.* ii, *Cap.* iv. Cf. Gauss, *Ges. Werke*, iii, p. 481.) [Add.]



Ex. 3. *A particular triangle.* Let X, Y, Z be a self-polar triad, of real points, in regard to the imaginary conic $x^2 + y^2 + z^2 = 0$. Let any line, PQR, meet YZ, ZX, XY, respectively, in P, Q, R, the lines YQ, ZR meeting in A, the lines ZR, XP in B, and the lines XP, YQ in C. The lines XA, YB, ZC will then meet in a point, say D. If the equation of PQR be

$a^{-1}x + b^{-1}y + c^{-1}z = 0$, the coordinates of A, B, C, D will respectively be $(-a, b, c)$, $(a, -b, c)$, $(a, b, -c)$, (a, b, c). Let d be the positive quantity $(a^2 + b^2 + c^2)^{\frac{1}{2}}$. In regard to $x^2 + y^2 + z^2 = 0$, the pole of the line XP lies in that segment YZ which does not contain P; the line through B, at an angular interval with the line BXC equal to $\frac{1}{2}\pi$, thus contains a point of this segment; so that the angular interval between BXC and BAR is greater than $\frac{1}{2}\pi$. Similarly the angular interval between AYC and ABR is greater than $\frac{1}{2}\pi$, and the angular interval between CXB and CYA is greater than $\frac{1}{2}\pi$.



This is true for all positions of P, Q, R in the segments YZ, ZX, XY. We may consider two cases, that in which a, b, c are all positive, and that in which a, b are positive, but c is negative. Let the angular intervals referred to, at A, B, C, be denoted, respectively, by α', β', γ'. We then have (see above, p. 174), the equations of XP, YQ, ZR being, respectively, $b^{-1}y + c^{-1}z = 0$, $c^{-1}z + a^{-1}x = 0$, $a^{-1}x + b^{-1}y = 0$, for the case in which a, b, c are all positive,

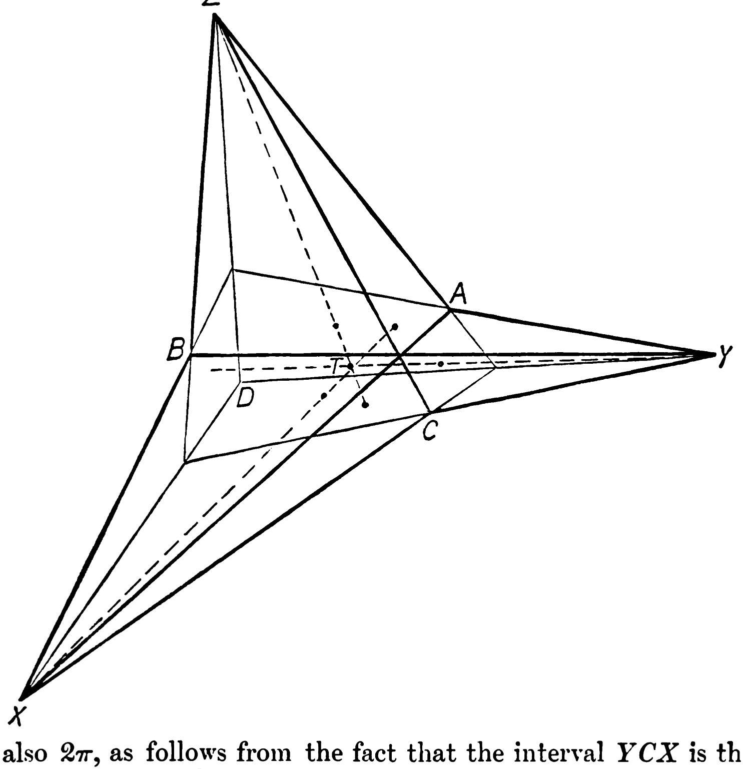
$$\cos\alpha' = -bc\,(a^2 + b^2)^{-\frac{1}{2}}(a^2 + c^2)^{-\frac{1}{2}},$$

and similar expressions, $\sin\alpha' = ad\,(a^2 + b^2)^{-\frac{1}{2}}(a^2 + c^2)^{-\frac{1}{2}}$, etc. .

From these we find $\cos\alpha' = \cos(\beta' + \gamma')$, and similar equations, and infer that $\alpha' + \beta' + \gamma' = 2\pi$. (Cf. p. 197.)

The same follows when c is negative; the values of $\cos\alpha'$, $\cos\beta'$, $\sin\gamma'$ are then changed in form, by the substitution of $-c$ for c.

If α, β, γ be the respective intervals BC, CA, AB for the segments which are appropriate to α', β', γ', in order to form a triangle, according to the definition above given (p. 172), it follows from the formulae such as $\cos\alpha\sin\beta'\sin\gamma' = \cos\alpha' + \cos\beta'\cos\gamma'$, that $\cos\alpha=(a^2-b^2-c^2).d^{-2}$, $\cos\beta=(b^2-c^2-a^2).d^{-2}$, $\cos\gamma=(c^2-a^2-b^2).d^{-2}$, while $\sin\alpha = 2a(b^2+c^2)^{\frac{1}{2}}d^{-2}$, and so on, the form for $\sin\gamma$ being $-2c(a^2+b^2)^{\frac{1}{2}}d^{-2}$ when c is negative. Of the expressions, $a^2-b^2-c^2$, $b^2-c^2-a^2$, $c^2-a^2-b^2$, two at least must be negative, as we easily prove, remarking that the sum of every two is negative; evidently, $1+\cos\alpha+\cos\beta+\cos\gamma$ is zero. It is interesting to remark also that if the angular intervals BCA, CAB, ABC be measured with reference to the two points $z=0$, $x\pm iy=0$, the sum of these intervals



is also 2π, as follows from the fact that the interval YCX is then $\frac{1}{2}\pi$ (cf. p. 167 preceding). The figure can be obtained by taking, upon the quadric $x^2+y^2+z^2=t^2$, the points $(-a, b, c, d)$, $(a, -b, c, d)$, $(a, b, -c, d)$, and $(-a, -b, -c, d)$, and projecting from the point $(0, 0, 0, 1)$ upon the plane XYZ, given by $t=0$. The planes TAB, TAC intersect in the line ATA', where A' is $(a, -b, -c, d)$, and are at an angular interval α'. Upon the quadric the four triangles

ABC, *BCD*, *CAD*, *ABD* have, every two, equal angles and segments (p. 197).

The relations for the angles and segments of the triangle *ABC* may be obtained also by remarking (see above, Chap. III, Ex. 14) that the tangents to the absolute conic from *A*, *B*, *C* meet, respectively, the lines *BC*, *CA*, *AB*, in points which lie in threes upon two lines. If we put $\xi = b^{-1}y + c^{-1}z$, $\eta = c^{-1}z + a^{-1}x$, $\zeta = a^{-1}x + b^{-1}y$, the equation of the absolute conic referred to *A*, *B*, *C* is

$$a^2(-\xi + \eta + \zeta)^2 + \ldots = 0, \text{ or } \xi^2 + 2\cos\alpha \,.\, \eta\zeta + \ldots = 0,$$

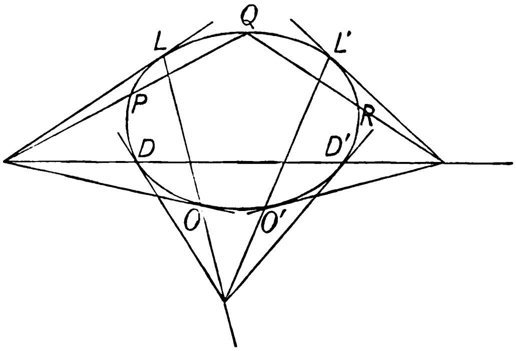
whose tangential form is $\sin^2\alpha \,.\, u^2 - 2\sin\beta\sin\gamma\cos\alpha' \,.\, vw + \ldots = 0$. The condition in question, writing l, m, n respectively for $u\sin\alpha$, $v\sin\beta$, $w\sin\gamma$, is, that there should be a line (l, m, n) for which each of the equations $m^2 + n^2 - 2mn\cos\alpha' = 0$, $n^2 + l^2 - 2nl\cos\beta' = 0$, $l^2 + m^2 - 2lm\cos\gamma' = 0$ is satisfied; which is so if $\alpha' + \beta' + \gamma' = 2\pi$.

Ex. 4. *General form of the theorem for the sum of the focal distances of a point of a conic.* If the common tangents of any conic, Ω, and the absolute conic, be taken, and *S*, *H* be a point pair through which all these tangents pass, we may prove that the intervals *PS*, *PH*, in regard to the absolute conic, for any point *P* of the conic Ω, have a constant sum (or difference). When the absolute conic is an imaginary point pair, this gives the familiar theorem of metrical geometry, for the sum (or difference) of the focal distances of a point of a conic.

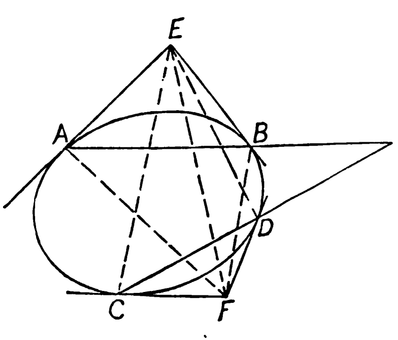
This result may be deduced from the following: Let *A*, *B*, *C*, *D* be four variable points of the absolute conic, such that *AB* passes through a fixed point, *S*, while *BC* passes through a fixed point, *M*, and *CD* through a fixed point, *H*, the points *S*, *H*, *M* being in line. Then *DA* passes through a further fixed point, *N*, of this line. And the locus of the intersection, *P*, of the lines *AB*, *CD*, is a conic, which touches the tangents to the absolute conic from the points *S* and *H*, and passes through the points of contact of this absolute conic with the tangents drawn to it from *M* and *N*.

Although an anticipation, it seems proper to mention, in connexion with this, two theorems given by Chasles, *Géom. Supér.* 1880, pp. 517, 528. If the points of the conic Ω be joined by lines to a point *O* not lying in the plane of the conic, the points of these lines are said to lie on a quadric cone; the points of the cone lying in any plane are points of a conic. If any plane be drawn through a common chord of Ω and the absolute conic, the conic in which this plane meets the cone is called a circular section of the cone. A plane through the complementary common chord of the two conics meets the cone in a circular section complementary to any one of the former system. Now let the angle between any two planes be measured by the interval between the lines in which these planes meet the plane of the absolute conic, in respect to this conic. Then we have the result that the sum (or difference) of the angles between any tangent plane of the cone and a pair of complementary circular sections, is constant. Again, if O be joined to one of the point pairs through which pass the common tangents of the conic Ω and the absolute conic, the two joining lines are called a pair of focal lines of the cone. If the angle between two lines, not lying in the plane of the absolute conic, be measured by the interval between the points in which these meet the plane of the absolute conic, taken with respect to this, we have the result that the angles which any edge of the cone makes with a pair of focal lines have a constant sum (or difference).

Ex. 5. If on a conic there be taken, arbitrarily, the points D, D', O, O', P, and then there be determined in succession, L, L', Q, R, by means of $(LO, DD') = -1$, $(L'O', DD') = -1$, $(QP, OL) = -1$, $(RQ, O'L') = -1$, so that L is the harmonic conjugate of O, on the conic, in regard to D and D', and so on, prove that (RP, DD') is equal to $(O'O, DD')^2$.



Ex. 6. If the tangents at the points C, D of a conic meet in F, and the tangents at the points A, B meet in E, prove that, measured with respect to this conic, the angular intervals AFE, EFB, CEF, FED are equal. Denoting this interval by α, and the angular interval between the lines AB and CD by β, prove that $\sin\alpha \sin\beta = \pm 1$.



Ex. 7. If PQ, PR be two tangents to a conic which touches the absolute conic in two points, the intervals PQ, PR are equal; and are the same as for any other point, P', lying on a conic through P which touches the absolute conic at the same two points as the former.

Ex. 8. Let V and W be two conics each of which touches the absolute conic in two points, not necessarily the same, and U be a conic touching each of V and W in two points; from any point, P, of U let a tangent PQ be drawn to V, and a tangent PR be drawn to W; prove that the intervals PQ, PR have a constant sum (or difference) as P varies on U. Shew that this includes the result given in Ex. 4.

Ex. 9. From a point, P, of a conic $f=0$, a tangent PT is drawn to a conic $\psi=0$, and PT meets $f=0$ again in P'. Let $f_1=\partial f/\partial x$, etc., and c_1, c_2, c_3 be arbitrary. Prove that the differential, taken along the conic $f=0$, at P, which is expressed by

$$\begin{vmatrix} dx, & dy, & dz \\ x, & y, & z \\ c_1, & c_2, & c_3 \end{vmatrix} \div (c_1 f_1 + c_2 f_2 + c_3 f_3)(\psi)^{\frac{1}{2}},$$

has the same value as the corresponding differential at P'.

The conics being in general relation, the form of the integral shews that there is no loss of generality in supposing $\psi=\xi^2+\eta^2-1$, $f=a\xi^2+b\eta^2-1$. Let $F(\xi)$ denote what f becomes by putting $\eta=\operatorname{cosec}\alpha\,.\,(1-\xi\cos\alpha)$, and $F'(\xi)=\partial F/\partial\xi$; by this substitution we have $\partial\eta/\partial\alpha=\operatorname{cosec}^2\alpha\,.\,(\xi-\cos\alpha)=\pm\operatorname{cosec}\alpha\,.\,\psi^{\frac{1}{2}}$. From $F(\xi)=0$, the integral $-d\xi/\eta\psi^{\frac{1}{2}}$ becomes $2b\,.\,d\alpha\,.\,[F'(\xi)\,.\,\psi^{\frac{1}{2}}]^{-1}\partial\eta/\partial\alpha$, or

$$\pm 2b\,.\,d\alpha\,.\operatorname{cosec}\alpha/F'(\xi);$$

and $F'(\xi)$ has opposite signs at P and P'.

Similarly for other forms of f. (Cf. Ex. 25, p. 147.)

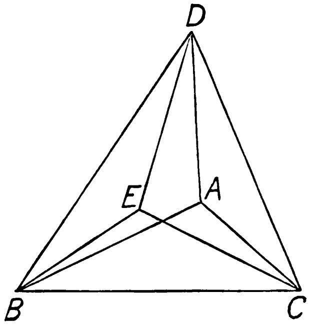
NOTE I

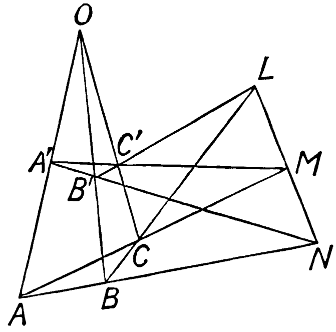
ON CERTAIN ELEMENTARY CONFIGURATIONS, AND ON THE COMPLETE FIGURE FOR PAPPUS' THEOREM

The present note deals in an incomplete way with certain configurations which present themselves naturally, especially in the consideration of the complete figure for Pascal's theorem which is considered in the succeeding note.

1. **The simpler Desargues' figure.** If A,B,C and A',B',C' be two triads of points in perspective, from a point O, and the lines BC, $B'C'$ meet in L, while CA, $C'A'$ meet in M, and AB, $A'B'$ meet in N, then L, M, N lie in line.

Regarded as a plane figure, there are here, in all, ten points, each lying on three lines, and ten lines, each containing three points; and the dual of the figure is of the same character. To express the incidences it may be denoted by $10_3 10_3$ (or simply 10_3), or by $10(\,.\,3)\,.\,10(3\,.\,)$.





Regarded as a figure in three dimensions, the figure is formed by the intersections of five planes, the ten points being the intersections of threes of these planes, and the ten lines the intersections of twos of these planes. Each point now lies in three lines and in three planes, each line contains three points and lies in two planes, and each plane contains six points and four lines. These incidences we may summarise by denoting the figure by

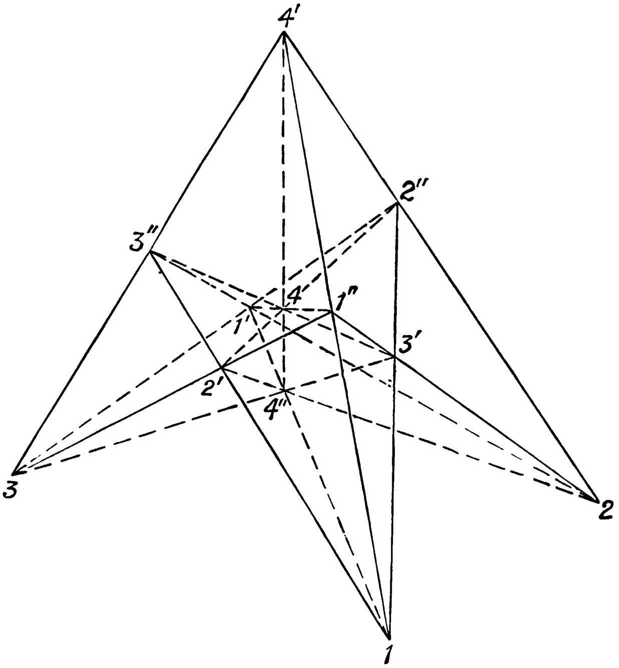
$$10(\,.\,3,3)\,.\,10(3\,.\,2)\,.\,5(6,4\,.\,).$$

The figure, however the points be taken, necessarily lies in a threefold space. Its dual, in this space, is formed by five points, the lines joining the pairs of these, and the planes containing the threes of these. But this dual figure may evidently be regarded as obtained by projection from a figure formed by taking five points in a space of four dimensions. For this figure, we shall naturally take into account, beside the lines and planes, also the threefold spaces defined by the fours of the five given points. The representation of the incidences will then be by a symbol

$$5\,(\,.\,4, 6, 4)\,.\,10\,(2\,.\,3, 3)\,.\,10\,(3, 3\,.\,2)\,.\,5\,(4, 6, 4\,.\,).$$

And the dual of this figure in four dimensions will be a figure of the same character.

2. **The figure of three desmic tetrads of points in space of three dimensions.** Two triads of points, A, B, C and A', B', C', which are in perspective, enable us to define two sets each of four planes, namely ABC, $AB'C'$, $BC'A'$, $CA'B'$ and $A'B'C'$, $A'BC$, $B'CA$, $C'AB$; these planes have the property that the sixteen lines in which any one of the first four planes meets the second four planes, lie by fours in four other planes.



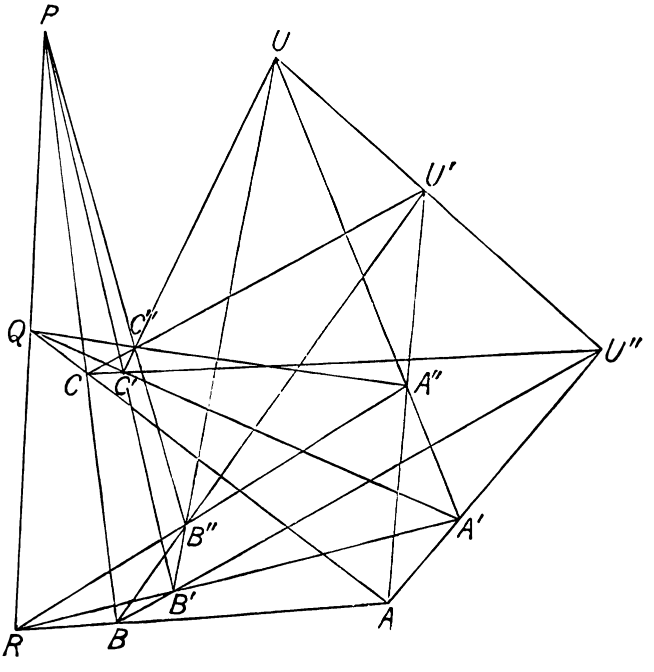
We consider the dual of this figure in three dimensions. We take six planes meeting in pairs in three lines which lie in a plane; namely the planes $234'$, $234''$; $314'$, $314''$; $124'$, $124''$; then the planes 314′, 124′ meet in a line, 14′; the intersection of this with the plane 234″ is a point, 1″; similarly the planes 314″, 124″ meet in a line, 14″; the intersection of this with the plane 234′ is a point, 1′. Let the points 2″, 2′ and 3″, 3′ be similarly defined. It can be shewn that the lines 1′1″, 2′2″, 3′3″, 4′4″ meet in a point, 4. Thus the twelve points lie in threes on sixteen lines in the following way:

11′4″, 12′3″, 12″3′, 11″4′,
23″1′, 22′4″, 23′1″, 22″4′,
31′2″, 31″2′, 33′4″, 33″4′,
41′1″, 42′2″, 43′3″, 44′4″,

and any two of the four tetrads of points 1, 2, 3, 4; 1′, 2′, 3′, 4′; 1″, 2″, 3″, 4″ are in perspective in four ways, the centres of perspective being the points of the other tetrad.

Beside the twelve points, and the sixteen lines, the figure contains twelve planes, consisting of the six from which we started, together with the three 14 2′3′2″3″, 24 3′1′3″1″, 34 1′2′1″2″, and the three 14 1′4′1″4″, 24 2′4′2″4″, 34 3′4′3″4″. The description of the complete figure is given by 12 (. 4, 6) 16 (3 . 3) 12 (6, 4 .). The dual of this figure is a figure of the same character.

3. **The figure formed from three triads of points which**



are in perspective in pairs, with centres of perspective in line. This figure, which is that used in the proof of Desargues' theorem for two triads in one plane (Vol. I, Frontispiece, and p. 7), may be described as consisting of two tetrads of points, Q, C, C', C'' and R, B, B', B'', in perspective from P, together with the six points of intersection of the corresponding joins in these tetrads, such as QC and RB, or $C'C''$ and $B'B''$, namely, the points A, A', A'', U, U', U'', which lie in threes in four lines lying in a plane. Any point of the figure may be taken, in place of P, as such a centre of perspective.

The figure may be in four dimensions, but not in higher dimensions. So considered it contains fifteen points, twenty lines and fifteen planes, namely the three planes, ABC, $A'B'C'$, $A''B''C''$, passing through the line PQR, and three similar planes through the line $UU'U''$, containing, respectively, the triads $AA'A''$, $BB'B''$, $CC'C''$, together with nine other planes, of which for instance there are three through P, namely, $PB'C'B''C''$, which contains the point U; $PB''C''BC$, which contains the point U'; and $PBCB'C'$, which contains the point U''. The figure also contains six spaces of three dimensions. One of these, for instance, contains the ten points $P, Q, R, A, B, C, A', B', C', U''$; another contains the ten points $U, U', U'', B, B', B'', C, C', C'', P$; the former of these contains two planes through the line PQR, the two planes which join the line $AA'U''$ to Q and R, and the plane $PBB'CC'$, five in all, and is, in fact, such a figure as considered above, in § 1. The whole description of the incidences of the figure is then given by the scheme

$$15\,(\,.\,4, 6, 4)\ 20\,(3\,.\,3, 3)\ 15\,(6, 4\,.\,2)\ 6\,(10, 10, 5\,.\,).$$

If this figure be projected into a plane, it becomes the dual of a generalisation of the complete figure for Pappus' theorem. We shall however obtain this by taking a section, by a plane, of the dual of this figure in four dimensions, which will appear to have great simplicity. But first we consider the complete figure of Pappus' theorem.

4. **The complete figure for Pappus' theorem.** The points A, B, C being in line, and the points A', B', C' in another line intersecting the former, the pairs of lines BC', $B'C$; CA', $C'A$ and AB', $A'B$ intersect in three points lying on a line, say k_1. This is Pappus' theorem referred to. We may however, retaining the order of A, B, C, take A', B', C' in six different orders, and so obtain in all six lines such as k_1, each containing three points of intersection. It is found however that the three lines, k, corresponding to the orders A', B', C'; B', C', A' and C', A', B' meet in a point, say G; and the three lines, k, corresponding to the orders A', C', B';

B', A', C'; C', B', A' also meet in a point, say G'. This was remarked by Steiner (*Werke*, I, pp. 451, 452). If now we omit the lines ABC, $A'B'C'$, and the points A, B, C, A', B', C', and add to

the points the two points G and G', we have a figure containing in all twenty points, each being an intersection of three lines, and containing fifteen lines (the nine lines originally arising as the joins of A, B, C with A', B', C', and the six lines k) upon each of which lie four of the points. The description of the incidences of the figure will then be 20 (. 3) 15 (4 .).

5. **The figure formed from six points in four dimensions.** Consider in four dimensions the dual of the figure described in § 3. We may construct it by the dual procedure to that before employed;

but it will be simpler to take the scheme of incidences which we can infer from that for the other figure. This will be

$$6(\,.\,5, 10, 10)\ 15(2\,.\,4, 6)\ 20(3, 3\,.\,3)\ 15(4, 6, 4\,.\,).$$

From this it can be seen at once that the figure consists of six points, the lines joining them in pairs, the planes containing threes of them, and the threefold spaces defined by fours of them.

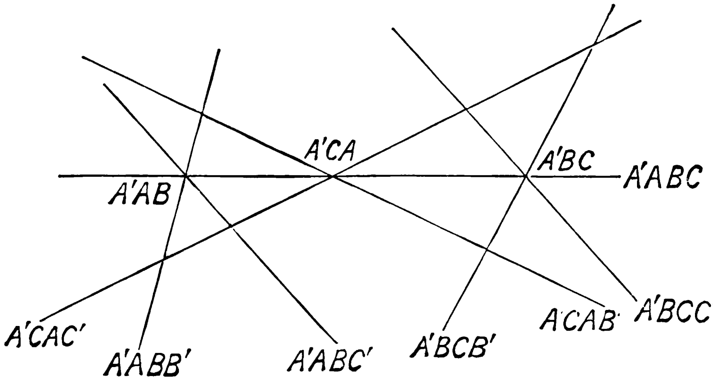
Consider now this figure, and the section of it by an arbitrary plane, ϖ. The figure being in four dimensions, a line of it will not in general have any intersection with ϖ; a plane of it will meet ϖ in a point; and a threefold space of it will meet ϖ in a line. Thus, the lines in which ϖ is met by two threefold spaces of the figure will meet in the point in which ϖ is met by the plane in which the two threefold spaces intersect; and the points in which ϖ is met by three planes which belong to the same threefold space of the figure, lie in a line, in which this threefold space meets ϖ.

Though the figure is symmetrical, we shall grasp the relations of the plane figure better, perhaps, if we choose out, from the figure in four dimensions, two planes which have no point in common, and the three spaces which contain each of these planes. Denoting the six fundamental points by A, B, C and A', B', C', we take the planes ABC and $A'B'C'$, and the six threefold spaces

$$A', A, B, C;\quad B', A, B, C;\quad C', A, B, C,$$
$$A, A', B', C';\quad B, A', B', C';\quad C, A', B', C'.$$

Save for the planes ABC and $A'B'C'$, no two of these six spaces have a plane in common.

With each of these six spaces we can now associate six other spaces—as we explain immediately. But of the thirty-six spaces so derived, each occurs four times in the enumeration. The nine different ones, together with the original six, are the whole fifteen spaces of the figure.



Take, for instance, the space A', A, B, C. Beside the plane ABC, this contains the three planes $A'BC$, $A'CA$, $A'AB$. Each of these lies in two other spaces beside $A'ABC$, namely, respectively,

	$A'BC$,	$A'CA$,	$A'AB$
lie in	$A'BCB'$,	$A'CAC'$,	$A'ABB'$
and in	$A'BCC'$,	$A'CAB'$,	$A'ABC'$.

We thus have, by section with the plane ϖ, a figure such as that occurring in Pappus' theorem, but in a generalised form. The two original triads of points of Pappus' theorem, each in line, are here replaced by triads of points which are not generally in line. The reader will easily find the specialisation of the six points sufficient to secure that they shall be.

Ex. 1. If two sets, each of n points, $A_1 \ldots A_n$ and $B_1 \ldots B_n$, in $(n-1)$ fold space, be in perspective, from a point O, there is an unique quadric $(n-2)$ fold, in regard to which any point, say A_1, of one set, is the pole of the $(n-2)$ fold containing the corresponding points, $B_2 \ldots B_n$, of the other. If C_{rs} be the intersection of the lines A_rA_s, B_rB_s, the points C_{rs} lie in a $(n-2)$ fold, which is the polar of O in regard to the quadric. Further, the figure is symmetrical, everyone of the $\frac{1}{2}(n+1)(n+2)$ points being a centre of perspective of two n-ads, and the pole of a corresponding $(n-2)$ fold, in regard to the same quadric.

Ex. 2. Shew that the figure is obtainable by projection of the points of intersection of $(n+2)$ arbitrary $(n-1)$ folds in a space of n dimensions, from an arbitrary point, T, of this. Further, that $(n+2)$ points $P_1 \ldots P_{n+2}$ can be found in this n-fold space (in ∞^{n+1} ways), such that the $\frac{1}{2}(n+1)(n+2)$ points are of symbols $P_r - P_s$ $(r, s = 1 \ldots n+2)$, where $P_1 \ldots P_{n+2}$ are the symbols of these points.

Ex. 3. Shew that the figure is also obtainable by section, with a $(n-1)$ fold, from that formed by the joins (lines, planes, etc.) of $n+2$ arbitrary points of a space of n dimensions.

Ex. 4. In Ex. 2, if the $(n-1)$ folds be $x_1 = 0, \ldots, x_{n+2} = 0$, the centre of projection, T, being such that $x_1 = x_2 = \ldots = x_{n+2}$, where $\Sigma a_r x_r = 0$, $\Sigma a_r = 0$, shew that there is polarity in regard to the cone $\Sigma a_r x_r^2 = 0$, or $\Sigma a_r u_r^2 = 0$, where $u_1, u_2, \ldots$ are such that any $(n-1)$ fold through T is $\Sigma a_r u_r x_r = 0$. Further, that the point P_m is $(h_1 \ldots h_{m-1} \sigma_m h_{m+1} \ldots h_{n+2})$, where $\Sigma a_r h_r = a_m (h_m - \sigma_m)$, and $h_1 \ldots h_{n+2}$ are arbitrary. Consider the cases $n = 2$, $n = 3$, $n = 4$.

Ex. 5. The aggregate of the points $P_1 \ldots P_{n+2}$, and the points $P_r - P_s$, is a figure, in space $[n]$, of the same kind as the original figure in $[n-1]$. [Add.]

NOTE II

ON THE *HEXAGRAMMUM MYSTICUM* OF PASCAL

If we have in a plane two triads of points, U, V, W and U', V', W', which are in perspective, the joins UU', VV', WW' meeting in a point, and the intersections of the pairs of lines, VW and $V'W'$, WU and $W'U'$, UV and $U'V'$ being in line, then the remaining intersections of the lines VW, WU, UV with the lines $V'W'$, $W'U'$, $U'V'$ are six points which lie on a conic, as we know from what we have in the text called the converse of Pascal's theorem; and, if we take these six points in any order, the triad formed by one set of alternate joins of these six points is in perspective with the triad formed by the other set of alternate joins, as we know from Pascal's theorem. The axes of perspective of these various pairs of triads are called Pascal lines; they are sixty in number. They cointersect in sets of three (or of four) in various ways, and these points of intersection lie in sets upon lines, as has gradually appeared from the work of many mathematicians, Steiner, Kirkman, Cayley, Salmon, Veronese, Cremona, and others. The proof of the properties in the plane, though interesting, is intricate. It depends upon successive applications of Desargues' theorem, which we have learnt to regard as deduced from Propositions of Incidence in three dimensions; and it is the fact that all the results which have elicited attention are such as may be obtained by projection from a figure existing in such a space; this manner of proof is much simpler than the proof in the plane. Applied by Cayley in a particular way (*Coll. Papers*, VI, pp. 129–134 (1868)), it was applied by Cremona to a figure more general than Pascal's (*Memorie d. r. Acc. d. Lincei*, I, 1877, pp. 854–874). Three distinct points of Cremona's treatment of the figure in three dimensions are, (*a*) That it depends upon a configuration of fifteen lines lying in threes in fifteen planes, of which three pass through each line, (*b*) That this configuration is deducible from a figure of six planes, forming, in Cremona's phrase, the *nocciolo* of the whole, (*c*) That when the equations of these planes are introduced, only one of the identical relations connecting these comes into consideration. It follows from the last that we may regard the six loci as being in a space of four dimensions. This procedure, which Richmond has used, leads to a very simple treatment of the whole matter, which is the more interesting because the figure in four dimensions is one which, as we shall see in a subsequent volume, is of fundamental importance. Cremona's figure of fifteen lines lying by threes in fifteen planes is an example of the (3, 3) correspondence which it is possible to set up (in various ways) between any two sets of fifteen things; this had been considered by Sylvester, in connexion with the problem of naming a function of six letters capable only of six values under permutation of the letters (Sylvester, *Coll. Papers*, I, p. 92 (1844); II, p. 265 (1861)); it is pertinent and instructive for the problem in hand to consider this. In the following note we have (1) dealt with this problem of arrangements, (2) shewn how this can be represented by figures in four, three and two dimensions, (3) pointed out the properties of the figures which lead to the classical properties of the Pascal figure, (4) explained the exact figure, relating to a cubic surface with a node, by which Cremona was led to the generalisation, (5) given some examples of the proof in the plane of the properties of Pascal's figure, and of the configurations arising from some selected portions of the figure in three dimensions, and (6) made reference to the more important original authorities. The reader may prefer to read (4) before the other sections.

(1) Consider six elements, which we denote, at present, by 1, 2, 3, 4, 5, 6. These can be arranged in three pairs, for example 12, 34, 56, wherein, in each pair, the order of the elements is indifferent, and the order of the pairs, in each such set of three pairs, is also indifferent. Such a set of three pairs, involving all the elements, is what was called by Sylvester a *syntheme*, each of the pairs being what he called a *duad*. The total number of possible duads is fifteen; this is also the total number of possible synthemes. It is possible to choose a set of five synthemes which contain, in their aggregate, all the fifteen duads. Such a set of synthemes is called a system. The total number of possible systems is six; if these be all taken, each containing five synthemes, every syntheme will occur twice, in different systems; as has been said, each duad occurs once in each system. Such an arrangement was given by Sylvester (see below). If we assign names to the systems, say P, Q, R, P', Q', R', each syntheme, as occurring in two systems, will correspond to two of these six letters. Thus every one of the fifteen pairs which can be formed by two of these six letters, say, a letter-duad, will correspond to three number-duads, chosen from the possible fifteen duads of numbers, forming a syntheme. The converse is also true; any duad of the numbers being taken, the remaining four numbers can be taken in pairs in three ways; thus any duad occurs in three synthemes, and each of these synthemes enters in two of the systems. The duad thus corresponds to three pairs of systems; or any one of the fifteen number-duads corresponds to three letter-duads, chosen from the possible duads of P, Q, R, P', Q', R'. Therefore, as any

fifteen things can be identified by naming them after the pairs which can be formed from six arbitrary symbols, we can have a (3, 3) correspondence between any two sets of fifteen things. As has been said, the importance of this for the present purpose was emphasized by Cremona (*loc. cit.* pp. 854, 866, 870). A further remark which is of use is that two synthemes which have no duad in common occur together in only one system, since two systems have only one syntheme in common. Two such synthemes thus serve to identify a system. [Add.]

Of the various possible ways of assigning the names $P, Q, \ldots, R'$ to the systems, one example is given in the following scheme, which can be read either in rows or columns.

	P	Q	R	P'	Q'	R'
P		14.25.36	16.24.35	13.26.45	12.34.56	15.23.46
Q	14.25.36		15.26.34	12.35.46	16.23.45	13.24.56
R	16.24.35	15.26.34		14.23.56	13.25.46	12.36.45
P'	13.26.45	12.35.46	14.23.56		15.24.36	16.25.34
Q'	12.34.56	16.23.45	13.25.46	15.24.36		14.26.35
R'	15.23.46	13.24.56	12.36.45	16.25.34	14.26.35	

With this table, the correspondence of the pairs of systems with the synthemes can be enumerated at once; for instance, (Q, R) is associated with (15.26.34), and (R, P') with (14.23.56). Conversely, the duads of the numbers are each associated with three duads of letters; for example, (14) with $(PQ \,.\, RP' \,.\, Q'R')$, since (14) occurs in the same syntheme in P and Q, in the same, other, syntheme in R and P', and in the same, still other, syntheme in Q' and R'. This set of three pairs of letters forms a syntheme, and the synthemes of the letters can similarly be arranged in six systems, with the names 1, 2, 3, 4, 5, 6.

We shall also denote the number-synthemes by the letters $a, b, c, d, a', b', c', d', e, l, m, n, p, q, r$, by the rule which is found by identifying the preceding scheme with the scheme subjoined:

	P	Q	R	P'	Q'	R'
P		e	d	a	b	c
Q	e		d'	a'	b'	c'
R	d	d'		l	m	n
P'	a	a'	l		r	q
Q'	b	b'	m	r		p
R'	c	c'	n	q	p	

Perhaps the easiest way to describe these notations is by the diagram given below in (2), p. 225, or, in another form, in the Frontispiece of the volume.

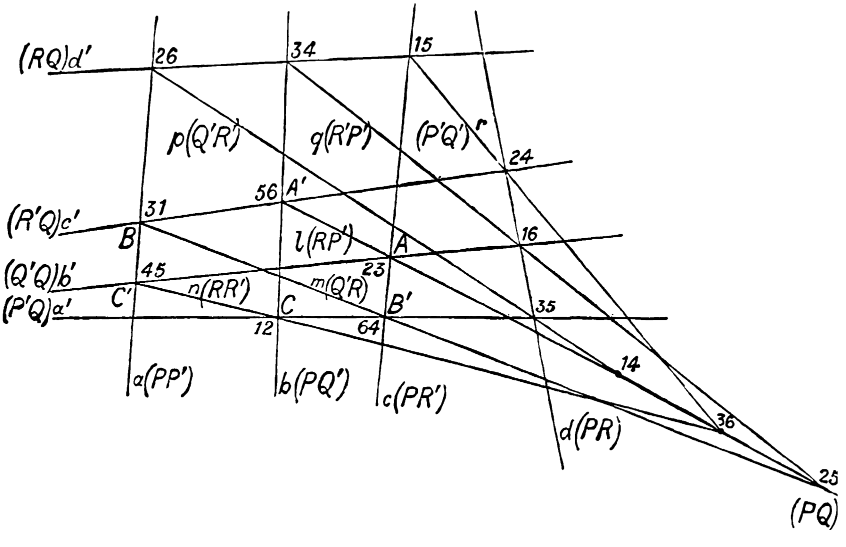
Now let us consider four of the six systems, considered as two pairs, say, for definiteness Q, R' and Q', R. The synthemes common to the two pairs, that is the syntheme common to Q and R', and the syntheme common to Q' and R, will necessarily have a duad in common. Further this aggregate of two letter-duads, Q, R' and Q', R, may be identified by the common number-duad of the two synthemes, taken with one duad from the first syntheme, and one duad from the second syntheme, so chosen as to have one of its numbers the same as one of the numbers of its companion duad from the first syntheme. In the particular case chosen, Q and R' have common the syntheme 13 . 24 . 56, while Q' and R have common the syntheme 13 . 25 . 46. These synthemes have the duad 13 common; we say that the combination $QR' . Q'R$ may be identified by the symbol 13 . 24 . 25, or by 13 . 42 . 46, or by 13 . 56 . 52, or by 13 . 65 . 64. All this is quite easy to see. For first, two synthemes, that have two duads identical, are themselves identical; and second, two synthemes that have no duad in common both occur in the same system, and nowhere else, as we have remarked. The two synthemes chosen, the former common to one pair of systems, the latter common to another pair, must therefore have a duad common. Using $\alpha, \beta, \gamma, \alpha', \beta', \gamma'$ to denote the numbers $1, 2, \ldots, 6$, in some order, let these synthemes be $\beta'\gamma' . \alpha\beta . \gamma\alpha'$ and $\beta'\gamma' . \alpha\gamma . \beta\alpha'$. From these we can form the symbol $\beta'\gamma' . \alpha\beta . \alpha\gamma$ (as well as three others). Conversely, if this be given, the formation of the two synthemes having $\beta'\gamma'$ in common and containing, respectively, also $\alpha\beta$ and $\alpha\gamma$, is without ambiguity; so that the symbol identifies the two pairs of systems from which it was formed. Such a symbol, or any one of the other three symbols which identify the same pair of systems, we speak of as defining a T-element. The total number of T-elements is thus $\frac{1}{4} . 15 . 4 . 3$, or forty-five. Now take the six systems in any particular order, say, $PQ'RP'QR'$, where it is to be understood that this is considered equivalent with its reverse order, $R'QP'RQ'P$, and may be named beginning with any one of its letters, as for instance by $RP'QR'PQ'$; thus the total number of orders is $(6!)/2 . 6$, or sixty. Then take, with each pair of letters in this order, that pair which is not contiguous with it on either side; thus, with QR' take $Q'R$, with RP' take $R'P$, and with $P'Q$ take PQ'. For each of these three sets of two pairs, form the corresponding T-element. It will be found that these can be represented by symbols of the respective forms $\beta'\gamma' . \alpha\beta . \alpha\gamma$, $\gamma'\alpha' . \alpha\beta . \alpha\gamma$, $\alpha'\beta' . \alpha\beta . \alpha\gamma$. For instance, with the order $PQ'RP'QR'$, the two pairs $QR', Q'R$ give a symbol 13 . 64 . 65, the two pairs $RP', R'P$ give a symbol 23 . 64 . 65, and the two pairs

PQ', $P'Q$ give a symbol $12 . 64 . 65$. And these three symbols have in common the duads $64 . 65$, which have the number 6 in common. Conversely consider the aggregate of two duads $\alpha\beta . \alpha\gamma$, having the number α in common; we shew that this leads to a particular order of the symbols $P, Q, \ldots, R'$. This aggregate belongs to only three symbols of T-elements, namely $\beta'\gamma' . \alpha\beta . \alpha\gamma$, $\gamma'\alpha' . \alpha\beta . \alpha\gamma$ and $\alpha'\beta' . \alpha\beta . \alpha\gamma$. Of these the first arises by combining the two synthemes $\beta'\gamma' . \alpha\beta . \gamma\alpha'$, $\beta'\gamma' . \alpha\gamma . \beta\alpha'$, and there is no ambiguity as to these; for the moment let these synthemes be denoted, respectively, by p and p'. The symbol $\gamma'\alpha' . \alpha\beta . \alpha\gamma$ similarly arises from the two synthemes $\gamma'\alpha' . \alpha\beta . \gamma\beta'$, $\gamma'\alpha' . \alpha\gamma . \beta\beta'$, which we denote, respectively, by q and q'. Lastly, the symbol $\alpha'\beta' . \alpha\beta . \alpha\gamma$ arises from the two synthemes $\alpha'\beta' . \alpha\beta . \gamma\gamma'$, $\alpha'\beta' . \alpha\gamma . \beta\gamma'$, which we denote, respectively, by r and r'. We have, however, remarked that two synthemes, which have no duad in common, determine a particular system. Thus the synthemes q and r', namely $\gamma'\alpha' . \alpha\beta . \gamma\beta'$ and $\alpha'\beta' . \alpha\gamma . \beta\gamma'$, determine one of the systems $P, Q, \ldots, R'$; this system we may, for a moment, denote by (qr'). It is easy to see that the whole of the six systems are thus determined by such pairs of the six synthemes, which we may arrange in the order $pq' . q'r . rp' . p'q . qr' . r'p$, there being no other pairs of these synthemes which have no duad in common. So arranged, every consecutive pair of these systems determines, with the pair which is not contiguous with it on either side, a T-element. For instance, if we take the systems pq', $q'r$, $p'q$, qr', the first pair have common the syntheme q' or $\gamma'\alpha' . \alpha\gamma . \beta\beta'$, the second pair have common the syntheme q or $\gamma'\alpha' . \alpha\beta . \gamma\beta'$, and these together determine the T-element represented by $\gamma'\alpha' . \alpha\beta . \alpha\gamma$.

We see then that the operation which we carry out when, in Pascal's figure, we form the Pascal line for six points $P, Q, \ldots, R'$ of a conic, taken in a particular order, can be carried out exactly with the symbols, the systems of synthemes taking the places of the points of the conic. The join of any two of the six Pascal points is replaced by one of the fifteen number-synthemes; the intersection of two of these joins is replaced by a T-element, represented by such a symbol as $\beta'\gamma' . \alpha\beta . \alpha\gamma$; and the Pascal line containing three of these intersections is replaced by a symbol, such as $\alpha\beta . \alpha\gamma$, consisting of two duads having a number (α) in common. We have seen that any such symbol leads back to a particular order of the six letters $P, Q, \ldots, R'$. It is in accordance with this, that the number of possible symbols $\alpha\beta . \alpha\gamma$ is $6 . 10$ or sixty. It is at once seen in the Pascal figure that through the intersection of two opposite sides of the hexagon there pass four Pascal lines, the two pairs QR', $Q'R$, for example, being non-contiguous in each of the four hexagons $PQ'RP'QR'$, $PQ'RP'R'Q$, $PRQ'P'QR'$, $PRQ'P'R'Q$; this corresponds to the fact remarked that the T-element $\beta'\gamma' . \alpha\beta . \alpha\gamma$ is capable also of the representations $\beta'\gamma'.\gamma\alpha'.\alpha\gamma$, $\beta'\gamma'.\alpha\beta.\beta\alpha'$, $\beta'\gamma'.\alpha'\gamma.\alpha'\beta$. The total intersections of the fifteen sides in the Pascal hexagon, in number $\frac{1}{2}15.14$ or 105, consist in fact of ten intersections at each of the six vertices $P, Q, \ldots, R'$, together with an intersection at each of forty-five T-points.

(2) We now consider a geometrical interpretation of the relations we have described. First, in four dimensions, we can set up a figure of fifteen points lying in threes on fifteen lines, of which three pass through each of the points, beginning in various ways. If we take six general points, say F, G, H, R, S, T, of which the symbols will be subject to one relation, which we write in the form $F+G+H+R+S+T=0$, there will be fifteen points of symbols each the sum of two of $F, G, \ldots, T$, and, for instance, the points $F+G$, $H+R$, $S+T$ will be in line; of such lines there will be fifteen. Three of these will pass through each point; for instance, the lines $(F+G, H+R, S+T)$, $(F+G, H+S, R+T)$, $(F+G, H+T, R+S)$ pass through the point $F+G$. Denoting the six points $F, G, \ldots, T$ by 1, 2, ..., 6, each duad, such as 12, may be supposed to represent one of these points, and each syntheme, such as 12.34.56, to represent one of these lines. Or, we may take four arbitrary lines of general position, say, a, b, c, d; every three of these will have, in four dimensions, a single transversal; let the transversal of a, b, c be denoted by d', that of b, c, d by a', and so on, the four transversals being a', b', c', d'. It is then easy to shew that the line, say n, joining the points (a, b'), (a', b) intersects the line, say r, joining the points (c, d'), (c', d); so, the line joining the points (c, a'), (c', a), say m, meets the line joining the points (b, d'), (b', d), say q; and likewise the line joining the points (b, c'), (b', c), say l, meets the line joining the points (a, d'), (a', d), say p. And further that these three points of intersection are in a line, say e. Six fundamental points $F, G, \ldots, T$, from which these statements can be justified, are obtained by regarding the points (b', c), (c', a), (a', b), (b, c'), (c, a'), (a, b') as being, respectively, the points 23, 31, 12, 56, 64, 45. These six points may in fact be taken arbitrarily to obtain such a figure; denoting them, respectively, by A, B, C, A', B', C', the six consecutive joins of the hexagon $BC'AB'CA'$ are the lines a, b', c, a', b, c'; the lines d, d' are then, respectively, the common transversals of a', b', c', and of a, b, c, and the figure can be completed. The fundamental points are then $F=\frac{1}{2}(B+C-A)$, $R=\frac{1}{2}(B'+C'-A')$, etc. The various relations and notations are represented by the diagram annexed; the fundamental importance of the figure justifies this lengthy description. We shall for clearness denote this figure by Ω. It depends on twenty-four constants. We do not now consider the dually corresponding figure in four dimensions. We consider however the figure obtained by projecting the figure Ω into space of

three dimensions, which we denote by S. It can be constructed, as in the diagram annexed, or as in the diagram given in the Frontispiece, by taking four points which lie in a plane, those denoted by 23, 35, 56, 62; then drawing, through 23, the two arbitrary lines b' and c, and, through 56, the two arbitrary lines b and c'; then, from 35, drawing the line d to meet b' and c', and the line a' to meet b and c, and also, from 62, drawing the line d' to meet b and c, and the line a to meet b' and c'. The remaining incidences of the figure then follow necessarily[1], as the reader may easily see. This figure depends on nineteen constants; so that there are ∞^1 possible figures when the six fundamental points, from which it can be constructed, are given. The figure in three dimensions which is the dually corresponding to S will be denoted by S'; it is the figure mainly considered by Cremona (*loc. cit.*), containing fifteen lines lying in threes in fifteen planes, of which three pass through each line. Finally we consider the figure obtained by projecting the figure S' on to a plane, which we denote by ϖ; it is in this figure, ϖ, that the various incidences which arise from Pascal's hexagram are found, and for a figure more general than Pascal's. This plane figure consists of two quadrilaterals, say $ABCD$, $A'B'C'D'$, the intersections of corresponding sides being X of AB and $A'B'$, Y of BC and $B'C'$, Z of CD and $C'D'$ and U of DA and $D'A'$, which are such that the points of intersection, O of XZ and YU, P of AC' and $A'C$ and



---

[1] A proof of this is given, *Proc. Roy. Soc.* LXXXIV, 1911, p. 599.

Q of BD' and $B'D$, are in line. This figure depends on fifteen constants; so that there are ∞^3 possible figures when the six fundamental points, from which it can be constructed, are given.

The correspondence between the figures and the Pascal configuration can now be described precisely, as in the preceding section. If we take a particular order of the systems, say $PQ'RP'QR'$, and consider either the figure Ω, or the figure S, it is clear that the lines $Q'R$, QR', or m and c', are those which join the points 64, 65 to the point 13, the lines RP', $R'P$, or l and c, are those which join the points 65, 64 to the point 23, and the lines $P'Q$, PQ', or a' and b, are those which join the points 64, 65 to the point 12. Thus we have three T-planes passing through the line 64 . 65. In the figure S', dually corresponding to S, we have correspondingly three T-points lying on a line. Projection of S' into the figure ϖ gives then three T-points lying on a line, as in the Pascal configuration. More particularly, each of the systems P, Q', ... consists of five lines, both in the figure S and the figure S'; the systems Q, R' have a definite line in common, as also have the systems Q', R. In order to project S' into ϖ, we must take a definite centre of projection, say O; from this, a transversal can be drawn to these two lines QR' and $Q'R$; it is the intersection of this with the plane of ϖ which gives the T-point. The consecutive lines obtained by the projections of the lines PQ', $Q'R$, RP', $P'Q$, QR', $R'P$ on to the plane of ϖ, similarly give six lines forming a hexagon; the three points of intersection of the pairs of opposite sides of this lie on a line. The vertices of the hexagon in the plane of ϖ therefore lie on a conic. If we take another order of the systems, for instance, $PQ'RP'R'Q$, and project from the same point O, we obtain another hexagon, whose vertices lie on a conic, with its Pascal line. This hexagon will not coincide with the former; in the particular instance, we shall have, instead of the vertex obtained by the intersection of the lines which are the projections of RP' and $P'Q$, the vertex obtained by the projections of the lines RP' and $P'R'$; and so on. As we shew in section (4) below, it is however possible so to specialise the figure as to obtain always the same conic in the plane ϖ.

(3) Dealing now with the figure Ω, or S, we have the fifteen points such as 12, which we may call the Cremona points; we also have the fifteen lines, each containing three of these points whose symbols form a syntheme, such as 12 . 34 . 56. Any two of the Cremona points whose symbols have a number in common may be joined by a line; for instance the line joining the points 12 and 13 is such a line. These lines we call the Pascal lines; their number is sixty. A plane containing three Cremona points whose duad symbols are formed with five of the six numbers, as for instance the plane 23 . 64 . 65, is called a T-plane; it contains four Pascal lines (64 . 65;

46 . 41 ; 56 . 51 ; 14 . 15), and three such planes pass through any Pascal line. In all there are forty-five such planes. There are however also sets of four Pascal lines which meet in a point. For instance the points 64, 61 are those which, in terms of the six fundamental points F, G, H, R, S, T, have the symbols $T+R$, $T+F$. The line joining these contains the point $R-F$; this we denote by [14]. Evidently there are fifteen such points, which we call Plücker points; and, for instance, through the point [14], there pass the four Pascal lines 21 . 24, 31 . 34, 51 . 54 and 61 . 64. The Plücker points lie in threes upon twenty lines; for instance the points [23], [31], [12], whose symbols are, respectively, $G-H$, $H-F$, $F-G$, lie upon a line. Such a line is called a *g*-line, or a Cayley-Salmon line. The Plücker points also lie in sixes upon fifteen planes. For instance the points [63], [64], [65], [45], [53], [34] lie on a plane. Such a plane is called an *I*-plane, or a Salmon plane. The Pascal lines lie in threes in planes, in two distinct ways. A plane containing three Cremona points whose duad symbols contain only three of the numbers, for instance the plane of the points 23, 31, 12, evidently contains the three Pascal lines 12 . 13, 23 . 21, 31 . 32. Such a plane is called a *G*-plane, or a Steiner plane; the total number of such planes is twenty. Again a plane containing three Cremona points whose duad symbols all contain one number in common, for instance the plane of the points 41, 42, 43, evidently contains the three Pascal lines 42 . 43, 43 . 41, 41 . 42. Such a plane is called a *K*-plane, or a Kirkman plane; the total number of such planes is sixty. Lastly, it is necessary to refer to fifteen lines, each joining a Cremona point to the Plücker point whose symbol is formed with the same numbers, for instance the line joining 12 to [12]. Such a line is called an *i*-line, or a Steiner-Plücker line. The Pascal lines will also be called *k*-lines. There are certain theorems of incidence among the various elements in addition to those which have been referred to. For instance, a Pascal line, or *k*-line, lies in one *G*-plane, and in three *K*-planes; this fact will be denoted, in the summary we now give, by writing *k*...*G*, 3*K*. Conversely a *K*-plane contains, not only three *k*-lines, as we have seen, but also one *g*-line; this fact will be denoted by writing *K*...*g*, 3*k*. We may then summarise the definitions, and the incidences referred to, which will be immediately proved, as follows: [Add.]

60 *k*-lines, Pascal lines, 12, 13,
60 *K*-planes, Kirkman planes, 14, 15, 16;

20 *g*-lines, Cayley-Salmon lines, [12], [13],
20 *G*-planes, Steiner planes, 56, 64, 45;

15 *i*-lines, Steiner-Plücker lines, 12, [12],
15 *I*-planes, Salmon planes, [63], [64], [65].

$k \ldots G, 3K$; $g \ldots G, 3K, 3I$; $i \ldots 4G$,
$K \ldots g, 3k$; $G \ldots g, 3k, 3i$; $I \ldots 4g$.

The proof of these last theorems of incidence is immediate:

(1) The k-line 12, 13 lies in the G-plane 23, 31, 12; and in the K-planes (12, 13, 14), (12, 13, 15), (12, 13, 16).

(2) The K-plane 14, 15, 16 contains the g-line ([56], [64], [45]), and the k-lines 15 . 16, 16 . 14, 14 . 15.

(3) The g-line [12], [13] lies in the G-plane (23, 31, 12), it lies in the K-planes (41, 42, 43), (51, 52, 53), (61, 62, 63), and it lies in the I-planes ([12], [13], [14]), ([12], [13], [15]), ([12], [13], [16]).

(4) The G-plane 56, 64, 45 contains the g-line [56], [64], [45], the k-lines 45 . 46, 56 . 54, 64 . 65, and also the i-lines (56, [56]), (64, [64]), (45, [45]).

(5) The i-line (12, [12]) lies in the G-planes (12, 23, 31), (12, 24, 41), (12, 25, 51), (12, 26, 61).

(6) The I-plane ([63], [64], [65]) contains the g-lines ([63], [64], [34]), ([64], [65], [45]), ([65], [63], [35]), ([45], [53], [34]).

It is interesting, however, further, to remark, that the relations expressed by

$$K \ldots g, 3k; \quad G \ldots g, 3k, 3i; \quad I \ldots 4g$$

can be verified by considering only a single threefold space which forms part of Ω, there being in Ω fifteen such spaces; and the relations expressed by

$$k \ldots G, 3K; \quad g \ldots G, 3K, 3I; \quad i \ldots 4G$$

can be verified by considering only elements passing through a single point of Ω, there being fifteen such points, which correspond dually in Ω to the threefold spaces just spoken of. For if we consider the space determined by four of the six fundamental points, say by G, H, S, T, which contains the points 23, 25, 26, 35, 36, 56, [23], [25], [26], [35], [36], [56], it is at once seen that this contains

four K-planes, four G-planes, one I-plane;

it contains also

twelve k-lines, four g-lines, six i-lines.

Correspondingly, consider elements passing through the Plücker point [14]; there are of such (cf. the Frontispiece of the volume)

four k-lines, four g-lines, one i-line;

any plane of the complete figure Ω which contains one of these lines necessarily contains the point [14]. There pass in all through this point

twelve K-planes, four G-planes, six I-planes;

one such K-plane is (21, 24, 23); one such G-plane is (21, 24, 14); one such I-plane is ([14], [15], [16]).

And in fact, if we introduce the equations to the spaces and planes of the figure Ω, we can make the duality suggested by the notation apparent analytically.

If now we suppose that in place of the figure S we consider the figure S', dually corresponding to S in three dimensions, we shall have therein k-lines, g-lines and i-lines, but we shall have K-*points*, instead of K-planes, G-points and I-points. If then we project on to a plane, obtaining the figure ϖ, we shall have therein lines from the lines of the figure S', and points from the points of S'. And therein the six theorems of incidence which we have obtained will continue to hold.

It is this fact which is the outcome of the many investigations made for Pascal's figure, of which the figure ϖ is a generalisation.

(4) We shew now how the exact Pascal's figure can be obtained from a figure in three dimensions; and it will appear at once that this figure is a particular case of the figure S' which we have considered.

Let x, y, z, t be coordinates in three dimensions. Let U be a homogeneous polynomial of the second order in x, y, z only, and M be a homogeneous polynomial of the third order in x, y, z only. Thus $U=0$ may be regarded as the equation to a conic, in the plane whose equation is $t=0$; similarly $M=0$ may be regarded as the equation to a curve in this plane which has the property of being met, by an arbitrary line of this plane, in three points, and is therefore said to be a curve of the third order, or a cubic. This cubic meets the conic in six points, as follows from the elements of the theory of elimination. These points we name, in some order, P, Q', R, P', Q, R'; a cubic curve can be drawn through nine arbitrary points, so that, by proper choice of M, we may regard these six points as arbitrary points of the conic $U=0$. Now consider the equation $M-tU=0$, which is homogeneous in the four coordinates x, y, z, t. It represents a surface which is met by an arbitrary line of the threefold space in three points, say, a cubic surface. But, in particular, any line of the threefold space which is drawn through the point of coordinates (0, 0, 0, 1), say, the point D, meets the surface in two coincident points at D, and in a further point; for this reason the point D is called a node of the cubic surface. More particularly, however, there are lines which lie entirely upon the cubic surface: for instance, whatever θ may be, if $(x, y, z, 0)$ be one of the six points for which $U=0$ and $M=0$, the point (x, y, z, θ) lies on the cubic surface, since its coordinates satisfy $M-\theta U=0$, and, for different values of θ, this point is any point of the line joining D to $(x, y, z, 0)$. Let the six lines so obtained, joining D to the six points $P, Q', \ldots,$ be named, respectively, p, q', r, p', q, r'; it is easy to see that these are the only lines passing through D which lie on the cubic surface. Then, further, it is at once clear that any plane meets the cubic surface in a cubic curve; thus a plane containing two of the lines $p, q', \ldots, r'$, will contain a further line lying entirely on the cubic surface. Thereby we obtain fifteen further lines of the surface, any one of which may be denoted by a duad symbol, such as qr'. There are however no other lines lying on the surface. For we have enumerated all those which pass through D; suppose then one which does not pass through D, and consider the curve in which the cubic surface is met by the plane joining D to this line; this consists of the line, and a curve of the second order; but this curve of the second order has the property of being met in two points coinciding at D by every line in the plane drawn through D, and must therefore itself consist of two lines intersecting at D. The plane is therefore one of those before considered, drawn through two of the lines $p, q', \ldots, r'$. Now consider the three lines of the surface, q, r' and qr', which lie in a plane. The first line, q, is evidently met by the four lines qp, qr, qp', qq', in addition to qr'; the other line, r', is evidently met by the four lines $r'p$, $r'r$, $r'p'$, $r'q'$, in addition to $r'q$. Beside the four lines which meet both q and r' at the point D, there remain then, of the total twenty-one lines of the surface, just six, namely those whose symbols are the duads from p, r, p', q'. These six lines do not lie in the plane of q, r' and qr'; each must meet, then, either q, or r', or qr'; but each meets two lines, other than q and r', of the lines of the surface which pass through D; it cannot, then, for example, meet also the line q, since else three of the lines through D would lie in a plane, and the conic $U=0$ would break into two lines, which we suppose not to be the case. Thus these six lines all meet the line qr'.

Consider, for instance, rp'; the plane containing qr' and rp' must then meet the cubic surface in another line, by an argument applied above; this other line, meeting both qr' and rp', will have for symbol a duad not containing either q or r', or r or p'; this symbol is, then, pq', the symbols of the three lines qr', rp', pq' containing all the six symbols p, q', r, p', q, r'. In this way we see that there are, beside the plane containing q and r', three planes through the line qr' each containing two other lines with duad symbols. Whence we see that the fifteen lines of the cubic surface, other than those through D, lie in threes in fifteen planes, of which three planes pass through every one of these lines.

If desired, the equations of the fifteen lines can be obtained, when the six points of intersection of the conic $U=0$, and the cubic $M=0$ are given. For if $ax+by+cz=0$, with $t=0$, be the equation of the join of two of these six points, and we suppose, for instance, that c is not zero, as the plane joining D to this line contains a line of the cubic surface, the substitution for z, in the quotient M/U, of $-(ax+by)/c$, must reduce this to a form $lx+my$; the line in question will then be given by the two equations $ax+by+cz=0$, $t-lx-my=0$.

Having obtained the figure of fifteen planes, and the lines lying in threes of these, we can denote any one of the planes by a duad formed from two of the six numbers 1, 2, 3, 4, 5, 6, and the line of intersection of three of these planes by a syntheme of three duads, such as 12.34.56, formed from the duads which represent the three planes passing through the line. We shall then have a figure which, combinatorially, has the same properties as the figure S' considered above, specialised however by the fact that the fifteen lines are arranged in sets of five all of which have a common transversal passing through D, any of the lines meeting two of the transversals. These sets of five are the systems of synthemes considered above in (1). But the incidence theorems obtained above will hold for the specialised figure; and, after projection on to the plane $t=0$, these give the properties of the Pascal figure which are the occasion of the present note.

It may be remarked that on a general cubic surface, which does not possess a node, there are sets of fifteen lines such as those here denoted by the duad symbols qr', together with twelve others, each of the six lines here found passing through D being replaced by a pair of skew lines. Moreover, we shall find that the general figure Ω in four dimensions, here considered, is of fundamental importance for the theory of the general cubic surface.

(5) We now give some particular examples of the theory.

Ex. 1. *The pairs of conjugate Steiner planes.* Let $\alpha, \beta, \gamma, \alpha', \beta', \gamma'$ denote the numbers 1, 2, ..., 6, in any order. In the figure Ω, there pass, as we have seen, through each of the three Cremona points, $\beta'\gamma'$, $\gamma'\alpha'$, $\alpha'\beta'$, three of the fifteen lines which are fundamental in the figure (beside two k-lines joining this point to the other two); and the nine lines so obtained meet in threes in the points $\beta\gamma, \gamma\alpha, \alpha\beta$. The two Steiner planes $(\beta'\gamma', \gamma'\alpha', \alpha'\beta')$ and $(\beta\gamma, \gamma\alpha, \alpha\beta)$ are called conjugate. In the Pascal figure there are two corresponding Steiner points, which are in fact conjugate to one another in regard to the fundamental conic. In the figure S', we have two Steiner points; through each of these there pass three Cremona planes, intersecting in pairs in three Pascal lines which pass through the point. The three planes through one of the two Steiner points meet the three planes through the other Steiner point in three triads of lines, of which any two are then in perspective, the axis of perspective being a Pascal line. By projection to the plane ϖ we obtain then a similar result, of which the elementary proof is indicated in more detail below. (Ex. 5. See also v. Staudt, *Crelle*, LXII, p. 142.)

Ex. 2. *The Steiner planes and Steiner-Plücker lines.* The plane determined by the Cremona points 23, 31, 12, is the same as that determined by the three points F, G, H, of the six fundamental points. The Steiner-Plücker line determined by joining the Cremona point 12 to the Plücker point [12], is that joining the two fundamental points F, G. The twenty Steiner planes are thus all the planes each containing three of the six fundamental points, and the fifteen Steiner-Plücker lines are all the lines each joining two of these points. In the figure S', the Steiner points are then the intersections in threes, and the Steiner-Plücker lines the intersections in twos, of six planes, which, so far as the configuration is concerned, may be taken arbitrarily. The corresponding points and lines in the Pascal figure are then the projection of this very simple configuration. (Cf. p. 218.)

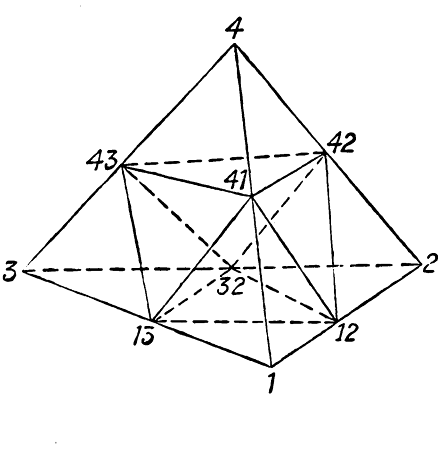
Ex. 3. *The separation of the complete figure into six figures.* In the figure Ω, the notation at once suggests that we consider together the set of five Cremona points such as 12, 13, 14, 15, 16; and there will be six such sets, each point belonging to two sets. The five points of a set are such that the join of any two is a Pascal line, and the plane of any three is a Kirkman plane. In the figure S', we have then six sets of five Cremona planes, of which any two meet in a Pascal line, and any three in a Kirkman point. In the plane ϖ, the sixty Pascal lines are thus divided into six sets of ten, meeting in threes in ten Kirkman points, each of the Pascal lines containing three of the Kirkman points. The configuration, in each of the six partial figures is that of two triads in perspective, with their centre and axis of perspective. These partial figures were considered by Veronese.

Ex. 4. *Tetrads of Steiner points each in threefold perspective with a tetrad of Kirkman points.* In the figure Ω, the six Cremona points 23, 31, 12, 41, 42, 43, which lie in the threefold space of the four fundamental points F, G, H, R, give four Steiner planes,

$\alpha=(24,43,32)$, $\beta=(34,41,13)$, $\gamma=(14,42,21)$, $\delta=(23,31,12)$, and four Kirkman planes,

$\alpha'=(12,13,14)$, $\beta'=(23,21,24)$, $\gamma'=(31,32,34)$, $\delta'=(41,42,43)$.

The planes α, α' meet in the



g-line ([23], [24], [34]), the planes β, β' meet in the g-line ([31], [34], [14]), the planes γ, γ' meet in the g-line ([12], [14], [24]), and the planes δ, δ' meet in the g-line ([12], [13], [23]); and these are the four g-lines which lie in the I-plane ([41], [42], [43]).

Hence if we consider the figure S', we have two tetrads of points, one formed by Steiner points, and the other by Kirkman points, which are in perspective, the lines joining corresponding points of the two tetrads being g-lines, and the centre of perspective being an I-point.

But in fact, in this figure S', the two tetrads are in perspective in three other ways. In this figure, $\alpha, \beta, \ldots, \alpha', \beta', \ldots$ are points; the lines (α, δ'), (β, γ'), (γ, β'), (δ, α') also meet in a point, namely the point (12, 13, [14]), or (12, 13, 56), a T-point. This fact we may denote by writing

$$12, 13, [14] \left\{\begin{matrix} 24, 43, 32 & 34, 14, 31 & 14, 24, 12 & 23, 31, 12 \\ 41, 42, 43 & 31, 32, 34 & 23, 21, 24 & 12, 13, 14 \end{matrix}\right.$$

The joins of corresponding points of these two tetrads are, respectively, the Pascal lines 42 . 43, 31 . 34, 21 . 24, 12 . 13.

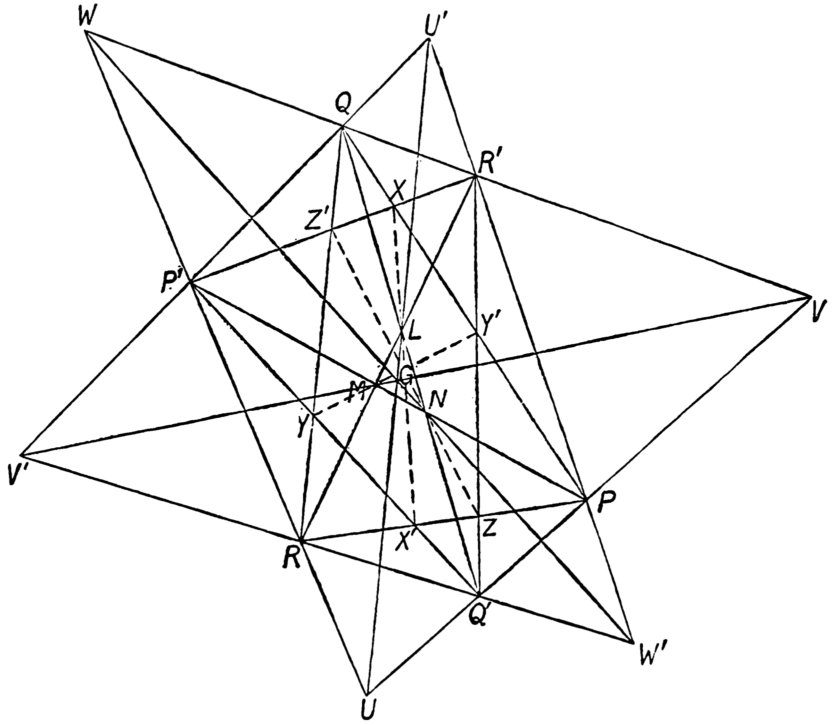
Similarly the tetrads $(\alpha, \beta, \gamma, \delta)$, $(\gamma', \delta', \alpha', \beta')$ are in perspective from the point (23, 21, [24]), or (23, 21, 56), and the tetrads $(\alpha, \beta, \gamma, \delta)$, $(\beta', \alpha', \delta', \gamma')$ are in perspective from (31, 32, [34]), or (31, 32, 56). The two given tetrads, and that formed by the four centres of perspective, form, therefore, what is known as a desmic system of three tetrads, of which the points can be supposed to have symbols of the form (cf. p. 213)

$$(P,Q,R,S),(-P+Q+R+S, P-Q+R+S, P+Q-R+S, P+Q+R-S),$$
$$(P+Q+R+S,\ P-Q-R+S,\ -P+Q-R+S,\ -P-Q+R+S).$$

Ex. 5. *Relation of the Cayley-Salmon lines and the Salmon planes.* The fifteen Plücker points in the figure Ω lie in threes on the twenty Cayley-Salmon lines, g-lines, and in threes also on the fifteen Salmon planes, or I-planes, forming a figure such as that occurring in the proof of Desargues' theorem for two triads in one plane (cf. p. 214).

The figure is evidently dual with itself, in threefold space, and has the same description in S' and in ϖ. Through each of the fifteen points there pass, in S or S', six planes and four lines, each of the twenty lines contains three points and lies in three planes, each plane contains four of the lines and six of the points. The figure has been considered in Note I (§ 3).

Ex. 6. Let U, V, W and U', V', W' be two triads of points in a plane, the lines UU', VV', WW' meeting in G; let the points $(UV, W'U')$, $(VW, U'V')$, $(WU, V'W')$ be denoted, respectively, by P, Q, R, and the points $(U'V', WU)$, $(V'W', UV)$, $(W'U', VW)$ be denoted, respectively, by P', Q', R'; so that, by the converse of Pascal's theorem, the six points P, Q', R, P', Q, R' lie on a conic. Prove, (1), that QQ', RR', UU' meet in a point, say, L; and, similarly, RR', PP', VV' meet in a point, say, M; and, likewise, PP', QQ', WW' meet in a point, say, N. Let the points $(PQ, R'P')$, $(QR, P'Q')$, $(RP, Q'R')$ be denoted, respectively, by X, Y, Z; and the points $(P'Q', RP)$, $(Q'R', PQ)$, $(R'P', QR)$ be denoted, respectively, by X', Y', Z'. Prove, (2), that X, L, X' are in line, as also Y, M, Y' and Z, N, Z'; and that



the lines XLX', YMY', ZNZ' meet in a point. Prove also, (3), that the lines YZ, PP', QR' meet in a point, as do the lines $Y'Z'$, PP', $Q'R$; that the lines ZX, QQ', RP' meet in a point, as do $Z'X'$, QQ', $R'P$; and that the lines XY, RR', PQ' meet in a point, as do the lines $X'Y'$, RR', $P'Q$. Thus any two of the triads U, V, W; L, M, N; X, Y, Z are in perspective, as also are any two of the triads U', V', W'; L, M, N; X', Y', Z', the lines XU, YV, ZW meeting in a point, as do $X'U'$, $Y'V'$, $Z'W'$.

Shew also, (4), that the lines UU', VV', WW' are Pascal lines each for a proper order of the six points P, Q', etc., on the conic, their point of meeting, G, being a Steiner point; and, (5), that the axis of perspective of the triads U, V, W and U', V', W' is a Pascal line;

that the axis of perspective of the triads U, V, W and L, M, N is a Pascal line, and that the axis of perspective of the triads U', V', W' and L, M, N is a Pascal line; and that these three Pascal lines meet in a Steiner point. Shew also, (6), that the lines XLX', YMY', ZNZ' are Pascal lines, meeting in a Kirkman point, that the lines XU, YV, ZW are Pascal lines, meeting in a Kirkman point, and that the lines $X'U'$, $Y'V'$, $Z'W'$ are Pascal lines, meeting in a Kirkman point.

These facts may all be obtained by application of Desargues' theorem.

They may also be obtained by shewing that, with that association of P, Q', R, etc. with the systems which has been adopted in this note, the points U, V, W, U', V', W' are the respective T-points (56, 21, 23), (56, 12, 13), (56, 31, 32), (64, 21, 23), (64, 12, 13), (64,31,32), so that the lines UU', VV', WW' are the respective Pascal lines (23,21), (12,13), (31, 32). Then that the points L, M, N are the respective T-points (45,23,21), (45,12,13), (45,13,23). Then that the points X, Y, Z are the respective T-points (25, 63, 61), (15, 62, 63), (35, 61, 62), and the points X', Y', Z' are the respective T-points (24, 61, 63), (14, 62, 63), (34, 61, 62), so that the lines XX', YY', ZZ' are, respectively, the Pascal lines (63, 61), (62, 63), (61, 62) and the lines YZ, $Y'Z'$ are, respectively, the Pascal lines (24, 26), (25, 26), with similar results for ZX, $Z'X'$, XY, $X'Y'$. The points (QR', PP'), (RP', QQ'), (PQ', RR') are, respectively, the T-points (31, 56, 54), (23, 56, 54), (12, 56, 54); the lines XU, $X'U'$, YV are, respectively, the Pascal lines (41, 43), (51, 53), (42, 43), and so on.

In what is said in the text, references to non-Euclidean geometry in three dimensions are excluded, as belonging later. Also questions of Transformation and Group-Theory are not considered (see S. Lie, *Transformationsgruppen*, III, 1893, which gives an exhaustive analytical study of the Riemann-Helmholtz problem). Further, the arbitrary limitation of the symbols adopted in Chapters IV and V leads to the omission of many general logical questions. Cf., for example, Dehn, *Math. Annal.* LIII (1900), pp. 404–439, and *Math. Annal.* LX (1905), pp. 166–174; R. L. Moore, *Tr. Amer. Math. Soc.* VIII (1907) (and Hilbert's *Grundlagen*).

ADDITIONS

p. 27. In Ex. 4, it follows, by Ex. 3, that the director conic of the given conic, in respect of B' and C', touches $A'B'$ and $A'C'$, at B' and C', and passes through the point, X, where CC' meets $A'B'$, and through the point, M, where BB' meets $C'A'$. From this it follows that AA' contains the point of intersection of $B'M$ and $C'X$, that is, of BB' and CC'. This simplification was suggested by Mr R. J. Lyons, of the University of Sydney, to whom also several other of the following remarks are due.

We may remark also that if the lines from three points A, B, C, respectively conjugate, in regard to a conic, to the joins of three other points A', B', C', be concurrent, the same is true of the lines from A', B', C' respectively conjugate to the corresponding joins of A, B, C. When the conic is a point-pair, the result is remarked by Steiner, *Werke*, I, p. 157.

And compare Moebius's theorem (Vol I, p. 61) that if a line meet $B'C'$, $C'A'$, $A'B'$ in P', Q', R', so that AP', BQ', CR' are concurrent, and meet BC, CA, AB in P, Q, R, then $A'P$, $B'Q$, $C'R$ are concurrent. (See also the Addition to p. 218.)

p. 29. The result in Ex. 7 suggests the consideration of a theorem with wide bearings, relating to three triads of tangents of a conic. See the addition to p 145.

p. 30. The proof of Ex. 8 may be given as follows (R. J. Lyons): By considering conics through the four points A, B, C, O, which determine an involution on IJ, we see that the four pairs of rays (OA, OL), (OB, OM), (OC, ON), (OI, OJ), are in involution. Hence it follows that the four pairs of rays (OA, OL'), (OB, OM'), (OC, ON'), (OI, OJ) are in involution. Whence, considering the ranges on AB, AC, by BC, OI, OJ, $M'N'$, we see that $M'N'$ touches the conic touching BC, CA, AB, OI, OJ, IJ, and, therefore, by symmetry, passes through L'. (Cf. Ex. 3, p. 82.)

p. 32. For the theorem of Ex. 10 see Hesse, *De Curvis...2. Ord.*, *Crelle*, XX (1840), p. 301. Another view of the proof that X, X' are conjugate is as follows (R. J. Lyons): Let y, z be the polars of Y, Z, meeting in T, and let a variable line through X' meet these in Y_1 and Z_1; then the point of intersection (X_1) of YZ_1 and ZY_1 describes the line XT. But, if P be the point of contact of one tangent from X', and ZP, YP meet y and z in Q and R, it can be proved that X', Q, R are in line. Thus P lies on XT; and X lies on the polar of X'.

p. 34. To prove, in Ex. 11, that QMN is a self-polar triad, we may argue as follows (R. J. Lyons): As two lines which are conjugate, in regard to the conic Σ, meet the polar of any point of either in two conjugate points, it follows that the involution on MN, by conics through the four points Q, R, Q', R', contains two pairs (by QR, $Q'R'$, and QQ', RR') which both consist of points conjugate in regard to Σ. Hence M, N are likewise conjugate.

p. 45. For the theorem of Ex. 20, it is easy to prove that the six tangents of two conics at three of their intersections are touched by a conic. The tangents at three points of a conic meet the respective joins of the other two points in three collinear points; and, if two lines be drawn intersecting the joins of three points, the six lines obtained by joining each of the three points to the two points where the opposite join is met by the two lines, touch a conic (cf. p. 121 below). Having so determined a conic, it is to be shewn that any tangent of this meets the two given conics in harmonically conjugate pairs of points.

But there is a simple view of the theorem, associating it with the theory of the director conic, which involves only such elements of the theory of quadric surfaces as are explained in Chap. v (p. 189):—Given two conics in a plane, of which I, J are two intersections, take an arbitrary point O, not lying in the plane of the conics, and describe any quadric surface containing the lines OI, OJ. Then the two given conics may be regarded as the projections from O of two plane sections, α, β, of the quadric. Any line l, of the original plane, meeting either of the given conics in two points which are conjugate in regard to the other conic (and therefore cutting the conics in a harmonic range), lies on a plane, γ, through O. The section of the quadric surface by the plane γ is met by the plane α in two points P, P' and by the plane β in two points Q, Q', such that the rays OP, OP' are harmonically separated by OQ, OQ'; the lines PP', QQ' are thus conjugate to one another with respect to the conic γ. Now let A, B, C be the respective poles of the planes α, β, γ in regard to the quadric surface, so that CA, CB are respectively the polar lines of PP' and QQ' in regard to this surface. It easily follows, by the reciprocity of pole and polar, that CA, CB are conjugate lines in regard to the enveloping cone of the surface drawn with vertex C, which touches the quadric surface along the conic γ; or that the segment AB is divided harmonically by this cone.

Now the locus of a point D such that the enveloping cone to the given quadric surface, Ω, divides the given segment AB harmonically, is easily seen to be another quadric surface, Φ, whose section by any plane through AB is the director conic of the section of Ω by this plane, in regard to A and B; namely the conic which is the locus of a point, D', for which $D'A$, $D'B$ are conjugate lines in regard to the section of Ω. The quadric surface Φ contains A and B and also the conic sections, α, β, of Ω, by the polar planes of A, B in regard to Ω.

The point C, spoken of, thus lies on this quadric Φ; and, as the plane γ passes through O, the point C describes the conic section in which Φ is met by the tangent plane of Ω at O. Wherefore the plane γ touches a quadric cone with vertex at O (the polar reciprocal, in regard to Ω, of the section of Φ by this tangent plane). This shews that the line l, in the original plane, touches a conic; which is the proposition.

If $f_x^2=0$ be the equation of Ω, and (y), (z) be A and B, the equation of Φ is $f_x^2 . f_{yz}=f_{xy}f_{xz}$. The equation of the envelope of the line l is given below in the Addition to p. 142. (Cf. also the Addition to p. 126.)

p. 49. The proposition of Ex. 25 is really stated in the second paragraph of p. 44 preceding (R. J. Lyons). For any conic, Φ, outpolar to Ω, meets the polar of J, in regard to Ω, in points A, B, conjugate in regard to Ω, and this polar contains the pole, O, of IJ in regard to Ω. (Cf. also p. 80 below.)

The proposition is in Gaskin, *The Geometrical Construction of a Conic Section...*, Cambridge, 1852, p. 33. See also Faure, *Nouv. Ann. de Math.* xix (1860), p. 234.

The following is a generalisation of Gaskin's theorem: Let $U=0$, $V=0$, $W=0$ be any three conics, and Σ be a conic which is inpolar to all these; let Φ be the director conic of Σ in regard to two arbitrary points I, J. There is then a definite conic $\lambda U+\mu V+\nu W=0$ which passes through I and J, in which λ, μ, ν are certain constants. The generalised proposition is that this conic cuts Φ at right angles with respect to I and J (*v.* p. 63). Gaskin's theorem is the particular case of this in which U, V, W are the three line-pairs containing a triad of points self-polar in regard to Σ.

p. 65. It may be noticed that the theorem of the centroid does not require Pappus's theorem, but the theorem of the orthocentre, as involving six points in involution, does require this (Vol. i, p. 60). Another related theorem is that the lines through the mid-points (in respect to I, J) of the joins of a triad of points, each at right angles to the join, meet in a point. If BI, CJ meet in P, and BJ, CI meet in P', the line PP' is at right angles to BC, and passes through the mid-point of BC, as is at once seen. If also CI, AJ meet in Q, and CJ, AI meet in Q', while AI, BJ meet in R and AJ, BI meet in R', the fact that PP', QQ', RR', meet in a point is a direct application of Pappus's theorem for the collinear triads QJR' and RIQ'. Or, otherwise, assuming the result of Ex. 1, p. 23, for any conic through B, C, I, J, the pole of PP' is the intersection of BC and IJ, so that the pole of IJ lies on PP'. Whence, taking the conic through A, B, C, I, J, the lines PP', QQ', RR' meet in the pole of IJ, the so-called *circumcentre* of A, B, C.

p. 70. We may remark, in Ex. 2 (R. J. Lyons), that we have the following sequence of related pencils of rays:

$$F(O, A, I, J),\quad F(O, B, I, J),\quad D(O, B, I, J),\quad D(O, C, I, J),$$
$$E(O, C, I, J),\quad E(O, A, I, J),$$

and the comparison of the first and last shews that a conic contains A, E, O, F, I, J.

p. 79. As an additional simple example, it may be proved that: the common tangents of any two circles whose centres are harmonic conjugates in regard to the foci of a given conic, touch a confocal conic.

p. 81. The theorem that the director circles are coaxal is ascribed to Plücker, *Analytisch-geometrische Entwicklungen* (1831), II, p. 198.

p. 83. The rectangular hyperbola which is also a parabola is also an equiangular spiral. For a conic touching the lines JI and JO at I and O, if the tangent at any point P, and the chord OP, meet IJ in T and Q, respectively, the angle TPQ, relatively to I and J (see p. 167), is constant as P varies. Using the symbols of points, we can suppose that $Q=I+J$, $T=2I+J$.

p. 90. We may remark also: (*a*) The rectangular hyperbolas which have a given self-polar triad of points all pass through four points, and their centres describe the circle through the points of the triad. (*b*) Given four points there is, corresponding to any point O, a definite other point, O', such that O, O' are conjugate in regard to all conics through the four points (Ex. 15, p. 37). Hence prove that, if OT, OT' be the tangents from a fixed point O to one of a system of confocal conics, the circle OTT' passes through another fixed point.

p. 96. We remark also

(*a*) If the perpendiculars from a fixed point S, to two fixed lines AM, AN, meet these in M and N, the conic with S as focus which touches AM, AN, MN, is a parabola. More generally: If the joins of a fixed point S to the poles, in regard to a given conic Ω, of two lines m, n, meet these in M and N, the conic touching the lines m, n, MN, and the tangents to Ω from S, also touches the tangents of Ω at the points where MN meets it.

(*b*) A variable chord of a conic which subtends a right angle at a fixed point, envelopes a conic having one focus at this point. The foot of the perpendicular from the fixed point to the chord describes a circle (cf. p. 85). This circle cuts at right angles the unique circle, with centre at the fixed point, which is inpolar to the given conic; and reduces to two lines if the given point be on the director circle of the given conic. If the fixed point be on the given conic, the chords of the conic subtending a right angle at this point, all pass through the same point on *the* normal to the conic at this point. (The Frégier point. *Gergonne's Annales*, VI, 1816, p. 231.)

p. 107. For a function of a real variable having a finite differential coefficient, there is at least one zero of this between two zeros of the function. The following extension to a polynomial function of a complex variable (in the first instance of the third order) seems to deserve mention: Let $(a_1, b_1, 1)$, $(a_2, b_2, 1)$, $(a_3, b_3, 1)$ be the coordinates of any three points, not lying on the line $z=0$. The tangential equations of these points will then be $ua_1+vb_1+w=0$, etc., say $U_1=0$, etc. It follows that the equation $U_2U_3+U_3U_1+U_1U_2=0$ is the tangential equation of a conic touching the three joins of the points. In particular the point of contact with the join of the points U_2, U_3, obtainable by the operator $u\partial/\partial u'+v\partial/\partial v'+w\partial/\partial w'$, is the point $U_2+U_3=0$. This is the harmonic of the point $U_2-U_3=0$, in which the join meets $z=0$ (whose coordinates are $u=0$, $v=0$, $w=1$), with respect to the two points U_2, U_3. Thus there exists a conic touching the three joins of the given points, at the mid-points of these joins with respect to $z=0$ (Ex. 29, p. 53).

Now the coordinates of the line joining a point (x, y, z) to the point $(1, i, 0)$, on $z=0$, are $(-z, -iz, x+iy)$; if these be substituted for u, v, w in the tangential equation of the conic, the result will express that the tangent from (x, y, z) passes through the point $(1, i, 0)$. The substitution in ua_1+vb_1+w leads to $x+iy-(a_1+ib_1)z$. Hence, if we write ζ for $(x+iy)z^{-1}$, and γ_1 for a_1+ib_1, and also write ζ' for $(x-iy)z^{-1}$ and γ_1' for a_1-ib_1, etc., the foci of the conic (cf. p. 119) are the intersections of the two lines expressed by the single equation

$$(\zeta-\gamma_2)(\zeta-\gamma_3)+(\zeta-\gamma_3)(\zeta-\gamma_1)+(\zeta-\gamma_1)(\zeta-\gamma_2)=0,$$

with the two lines expressed by the result of substituting $\zeta', \gamma_1', \ldots$ for $\zeta, \gamma_1, \ldots$ in this equation. This equation is obtainable by differentiating, in regard to ζ, the equation

$$(\zeta-\gamma_1)(\zeta-\gamma_2)(\zeta-\gamma_3)=0.$$

We may thus say, if on the plane representing a complex variable ζ, a triad of points be given by $f(\zeta)=0$, the foci of the conic touching the joins of the pairs of the triad at their mid-points are given by $df(\zeta)/d\zeta=0$.

A precisely similar treatment determines the tangential equation of a curve of *class* $(n-1)$ touching the joins of n arbitrary points, taken in order, each at its mid-point; and determines the foci of this curve.

p. 114. For the final statement in Ex. 8, see Morley, *Bull. Amer. Math. Soc.* I (1895), p. 116, and the Note, *Proc. Camb. Phil. Soc.* XX (1920), p. 119.

p. 126. It may be verified that the tangents at the common points of the two circles

$$x^2+y^2-2axz-h^2z^2=0, \quad x^2+y^2+2bxz-h^2z^2=0$$

touch the conic $\qquad A\,[x-\tfrac{1}{2}(a-b)z]^2+By^2=z^2,$

where $A^{-1}=h^2+\frac{1}{4}(a-b)^2$, $B^{-1}=h^2-ab$. This conic has foci at the centres of the two circles; its tangents cut the two circles harmonically. (Cf. the Addition to p. 45.)

p. 142. The simplicity of the theory of the invariants of conics is readily seen with the use of a certain symbolical notation, first introduced by Cayley (*Papers*, I, p. 95 (1846), etc.), but systematised by Clebsch (*Bin. alg. Formen*, 1872).

Consider first an ordinary binary quadratic form, $ax^2+2hxy+by^2$. Change the notation, writing x_1, x_2 for x and y, and a_{11}, a_{12}, a_{22} for a, h, b. Now introduce two symbols, a_1, a_2, subject to the ordinary laws of algebra, but capable of interpretation as numbers only in products of two, according to the rule $a_ia_j=a_{ij}$. Then the form $a_{11}x_1^2+2a_{12}x_1x_2+a_{22}x_2^2$ can be represented by $(a_1x_1+a_2x_2)^2$, which is expressed by a_x^2. And a symbolic form a_xa_y, meaning

$(a_1x_1+a_2x_2)(a_1y_1+a_2y_2)$, being $a_1^2x_1y_1+a_1a_2(x_1y_2+x_2y_1)+a_2^2x_2y_2$, represents $a_{11}x_1y_1+a_{12}(x_1y_2+x_2y_1)+a_{22}x_2y_2$. This vanishes when the point (x_1, x_2) is the harmonic conjugate of the point (y_1, y_2) in regard to the pair of points given by the vanishing of the original form a_x^2. If we have a second quadratic form $b_{11}x_1^2+\ldots$, or b_x^2, the condition that the pair of points given by the vanishing of one of these forms should be harmonic in regard to the pair of points given by the other, which is

$$a_{11}b_{22}-2a_{12}b_{12}+a_{22}b_{11}=0,$$

can be represented symbolically by $(a_1b_2-a_2b_1)^2=0$, which can be written $(ab)^2=0$. We cannot, however, without further convention, express in the symbolic form, for instance, the discriminant $a_{11}a_{22}-a_{12}^2$ of the original quadratic, since $a_1^2a_2^2-(a_1a_2)^2$ vanishes. We thus replace the discriminant by $\frac{1}{2}(a_{11}a_{22}'+a_{22}a_{11}'-2a_{12}a_{12}')$, where $a_{11}', a_{12}', a_{22}'$, are ultimately to be a_{11}, a_{12}, a_{22}, and introduce symbols a_1', a_2', to represent a_{11}', etc., which are ultimately equivalent with a_1, a_2. Then we have the symbolic form

$$\tfrac{1}{2}(a_1^2\,.\,a_2'^2+a_2^2\,.\,a_1'^2-2a_1a_2\,.\,a_1'a_2'),$$

or $\frac{1}{2}(a_1a_2'-a_2a_1')^2$, and this can be written $\frac{1}{2}(aa')^2$.

When we pass to a quadratic form in three homogeneous variables x_1, x_2, x_3, if we similarly introduce three symbols a_1, a_2, a_3, the equation of a conic may be represented by $(a_1x_1+a_2x_2+a_3x_3)^2=0$, which may be written $a_x^2=0$. Then the condition that two points, (x_1, x_2, x_3) and (y_1, y_2, y_3), or say (x) and (y), should be conjugate in regard to this conic is represented by a_xa_y. This is obvious at once on interpretation. But also it may be remarked that the points, on the line joining (x) and (y), with coordinates $(\lambda x_1+y_1, \lambda x_2+y_2, \lambda x_3+y_3)$, which lie on the conic $a_x^2=0$, correspond to the two values of λ given by the equation

$$\lambda^2a_x^2+2\lambda a_xa_y+a_y^2=0,$$

which is $(\lambda a_x+a_y)^2=0$, and, in order that these points should be harmonic in regard to (x) and (y), it is necessary that the two values of λ should be equal and of opposite sign. This leads to the equation $a_xa_y=0$. A similar method at once gives the condition for a line, of coordinates u_1, u_2, u_3, to meet two conics $a_x^2=0$, $b_x^2=0$, in two pairs of mutually harmonic points. For if (y), (z) be any two points of this line, and therefore

$$u_1=y_2z_3-y_3z_2,\quad u_2=y_3z_1-y_1z_3,\quad u_3=y_1z_2-y_2z_1,$$

the condition that the roots of one of the quadratic equations in λ

$$\lambda^2a_y^2+2\lambda a_ya_z+a_z^2=0,\quad \lambda^2b_y^2+2\lambda b_yb_z+b_z^2=0,$$

should be harmonic conjugates in regard to the roots of the other is (p. 111)

$$a_y^2\,.\,b_z^2-2a_ya_z\,.\,b_yb_z+a_z^2\,.\,b_y^2=0,$$

which is $(a_yb_z-a_zb_y)^2=0$, or

$$[(a_2b_3-a_3b_2)u_1+(a_3b_1-a_1b_3)u_2+(a_1b_2-a_2b_1)u_3]^2=0.$$

This we write $(abu)^2=0$. It is the tangential equation of the conic of Ex. 20, p. 44.

The condition that the line (u) should touch the conic $a_x^2=0$, found as the condition that the former of the two quadratics in λ should have equal roots, is $a_y^2\,.\,a_z^2-(a_ya_z)^2=0$; but as this involves the coefficients in the equation of the conic to the second degree, it can be expressed symbolically only by introducing other symbols a_1', a_2', a_3', ultimately equivalent with a_1, a_2, a_3; namely by writing it as

$$\tfrac{1}{2}(a_y^2a_z'^2-2a_ya_z\,.\,a_y'a_z'+a_z^2a_y'^2)=0,$$

or $\frac{1}{2}(aa'u)^2=0$. This is the tangential equation of the conic. It is very usual to write $\alpha_1, \alpha_2, \alpha_3$ respectively for $a_2a_3'-a_3a_2'$, $a_3a_1'-a_1a_3'$, $a_1a_2'-a_2a_1'$; then the tangential equation is written $u_\alpha{}^2=0$.

To express symbolically the discriminant of the conic, which is of the third degree in the coefficients, it is similarly necessary to use three ultimately equivalent sets of symbols, say (a), (a'), (a''). The methodical manner of introducing these is to operate on the real cubic form of the discriminant

$$a_{11}a_{22}a_{33}+2a_{23}a_{31}a_{12}-\text{etc.},$$

in succession by

$$a_{11}'\frac{\partial}{\partial a_{11}}+\ldots+a_{23}'\frac{\partial}{\partial a_{23}}+\ldots,\quad a_{11}''\frac{\partial}{\partial a_{11}}+\ldots+a_{23}''\frac{\partial}{\partial a_{23}}+\ldots,$$

so reducing it to a form linear in each of

$$(a_{11},\ldots, a_{23},\ldots), (a_{11}',\ldots, a_{23}',\ldots), (a_{11}'',\ldots, a_{23}'',\ldots),$$

and then to replace each coefficient by the symbols, a_{ij}' by $a_i' a_j'$, a_{ij}'' by $a_i'' a_j''$. The result is that the discriminant is represented by $\frac{1}{6}(aa'a'')^2$, where $(aa'a'')$ means, as before, the determinant of three rows and columns of which the diagonal term is $a_1a_2'a_3''$.

Hence we may express the discriminant of the conic $\lambda a_x{}^2+b_x{}^2=0$, formed from two different conics $a_x{}^2=0$, $b_x{}^2=0$, in the form

$$\tfrac{1}{6}[\lambda^3(aa'a'')^2+3\lambda^2(aa'b)^2+3\lambda(abb')^2+(bb'b'')^2],$$

where b, b', b'' are also equivalent symbols; so that, in the notation of p. 142 of the text,

$$\Delta=\tfrac{1}{6}(aa'a'')^2,\quad \Theta=\tfrac{1}{2}(aa'b)^2,\quad \Theta'=\tfrac{1}{2}(abb')^2,\quad \Delta'=\tfrac{1}{6}(bb'b'')^2.$$

Whence, using as above $\alpha_1=a_2a_3'-a_3a_2'$, etc., $\beta_1=b_2b_3'-b_3b_2'$, etc., we may write $\Theta=\frac{1}{2}b_\alpha{}^2$, $\Theta'=\frac{1}{2}a_\beta{}^2$. And *the condition that the conic $a_x{}^2=0$ should be outpolar to the conic $u_\beta{}^2=0$ is expressed by $a_\beta{}^2=0$.*

The equation of the director conic (p. 26) of a given conic $a_x{}^2=0$, in regard to two given points $(y),(z)$, being the condition that the lines joining the variable point (x) to (y) and (z) should be conjugate in respect to the conic envelope $u_\alpha{}^2=0$, is expressed, in terms of the coordinates $(v),(w)$ of these joining lines, by $v_\alpha w_\alpha=0$, or, at fuller length, by $(xy\alpha)(xz\alpha)=0$. This last, in terms of the equivalent symbols $(a), (a')$ for the point-equation of the conic, α_1 being $a_2a_3'-a_3a_2'$, etc., as before, is the same as

$$(a_xa_y'-a_ya_x')(a_xa_z'-a_za_x')=0;$$

this, in unsymbolical form, is

$$a_x{}^2 \,.\, a_y a_z - a_x a_y \,.\, a_x a_z=0,$$

and is then easily verified to be the condition that the segment joining (y) to (z) should be divided harmonically by the two tangents from (x) to the conic, whose equation, with (ξ) as current coordinate, is $a_x{}^2 . a_\xi{}^2-(a_xa_\xi)^2=0$.

It is easy also to verify (a), that the condition that the line (u) should meet the conics $a_x{}^2=0$, $b_x{}^2=0$, $c_x{}^2=0$ in three pairs of points in involution, is expressed by

$$(bcu)(cau)(abu)=0;$$

this is then the tangential equation of the cubic envelope considered below, in the Addition to p. 145, and called the *Cayleyan* of the three conics; and (b), that the Jacobian of the three conics is expressed by $(abc)\,a_x b_x c_x=0$.

p. 145. The theorem, proved in Ex. 7, p. 29, that the three intersections of a triad of tangents of a conic lie, with the intersections of another triad of tangents, upon a conic, is capable of generalisation. If three triads of tangents of the same conic be taken, and we consider the three conics, each containing the six intersections of the pairs in two of the triads, then these three conics meet in a point. More precisely, if $BC, CA, AB, B'C', C'A', A'B'$, and IJ, JS, SI be tangents of a conic, the conics containing respectively (A, B, C, S, I, J), (A', B', C', S, I, J), (A, B, C, A', B', C') meet in a point; or, in metrical language, if BC, CA, AB as well as $B'C', C'A', A'B'$, be tangents of a parabola, the circles A, B, C and A', B', C' have, beside the focus, S (p. 81), another common point H; this lies on the conic containing A, B, C, A', B', C'. This can be proved (C. Taylor, *Anct. and Mod. Geom. of Conics*, 1881, p. 360) by shewing that in metrical language, the angle subtended at H by any two of the six points A, B, C, A', B', C' is equal to the angle between the two joins respectively opposite to these points. Of this statement a non-metrical proof is added below.

The theorem converse to the general theorem is also true, namely, if three conics have a common point, the nine common chords of pairs of these, other than the common chords through the common point, all touch a conic.

The theorems however arise from the result referred to in the preceding Addition, that a line which meets three conics in pairs of points belonging to the same involution, touches a curve of the third class. For, if this be assumed, it is clear that the eighteen common chords of the pairs of the conics belong to the envelope; and that, if the three conics have a common point, all lines through this point equally belong to the envelope. In this case, then, the envelope degenerates into the pencil of lines through the common point of the conics (expressed by a linear equation in the coordinates of the variable line), and a conic envelope, which is the conic of the converse theorem just stated (Picquet, *Étude Géom....de sections coniques*, Paris, 1872, p. 27, etc.).

We prove the theorem of the cubic envelope in a manner different from that of the preceding Addition: If a line $ux+vy+wz=0$ meet the conics $U=0$, $V=0$, $W=0$ in pairs of an involution (to which will then belong the pair in which the line cuts any conic $\lambda U+\mu V+\nu W=0$, in which λ, μ, ν are any constants), there must be, of the involution determined on the line by the conics $\lambda U+\mu V=0$, one pair lying on $W=0$; and, therefore, for proper values of $\nu, l, m, n, \lambda, \mu$, there must exist an identity

$$\lambda U+\mu V+\nu W+(lx+my+nz)(ux+vy+wz)=0.$$

Equating to zero the coefficients of $x^2, y^2, z^2, yz, zx, xy$ in this, and eliminating the constants $\lambda, \mu, \nu, l, m, n$ from the resulting six equations, we find for u, v, w a homogeneous cubic relation expressible by the vanishing of the determinant of six rows

$$\begin{vmatrix} u & 0 & 0 & 0 & w & v \\ 0 & v & 0 & w & 0 & u \\ 0 & 0 & w & v & u & 0 \\ a & b & c & 2f & 2g & 2h \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \end{vmatrix}$$

in which the last three rows contain the coefficients in U, V and W.

If the three conics have a common point, we may suppose this taken for $y=0$, $z=0$; then the three coefficients a vanish, and the determinant divides by u. The locus then breaks up into a conic envelope, and the common point, whose tangential equation is $u=0$. If the three conics have two common points, we may suppose, beside the three coefficients a, that also the three coefficients b are zero. The determinant is then the product of uv and a factor linear in u, v, w; the envelope then consists of three pencils of lines, two with centres at the common points, and another. If, in metrical terms, we speak of the conics as circles, in this case, this is the theorem that any line through the radical centre of the circles, in which the three radical axes of the circles cointersect (p. 70 above), cuts the circles in three pairs of points in involution. If the three conics be such that there is a point whose polar line is the same for all, we may suppose the coefficients g, h in all the conics to be zero; the determinant then again divides by u, and the envelope contains the pencil of lines through the common pole. In metrical terms we may say that the twelve common chords of three conics which have a common centre, other than the six common diameters, all touch the same conic. Conversely, by considering the lines of the envelope through the intersections of two of the conics, we prove that if the cubic envelope contain a pencil of lines through a point, then this point is either common to the three conics, or has the same polar line in regard to all; the former requires only one condition for the conics, while the latter requires two.

Now, returning to the hypothesis of three triads of tangents of a given conic, we may take for the conics U, V, W those of which each contains the six intersections arising from two triads of tangents. The cubic envelope belonging to U, V, W must then contain all the nine tangents of the original conic, each of which is a common chord of two of the conics U, V, W. As a cubic envelope contains in general only six tangents of the original conic envelope, we infer that the cubic envelope in this case consists of this conic envelope, together with a pencil of lines through a point, and hence, in general, that the three conics U, V, W have a common point. Conversely, the theorem stated as to the nine common chords of pairs of three conics which have a common point (other than the chords through this point)—that these nine chords touch a conic—follows at once.

In regard now to the proposition referred to above, from which a proof of this result may be constructed independently of the cubic envelope: Let the lines BC, CA, AB, as well as the lines $B'C', C'A', A'B'$, and the lines IJ, JS, SI, be nine tangents of a conic Φ. Let f denote the conic containing A, B, C, S, I, J, and f' the conic containing A', B', C', S, I, J; and let H be the fourth common point of the conics f, f'. Further, let BC, $B'C'$ meet IJ in X and X', respectively, and HA, HA' meet IJ in U, U', respectively, while HS meets IJ in K, and the conic Φ touches IJ in F. Then the involution determined by the two pairs I, J and K, F contains the pairs X, U and X', U'; and hence contains four other pairs obtained by replacing A by B or C and A' by B' or C'. For the triads A, B, C and S, I, J are (Ex. 21, p. 45) both self-polar in regard to the same conic, with respect to which f and Φ are polar reciprocals (Ex. 24, p. 47); thus the range of points A, B, C, S, I, J on the conic f, as seen from any point O of this conic, is related to the range, on any tangent of the conic Φ, obtained by the intersections of this with the respectively opposite tangent lines of Φ, BC, CA, AB, IJ, JS, SI. We consider this range on IJ; if $BC, CA, AB, OA, OB, OC, OS$ meet IJ respectively in X, Y, Z, P, Q, R, T, these last four varying as O varies on f, and F be the point where Φ touches IJ, we infer that the range P, T, I, J is related to the range X, F, J, I, which shews that X, P belong to the involution determined by I, J and T, F. In particular when O is at H, the points P, T become those above denoted by U, K, respectively, and we have the result stated above. To complete the theorem under consideration, it is then to be shewn, from the relations obtained, that the conic containing A, B, C and A', B', C' has H for its fourth intersection with f or f'.

It can be shewn that any three conics $U=0$, $V=0$, $W=0$ may be regarded as the polar conics of three properly chosen points with respect to a single cubic curve, say F. Any conic $\lambda U+\mu V+\nu W=0$ is then the polar conic of another point, in regard to the same cubic F. The cubic envelope we have discussed is then called the *Cayleyan* of F. It is clear from our deduction that any line of the Cayleyan makes up, with another line, a degenerate conic of the system $\lambda U+\mu V+\nu W=0$ (and the other line is then evidently also a line of the Cayleyan). If we now consider the conic envelopes which are inpolar to all of $U=0$, $V=0$, $W=0$, these, expressed in tangential coordinates, will equally form a linear system of three terms, say $\rho\Theta+\sigma\Phi+\tau\Psi=0$, in which ρ, σ, τ are parameters (cf. p. 142); and we may, dually to what has preceded, consider the locus of the points of degenerate point-pairs belonging to this latter system. But a point-pair inpolar to a conic consists (pp. 36, 144) of two points which are conjugate in regard thereto. Thus the locus whose consideration is suggested is that of pairs of points which are conjugate to one another in regard to all the conics of the system $\lambda U+\mu V+\nu W=0$. Such points arise naturally from what has been said. For on any tangent of the Cayleyan there is a pair of points which are the double points of the involution cut thereon by all the conics of this system; and these are conjugate to one another in regard to all these conics. Thus the locus suggested is that of points whose polar lines in regard to $U=0$, $V=0$, $W=0$ are concurrent; as we see at once by forming the determinantal equation which expresses the condition, the locus is a cubic curve. It is that known as the Jacobian of the three conics. Another definition of the curve is possible, namely the locus of the point of intersection of the two lines of a line-pair of a degenerate conic of the system $\lambda U+\mu V+\nu W=0$—as we may easily prove; at a double point of the involution, on a tangent of the Cayleyan, by these conics, there are two coincident intersections of this line with a conic of the system; there is in fact a line-pair, of two tangents of the Cayleyan, which intersect at this point. From this it follows that we may regard the Cayleyan as the Jacobian of the system of conic envelopes, $\rho\Theta+\sigma\Phi+\tau\Psi=0$, inpolar to the original system; or the Jacobian of the original system as being the locus of points from which the pairs of tangents to Θ, Φ, Ψ form a pencil in involution.

In regard to the matters here dealt with reference may be made to Hesse, *Ueber Curven dritten Ordn.*, *Crelle*, XXXVI (1848); Cayley, *Curves of the third order* (1856), *Papers*, II, p. 381; Cremona, *Introduzione ad una teoria geometrica delle curve piane*, Bologna, 1861 (*Opere*, t. I); Salmon, *Higher Plane Curves*; Picquet (*loc. cit.*). Several of the following examples are suggested by this last.

(*a*) In a system of conics $\lambda U+\mu V+\nu W=0$ are three whose equations can be taken to have the forms

$$x^2+2myz=0,\ y^2+2mzx=0,\ z^2+2mxy=0,$$

where m is a constant; and the system of conics inpolar to this system is based upon three expressed by

$$mu^2-vw=0,\ mv^2-wu=0,\ mw^2-uv=0.$$

(*b*) Three conics having two common points can be supposed to have equations

$$z^2+2xy+2g_ixz+2f_iyz=0, \qquad (i=1, 2, 3),$$

and the Jacobian of these has the equation

$$z(z^2-2xy)=0.$$

The conic $z^2-2xy=0$ cuts all three given conics at right angles in respect of the two common points.

(*c*) Three conics with a common pole and polar line are capable of the forms

$$x^2+b_iy^2+c_iz^2+2f_iyz=0, \qquad (i=1, 2, 3)$$

and their Jacobian consists of the common polar line $x=0$, together with a pair of lines through the common pole.

(*d*) Through the four common points of any two of a set of three conics can be drawn a conic to have two given points as conjugate points. The three such conics have four common points.

(*e*) If conics which are rectangular hyperbolas in regard to two arbitrary points I, J (p. 83) be drawn through two given points A, B, any line which is at right angles to AB, in regard to I, J, cuts these conics in pairs of points of an involution.

(*f*) In a system of conics $\lambda U+\mu V+\nu W=0$ there is one which is a circle, say Ω, with respect to two arbitrary points I, J. The circle, with centre on any tangent of the Cayleyan of U, V, W, which contains the two double points of the involution on this tangent, cuts the circle Ω at right angles (p. 66). Cf. the generalisation of Gaskin's theorem given above in the Addition to p. 49.

(*g*) Given any four conics, there are three lines each cutting the conics in four pairs of points of the same involution. There are in fact two linearly independent conic envelopes, say Θ, Φ, which are inpolar to all the four given conics (p. 142); and in the system $\lambda\Theta+\mu\Phi=0$ there are three degenerating into a point-pair.

p. 147. The form to which a pair of quadratic polynomials U, U', homogeneous in n variables, can be simultaneously reduced by linear transformation of the variables, depends upon the character of the discriminantal equation in λ of the quadratic $U-\lambda U'$. We suppose here that the discriminant of both U and U' is other than zero. The various possibilities are then all included in the statement following: Form a symbol $\vartheta_p\phi_q\ldots\psi_r$, where the number of ϑ, $\phi, \ldots, \psi$ may be n, or $n-1, \ldots$, or only 1, and the positive integers $p, q, \ldots, r$ have a sum equal to n. Corresponding to ϑ_p take p variables, say $\xi_1, \ldots, \xi_p$; corresponding to ϕ_q take q variables, say $\eta_1, \ldots, \eta_q$; ..., and finally, corresponding to ψ_r take r variables, say $\zeta_1, \ldots, \zeta_r$. The n variables $\xi, \eta, \ldots, \zeta$ are the transformed variables. Then, corresponding to ϑ_p write down a pair of quadratic polynomials in $\xi_1, \ldots, \xi_p$, of forms given immediately, say Θ_p and Θ_p'; corresponding to ϕ_q write down a pair of quadratic polynomials in $\eta_1, \ldots, \eta_q$, say Φ_q and Φ_q'; ...; finally, corresponding to ψ_r write down a pair of quadratic polynomials in $\zeta_1, \ldots, \zeta_r$, say Ψ_r and Ψ_r'. The rule for the forms which these polynomials may have is the same in each case, and may be stated for Θ_p, Θ_p' only; these are respectively

$$\Theta_p=\xi_1\xi_p+\xi_2\xi_{p-1}+\ldots+\xi_p\xi_1,$$
$$\Theta_p'=\vartheta\,\Theta_p+\xi_1\xi_{p-1}+\xi_2\xi_{p-2}+\ldots+\xi_{p-1}\xi_1.$$

The reduced forms for the two original polynomials are then simply

$$U=\Theta_p+\Phi_q+\ldots+\Psi_r,$$
$$U'=\Theta_p'+\Phi_q'+\ldots+\Psi_r';$$

these contain explicitly only the constants $\vartheta, \phi, \ldots, \psi$, whose number may be n, or $n-1, \ldots$ or only 1. These constants need not all be different, and, in the extreme case, may all be equal.

For the case of two conics considered in the text, the symbols $\vartheta_2\phi_1$, ϑ_3 correspond to the cases of two, or three, coincident intersections, respectively. For the other cases given in the text the respective symbols, in order, are $\vartheta_1\phi_1\psi_1$, $\vartheta_1\vartheta_1\phi_1$, $\vartheta_2\vartheta_1$.

The reduction of two quadratic polynomials, as depending on the discriminantal equation, was initiated by Sylvester, *Math. Papers,* I (1904), pp. 119, 139, 219. The classical account is by Weierstrass, *Werke,* II (1895), p. 19. It may be remarked that the form for Θ_p is arbitrary, and may for instance be a sum of squares, subject to a suitable change for Θ_p'. For the determination of a quadratic in regard to which the two given quadratics are polar reciprocals, reference may be made to *Proc. Camb. Phil. Soc.* XXIII (1926), p. 22, where references are given.

p. 152. We add the three following examples:

(*a*) Anticipating the definitions of angle and distance given in Chap. v, we may associate with a circle whose equation is as in Ex. 5, p. 111, a *radius,* r, such that $g^2+f^2-c=r^2$. Then we may prove that the cosine of the angle between the lines drawn from the centres of two circles to one of their common points is the sum of the products of corresponding elements of the two sets

$$(g_1/r_1,\ f_1/r_1,\ \tfrac{1}{2}c_1/r_1,\ -1/r_1),\quad (g_2/r_2,\ f_2/r_2,\ -1/r_2,\ \tfrac{1}{2}c_2/r_2).$$

This sum is then zero when the circles cut at right angles; and is $+1$ or -1 when the circles touch; we may say that they *touch internally* when the sum is $+1$, and *externally* when it is -1.

We may denote this sum by $(1, 2)$. If we take five circles, by combining them in pairs there will arise sums (i, j), for $i, j=1, 2, \ldots, 5$. Prove *that the determinant of five rows and columns, of which (i, j) is the element in the i-th row and j-th column, is identically zero.*

As a particular application prove that if every two of the circles (1), (2), (3) touch externally, and all these circles touch (4) internally, while (5) cuts (1), (3) and (4) at right angles, then $(25)^2=4$. And interpret this when (5) is a line (not meeting the circle (2) in real points). This particular problem goes back to Pappus (*Coll. Math.* IV, xii). See Steiner, *Ges. Werke,* I (1881), p. 47, who suggests (p. 51) a general problem which may be solved by the determinantal equation suggested. See also Cayley, *Papers,* I (1841), p. 4; Darboux, *Ann. d. l'École norm.* I, 1872; and Frobenius, *Crelle,* LXXIX, 1875. An account of Pappus's results is given by Heath, *History of Greek Math.* II (1921), p. 376. A more general result, including the above, is this: Circles (1), (2), (3) touch one another in pairs externally; circle (4) touches (1) and (2), and surrounds all three circles (1), (2), (3). Circle (5) cuts (3) and (4) at right angles. If x, y be the cosines of the angles made by (5) with (1) and (2), prove that

$$(x-y)^2+m(x+y)^2=4,$$

where m depends on the angle between (3) and (4), vanishing when these touch (cf. Steiner, *Werke,* I, pp. 43, 135).

(*b*) Let A, B, C be any three points of a conic and H the pole of the Hessian line of A, B, C, so that AH, BC are conjugate lines, etc.; and let any line through H meet the conic in O and O'. Next let P, Q, R be other three points of the conic which are apolar with A, B, C. Prove that the conics through O, P, Q, R cut the same involution on the Hessian line of A, B, C as do the conics through the four points O, A, B, C; and that the double points of this involution are on the conic through O', H, A, B, C (cf. Ex. 26, p. 147).

Prove that there are three points, A, B, C, of a conic whereat the circle of curvature passes through any given point O of the conic—the circle of curvature at A being that circle having three intersections with the conic coincident at A, etc.; further that the four points O, A, B, C lie on a circle, and the normals of the conic at A, B, C meet in a point, while the centroid of the triad A, B, C is the centre of the conic (cf. p. 93, above. See Steiner, *Werke,* II, pp. 377, 691, and Joachimsthal, *Crelle,* XXXVI, p. 95).

(*c*) We may have two sets of *four* points, or more, on a line or on a conic, apolar to one another, the condition, as for two sets of three points, being the vanishing of the bilinear invariant of the two equations which determine the sets. Prove, for example, that any conic dividing harmonically one join of a triad of points which are self-polar in regard to a given conic Ω, meets Ω in four points which are apolar with the four intersections of Ω with the other two joins of the self-polar triad.

p. 155. A discussion of non-Archimedean geometry will be found in Enriques, *Enzyklopädie d. Math. Wiss.* III, 1, pp. 117–129; Hilbert, *Grundlagen d. Geom.*; K. Th. Vahlen, *Abstrakte Geom.* See also the treatise of Veronese, *Fondamenti di geometria*, Padova, 1891.

p. 157. For exposition of some of the many proofs of the existence of the roots of an algebraic equation, reference may be made to Netto's *Algebra*, I (1896), pp. 25, 173; and to Enriques, *Le Matematiche elementari*, II (1925), p. 186.

p. 165. If we can construct the polar of a given point in regard to a given conic, we can find the point P' which is the intersection of the polars of a point P in regard to two given conics. As P moves on an arbitrary line, P' describes a conic through the triad of points self-polar in regard to both conics (see p. 38). This triad is then determinable by taking three arbitrary lines. The reader should consult the detailed discussion in Poncelet, *Traité des Propriétés Projectives* (1865), I, p. 193, etc.

p. 178. For an entirely different discussion see Hilbert, *Grundlagen der Geom.* 1923, p. 117.

p. 181. See also Bonola, in Enriques, *Le Matematiche elementari*, II (1925), p. 309; K. Th. Vahlen, *Abstrakte Geom.* (1905), pp. 258, 261; J. Hjelmslev, *Math. Ann.* LXIV (1907), p 472; Hilbert, *Grundlagen*, p. 33; and the general references in Note III, p. 237, above. The quadrangle for which three angles are right angles is sometimes called a Lambert quadrilateral.

p. 186. A notable deduction that the three possibilities for the Absolute conic which are discussed in the text arise logically from the properties which seem to characterise the space of our experience is found in Lie, *Transformationsgruppen*, III, 1893 (in particular, Theor. 28, p. 353). See also Poincaré's discussions in his four volumes of essays (Paris, Flammarion); and the general references in Note III, p. 237, above.

That, in the Greek efforts to construct a logical theory of our conception of rigid solid bodies, Euclid's postulate of the unique parallel was recognised as the adoption of one alternative, seems clear from the words of Geminus (? 70 B.C.) quoted in Proclus's *Commentary on Euclid*, Book I (? 450 A.D.). See Heath's *History of Greek Math.* (Oxford, 1921), II, p. 227: "The fact that the straight lines converge is true and necessary, but the statement...they will sometime meet...is not necessary."

In the view adopted in this volume, full clarity is obtainable only by giving up, beside the postulate of the unique parallel, also the postulate of absolute "length," this being regarded as only one of possible correspondences between one pair of points and another pair of points.

Bare reference may be made here to Clifford's suggestion for parallel lines, defined in regard to one of the two systems of generators of an absolute quadric surface; the line through a given point parallel, in this sense, to a given line, is the transversal from this point to the two generators of the quadric which meet the given line. In this connexion also the reader may prove that, considered relatively to the imaginary surface $x^2+y^2+z^2+t^2=0$, the angle, a, between any two intersecting generators of the surface $x^2+y^2-m^2(z^2+t^2)=0$ is the same, given by $\tan^2\frac{1}{2}\alpha=m^2$; and the interval between any two neighbouring points of the surface is given by

$$ds^2=du^2+dv^2+2du\,dv\cos\alpha,$$

where u, v are constant along generators. Regarded relatively to the former, this latter is that called Clifford's surface; its whole extent is finite, and the geometry upon it is Euclidean. See Klein, *Abhandl.* I (1921), p. 362.

p. 199. For a fuller discussion the reader may see Bianchi, *Geometria differenziale*, II (1923), pp. 434, 506, etc.

p. 202. The $d\sigma^2$ can also be expressed by

$$\begin{aligned}d\sigma^2&=t^{-2}(dt^2-dz^2+dx^2+dy^2)\\&=(z^2-x^2-y^2)^{-2}[(z\,dx-x\,dz)^2+(z\,dy-y\,dz)^2-(x\,dy-y\,dx)^2]\\&=[d(x/t)]^2+[d(y/t)]^2-[d(z/t)]^2.\end{aligned}$$

p. 206. In regard to the history of the star pentagon see Heath, *Hist. of Greek Math.* (Oxford, 1921), I, p. 161.

p. 218. For configurations in general there is an Article, E. Steinitz, *Konfigurationen der proj. Geom., Enzykl. der Math. Wiss.* III, 1, pp. 481-516.

For the particular figure of p. 218, see Veronese, *Behandlung der proj. Verhältn....Projizierens und Schneidens, Math. Ann.* XIX, 1882. This figure may be regarded from many points of view. For instance, for the figure of ten lines and ten points in a plane we may state the theorem: Omitting four lines of the figure of which no three meet in a point, and their six intersections, there remains a set of four points; and there are, in all, five such sets of four points. If an arbitrary point, O, be taken in the plane, the five conics, each through O and one set of four points, have two further points, P, Q, in common; and O, P, Q is a self-polar triad in regard to the conic with respect to which the whole figure is self-polar. Of this result (A. C. Dixon, *Quart. J. of Math.* XXIII, 1889, p. 343), a simple proof can be given by projection (cf. Vol. IV of this book, p. 11; also Vol. III, p. 202).

For the general figure, a simple notation for the points and spaces may be explained as follows: Let the aggregate of $(k+1)$ independent points which determine a space $[k]$, of k dimensions, be called a *simplex*, and a flat space of $(k-1)$ dimensions lying therein be called a *prime*. Suppose, in space of $(n-1)$ dimensions, we have two simplexes, each of n points, in perspective by n lines from a point O, every line containing a vertex of each simplex. Denote the vertices of one simplex by the pairs of symbols $(a1)$, $(a2)$, ..., (a, n), and the corresponding vertices of the other simplex by $(b1)$, $(b2)$, ..., (b, n), the centre of perspective, O, being denoted by (ab). The edge joining the vertices (ar), (as) of one simplex will meet the edge containing the vertices (br), (bs) of the other simplex, say in the point (rs). The $\frac{1}{2}n(n-1)$ points (rs) lie in a prime, which we may denote by $[ab]$. In all, including O, we thus have

$$1+2n+\tfrac{1}{2}n(n-1),\ =\tfrac{1}{2}(n+1)(n+2),$$

points $(\rho\sigma)$, in which ρ (or σ) has the range of values a, b, 1, ..., n; and every three points of such symbols as $(\rho\sigma)$, $(\sigma\tau)$, $(\tau\rho)$ are in line. If, omitting the four points $(a, n-1)$, (a, n), $(b, n-1)$, (b, n) for a moment, we consider the prime containing O and the $(n-2)$ points $(a1)$, $(a2)$, ..., $(a, n-2)$, this will contain the points $(b1)$, $(b2)$, ..., $(b, n-2)$, and, also, all the $\frac{1}{2}(n-2)(n-3)$ intersections (pq) in which neither p nor q is $(n-1)$ or n. This prime also will thus contain

$$1+2(n-2)+\tfrac{1}{2}(n-2)(n-3),$$

or $\frac{1}{2}n(n-1)$ points; and we may denote it by $[n-1, n]$. We may likewise denote the prime containing all the points of the original first simplex, other than (ar), by $[br]$, and similarly denote the primes of the second simplex by symbols $[ar]$. The whole figure thus contains the prime $[ab]$ and the primes $[ar]$, $[br]$, $[rs]$; in all

$$1+2n+\tfrac{1}{2}n(n-1), \text{ or } \tfrac{1}{2}(n+1)(n+2),$$

primes $[\rho\sigma]$. The prime $[\rho\sigma]$ then contains all points (rs) in which neither r nor s is one of ρ or σ; and it may be proved that it contains all the $\frac{1}{2}(n-1)(n-2)$ points of the figure which are common to the two primes $[\rho\tau]$, $[\sigma\tau]$, whatever τ may be $(\tau=a, b, 1, \ldots, n)$. If now we replace a, b by $(n+1)$ and $(n+2)$, the notation expresses that the figure is completely symmetrical, and may be initiated by taking any one of the $\frac{1}{2}(n+1)(n+2)$ points as centre of perspective of two simplexes properly taken in the figure; and it is not only thus self-dual, but there exists a quadric locus, expressed by a single quadratic equation connecting n homogeneous coordinates of the space, in regard to which the prime $[\rho\sigma]$ is the polar of the point $(\rho\sigma)$, for every one of the $(n+2)$ values of ρ and σ.

A remark may be added in regard to a particular configuration, not referred to in the text, especially as this can be used to illustrate the theory, explained in pp. 165–173 of Vol. I, of the representation of imaginary points and lines by means of triads of real elements. The figure referred to is that of nine points in a plane lying by threes on twelve lines, four of which pass through every one of the points; so that the join of any two of the nine points contains another of them. Take any four of these points of which no three lie in a line, so that the join of two of them meets the join of the other two in a fifth point of the nine; denote these four by the symbols A, B, C, D, subject to $A+B+C+D$, so that the fifth point on the pair of joins is $A+C$ or $B+D$. Then it can be proved that the nine points are those represented in the scheme

$$\begin{vmatrix} A, & D_1, & D \\ A_1, & A+C, & C_1 \\ B, & B_1, & C \end{vmatrix}$$

in which, if ω denote one of the two roots of $\theta^2+\theta+1$, we have

$$A_1=A-\omega B, \quad B_1=B-\omega C, \quad C_1=C-\omega D, \quad D_1=D-\omega A;$$

these lead to

$$A+B_1-\omega^2C_1=0, \quad B+C_1-\omega^2D_1=0, \quad C+D_1-\omega^2A_1=0, \quad D+A_1-\omega^2B_1=0,$$

and the twelve lines of the figure are those containing the triads of points in the six lines and columns of the scheme, with the six containing triads of the scheme in which no two elements are in the same row and column (corresponding to the terms in the expansion of a determinant).

Thus also the figure consists of two plane tetrads of points, each of four points joined in order, which are inscribed and also circumscribed to one another, these tetrads having the same diagonal point which is the ninth point of the figure. The twelve lines consist then of the four joins of both tetrads together with the two diagonals of both tetrads.

Recurring to the representation explained in Vol. I, p. 165, it follows that the four imaginary points of the configuration, other than the points A, B, C, D, $A+C$, are representable by triads of points on the cross joins of A, C with B and D, requiring no additional points but the intersections of these cross joins; and that the six imaginary lines of the configuration, other than the six joins of A, B, C, D, are likewise representable by triads of lines already drawn. This interesting remark is due to Mr T. G. Room.

By proper choice of coordinates the nine points may be given as the intersection of three lines represented by $u \equiv (x^2-y^2)(az+y)=0$, with three lines represented by $v \equiv (x^2-z^2)(ay-z)=0$, where $a^2=-3$. The Hessian of the cubic curve $u+\lambda v=0$ is a curve of the same form, $u+\mu v=0$.

Apolar triads, 114, 117, 124, 147

Asymptotes of a conic, 77

Auxiliary circle of a conic, 85, 88, 119, 133

Axes and foci of a conic, 77, 160

Axis of relation, or axis of homography, 16

Bauer, 235

Bipunctual conic, in regard to a triad of points, 123

Bolyai-Lobatschewsky geometry, angle of parallelism, 182; circle, 182; equidistant curve, 183; horocycle, 183; interpretation with minimal lines as circles, 203

Boscovich, 88

Brianchon's theorem, 25, 235

Burnside, 186

Caporali, 236

Castelnuovo, 236

Cayley's measure of interval deduced from Laguerre's, 195–197; Cayley-Salmon lines, 227

Centre and axes of a conic, equation referred to, 118

Centres of similitude of two circles, 112

Centroid of three points, 64

Circle: definition and centre, 65; circles at right angles, or cutting orthogonally, 66; coaxial circles, 66; limiting points and radical axis, 66; inversion in regard to, 67; Miquel's theorem, 70; circles determined by threes of four points meet in a point, and their centres lie on a circle, 71, 72; angle properties for, 76; common chords of circle and conic, 79; through three points whose joins touch a parabola, contains the focus, 81; auxiliary circle of a conic, 85, 88, 119, 133; equation of, 107, 108; circle through centres of similitude of two circles, with centre on line of centres, 132; after Lobatschewsky, 182; angle between two circles interpreted on a quadric, 193

Cone, circular sections and focal lines, 209

Configurations, some examples of, 212; a primary theorem, 218; see also Note II

Confocal conics, 79, 119; polars of fixed point in regard thereto, touch a parabola, 90; intersection of tangents at right angles describes a circle, 133

Conic, Absolute, 166, 196

Conic constructed: having two triads, lying on another conic, as self-polar triads, 45; given self-polar triad and pole and polar, 46; given self-polar triad and two points, 46; given three points and two pairs of conjugate points, 165

Conic, first properties: definition, 10; degenerate, 10; tangent of, 11, 14; Maclaurin's definition of, 13; Pascal's theorem, 13, 16, Note II; Related ranges and involution on, 14; symbols applied to, 16, 97; polar lines, 20; dual definition, 22; two through four points to touch a line, 24; four through two points to touch three lines, 39; dual of this, 41; conics through two points containing the threes of four given points, 61; conic outpolar to another, 33; triangularly circumscribed, 48

Conics associated with a triad, 53, 121; conic harmonically conjugate to a given one, 122; see also *Feuerbach's theorem*, *Nine points circle*, and *Bipunctual*

Conics through four points; their common self-polar triad, 23; cut

an arbitrary line in pairs of points in involution, 12; conjugate points in regard thereto, 38; poles of a line in regard thereto, 41; two such, whose eight tangents at the common points meet in two points, 42; Poncelet's porism, 55
Conics touching four lines: tangents from a point are in involution, 25; director circles are coaxial, 80
Conics, two, reduced equations, 146
Conjugate diameters of a conic, 77
Conjugate lines, 26, 31
Conjugate points, 28, 31; given three points of a conic, line conjugate to one join meets other joins in conjugate points, 28; conjugate points in regard to conics through four points, 38; conjugate points, lying on two conics, envelope of join of, 127; conjugate imaginary points, 158
Contact, point of, of conic, with one of five given tangents, 25
Coordinates of a point, 97; of a line, 99
Correspondence of two points in regard to conics through four points, 39; of foci of conic touching three lines, 77; of points of a conic, 135
Cremona, 219, 235, 236
Cross-ratio, or anharmonic ratio, for four points, 166; example of, 210
Cubic surface with node, applied to Pascal's figure by Cremona, 229
Curve of third order, 229

Delambre's formulae in spherical trigonometry, 205
Desmic tetrads, 213, 233
Director conic of a conic, 26; director circle, 80, 95, 125, 127, 151
Directrix of a parabola, 81
Discussion of a turning point in the logical theory, 153
Distance, Riemann's formula in space of constant curvature, 199
Double points of an involution, 3, 158
Duality in regard to a conic, 21, 22; dual of Pascal's theorem, 25

Eleven-point conic, 41
Elliptic, hyperbolic and parabolic plane, 186
Elliptic integral, from two conics, 211
Envelope of a line cutting two conics in harmonic conjugates, 44, 125; of polar lines of a point in regard to confocal conics, 90, 120; of line meeting two conics in points conjugate in regard to a third conic, 127; the same generalised, 134; of line joining points of two circles bisected by radical axis, 132
Equation of a line, 98; of a point, 100; of a conic, 101; of tangent, and polar, 104; of a circle, 107, 108; of a conic referred to self-polar triad, 107; of coaxial circles, 109; of conic referred to centre and axes, 118; of confocal conics, 119; of a plane, 190, 191
Equidistant curve, 183
Euclid's distance, and triangle, 184, 185
Exponential function, 157
Extent, between two lines, in elliptic plane, equal to twice their angular interval, 188; of a plane, 188, 201; of a triangle, 188, 203; of a circle, 189
Exterior and interior points of a real conic, 159, 164

Feuerbach's theorem, 59, 75, 89, 113, 122; Hamilton's extension of, 59, 117
Fifteen points on fifteen lines, three on each, Note II
Figure determined by $(n+2)$ points, or hyperplanes, in n dimensions, 218
Focal distances for a conic, in general form, 209, 211
Focal lines of a cone, 209
Foci and axes of a conic, 77; of a parabola, 81
Fontené, 75
Four lines in four dimensions, figure derived from, 225

Gaskin's theorem, for conics through two points outpolar to another conic, 48
Gauss, 154, 237
Grossmann, 235

Hamilton's modification of Feuerbach's theorem, 59, 117
Harmonic, condition for two pairs of points to be, 111; harmonic images, 37
Hatton, 62

Helmholtz, 237
Hesse's theorem, 31
Hessian line of three points of a conic, 30, 124; of a circle, 148; Hessian point of three tangents, 30; of a parabola, 149
Horocycle, construction of, 183; another view of, 203
Hyperbolic, parabolic and elliptic plane, 186; see *Lobatschewsky*

Imaginary points, 9, 158, 161; imaginary and real symbols, 154; imaginary conic, 163
Inpolar conic, 33-36; algebraic condition for, 142; expressed by sum of four squares, 144, 218
Interior and exterior points of a real conic, 159, 164
Intersections of two conics, number assumed, 9
Interval of two points, or two lines, after Laguerre, 166, 167; interval in regard to an Absolute conic, 168; interval for circumference of circle, 189
Invariants of two conics, 141; their geometrical significance, 142
Inversion in regard to a circle, 67; inverse of a circle is a circle or line, 68; circles at right angles invert into circles at right angles, 69; circle and two inverse points invert into similar figure; inverse of centre of circle, 69; Feuerbach's theorem by inversion, 74
Involution, 2; common pairs of two involutions, 3, 158; composition of a projectivity from two involutions, 6, 50; on a line by conics through four points, 4, 12; dual of this, 4, 25; on a conic, 14; symbolic representation of, 111; reality of double points, 158; general involution, 135; determined by two sets, 136; determined by conics through four points, 138; apolar triads as particular case, 147

Kirkman, 227, 235
Klug, 236

Laguerre interval, 167; angle interpreted on a quadric, 192, 196
Lambert's quadrilateral, 181
Length, and movement, 169
Limiting points of coaxial circles, 66
Lobatschewsky-Bolyai geometry, angle of parallelism, 182; circle, 182; equidistant curve, 183; horocycle, 183; interpretation with minimal lines as circles, 203
Locus of point from which tangents to two conics form a harmonic pencil, 125; of intersection of tangents at right angles of two confocals, 133; of poles of line in regard to conics through four points, 4
Logarithmic function, 157

Maclaurin's definition of a conic, 13
Magnitude, order of, for real symbols, 156
Measurement in regard to two points, 166; in regard to a conic, 170, 178, 184; comparison of the several methods, 186, 187
Metrical properties, 63; metrical geometry in a plane with two Absolute points deducible from geometry on quadric surface, 189
Middle point of two points, 63
Miquel's theorem, for a triad of points and three circles, 70
Morley, 114
Moulton, 186
Movement, 169

Nanson, 61
Napier's analogies, 206
Nine points circle, see *Feuerbach's theorem*; of self-polar triangle of parabola contains the focus, 83; is locus of middle point of orthocentre and point of circumcircle, 89; point of contact with inscribed circle, 114
Non-Archimedean (non-Eudoxian) symbols, 155
Normal of a conic, 91; four can be drawn from an arbitrary point, 91; feet lie on a rectangular hyperbola, 91; three of the feet and the opposite of the other lie on a circle, 93, 119; normals to a parabola from a point, their feet lie on a circle through the vertex, 94; condition three normals meet in a point, 119

Orthocentre of three points, 64
Orthogonal circles, condition for, 110; line through centre of either cuts

circles harmonically, 66, 126; invert into orthogonal circles, 69
Outpolar conics, 33-36; algebraic condition for, 142; and triangularly circumscribed conic, 146

Pappus' theorem, complete figure, 215
Parabola, 81; obtained as envelope of polars of a point in regard to confocal conics, 90
Parabolic, or Euclidean, plane, 186
Parameter expression for a general conic, 103; for conic referred to its centre and axes, 118
Pascal's theorem, 13; and related ranges of points on a conic, 15; converse of, 16; dual of, 25; Pascal's *hexagrammum mysticum*, 219; Pascal line, symbol for in general figure, 223, 227; Pascal's figure derived from four dimensions, 224
Pedal line of three points of a conic, 29; of a circle, 71; pedal of conic from focus is auxiliary circle, 85; of parabola is tangent at vertex, 82; pedal circle of a point for three lines, 87; when point moves on a line through circumcentre, 88; pedal line for a triad in involution, 139
Perpendicular lines, 63
Plane, equation of, 190, 191
Plücker, 227, 235
Poincaré, 197
Polar line and point, in regard to a conic, 20; self-polar triad, 23; polars of three points give a triad in perspective with original, 27, 31, 123; polar lines of a point in regard to conics through four points meet in a point, 37; poles of a line in regard to conics through four points lie on a conic, 41; dual of this, 42, 90; polar reciprocal of one conic in regard to another, 47, 91, 140, 147; polars of a point in regard to conics through fives of six points touch a conic, 61; polar reciprocal of a certain parabola gives the rectangular hyperbola of Apollonius, 91
Polynomial, roots of, 110, 135, 157
Poncelet's theorem, for porism of tangents of conics through four points, 55, 96
Positive and negative real symbols, 155
Projectivity on a conic resoluble into succession of two involutions, 50

Quadratic system of conics, inpolar to another conic, 145
Quadric surface, elementary properties of, 190
Quadrilateral with three right angles, 181

Radical axis of two circles, 66; radical axes of three circles meet in a point, 70, 112
Range of points on a conic, 14, 52; on variable line, by conic and joins of three points of this, 28
Real and imaginary points, 9, 160; real and imaginary symbols, 154; real and imaginary conic, 163
Reality of common harmonic conjugates with respect to two given pairs, 158; reality a relative term, 160; reality of common self-polar triad of two conics, 164
Reciprocal polar of one conic in regard to another, 47, 140, 147
Rectangular hyperbola, definition, 83; contains orthocentre of three of its points, 84; conjugate diameters of, examples of, 84; through three points, locus of centres, 88
Related ranges on the same line, 1; condition two ranges be related, abbreviated argument for, 8; relation of two ranges reduced to two involutions, 6, 50; envelope of line joining corresponding points of two related ranges on a conic, 52
Richmond, 219, 236
Riemann's space, as derived from projective space, 199
Right angles, lines at, 63, 110; circles cutting at, 110, 111

Salmon, 59, 227, 236
Schoute, 236
Segre, 236, 238
Self-polar triad, in regard to a conic, 23; of two conics, algebraic determination of, 140; self-conjugate tetrad, Hesse's theorem, 31
Similitude, centres of, for two circles, 112; circle through, with centre on line of centres, 112, 132
Soal, 62

Sphere, division of surface into four equal and congruent triangles, 197, 207
Spherical and elliptic geometry, 178; spherical geometry and plane geometry, 196, 197
Staudt, von, 232, 235; theorem of Seydewitz, 28
Steiner, 72, 216, 231, 232, etc.
Sylvester, 220, 235
Symbols applied to involutions, 4; applied to initial theorems for a conic, 16; symbol of a line, 99, 100; applied to general theory of conics, Chap. III; applied to measurement of intervals, Chap. V
Syntheme, 220

Tangent of a conic, 11, 14; when tangents at intersections of two conics meet in two points, 42, 66; tangents of two conics, at intersections with a line, meet on another conic, 54; general tangent of a conic which touches three lines at given points, 58; tangents common to pairs of three conics which touch three lines, 60; tangents of confocal conics which are at right angles meet on a circle, 133
Tangential coordinates, and tangential equation, 100, 105, 106; of confocal conics, 119
Taylor, H. M., 61; J. P., 75; C., 88
Tetrads of points of a conic whose joins touch another conic, 96, 127; see also *Poncelet's theorem*
Three conics related in a particular way, 149
Triads, two, of points of a conic: their joins touch another conic, 29; two self-polar triads are points of another conic, 35, 45, 48; three triads of points of a conic are in perspective with another triad, 52; relation of a conic to a triad of general points, 53; centroid and orthocentre of a triad, 64
Triangle, definition of, 173; trigonometrical formulae for, 176, 177, 179
Triangularly circumscribed conic, 48, 145
Two conics, enumeration of reduced equations in all cases, 146
Two-two relation on a conic, condition it be derived from a general involution, 137

Veronese, 235
Vertex of a parabola, 82

Wallace line (pedal line), 29, 71
Weill, 139
White, 236

1923

PRINTED IN GREAT BRITAIN

PREFACE

THE present volume is devoted to geometry in three dimensions. The discussion of the logical standpoint, to which sufficient space has been given in the preceding volume, is left aside; and, from a desire to limit the size of the volume, many things are omitted which might well have been included. What is given may, however, be regarded as essential to any student who professes to have received a mathematical education. The aptitude for geometrical construction in space, important as it is in the applications of mathematics to physics and engineering, receives, in our educational system at present, less training than it deserves. It is the writer's hope that this volume may help to emphasize this; and may convey to readers something of the fascination and freedom which belongs to the reduction of intricate geometrical relations to the properties of a constructed figure. Only by such methods, moreover, can progress be made beyond the first principles of the subject.

Up to the end of Chapter III, this volume was in type when death severed an association to which the writer owed more help than he can well express. In business, James Bennet Peace was clear and honest; in friendship, constant and self-regardless; many beside the writer deplore his loss. To him, and to the co-operation of the other members of the Staff of the University Press, great acknowledgment is due.

H. F. BAKER.

14 *July* 1923.

“TEODORO REYE, ..., *che avevo cominciato ad ammirare fin da studente, leggendo la sua classica* Geometrie der Lage; *e col quale poi non avevo tardato ad entrare in relazione scientifica, ed anche personale, sì da poter apprezzare, oltre al valore del matematico, la grande bontà d'animo dell'uomo: vero gentiluomo!*

Nato a Cuxhaven il 20 giugno 1838, ..., era passato verso il 1864 ad insegnare nel Politecnico di Zurigo. ......Aveva esordito nella scienza con lavori di Fisica matematica e di Meteorologia. Ma, poichè a Zurigo il corso del Culmann, fondatore della Statica grafica, si basava sulle teorie della Geometria di posizione, e il classico trattato di Staudt era troppo difficile per gli studenti; Reye fu condotto ad insegnare quelle teorie e ad esporle in un nuovo trattato, che uscì in due parti nel 1866 e nel 1868. ....

....

Artista non meno che scienziato, Reye ha molto contribuito a quella grandiosa e pure snella costruzione scientifica che è la Geometria di posizione, introducendo o svolgendo idee semplici e geniali; studiando, com' è carattere di essa, svariate figure in tal maniera da illuminarne di vivida luce le proprietà più profonde, e i legami che le uniscono. Non solo ci ha fatto conoscere nuovi veri; ma ci ha procurato squisiti godimenti estetici, quali solo può dare il bello. Onore e gratitudine a Lui!”

Corrado Segre, *Rendiconti...dei Lincei,* 2 Aprile 1922.

TABLE OF CONTENTS

CHAPTER I. INTRODUCTION TO THE THEORY OF QUADRIC SURFACES

PAGES

Preliminary remark. Equation of a quadric surface . . . 1
Definition of a quadric surface by means of its lines . . . 1—3
Definition of a quadric cone 4
The duality of the definition of a quadric 4
Application of the symbols; equation of a quadric . . . 5—7
Quadric defined by two conics having two points in common, and a line meeting these conics . . . . 7—10
Three conics of which every two have two points in common lie on a quadric 10
Two conics which have two points in common lie on two quadric cones 10
Quadric defined by two dually related central systems . . . 11—13
Quadric representing a plane with two fundamental points . . 13, 14
General homogeneous quadric polynomial in four variables . . 15, 16
Equation of a quadric cone 17
Condition for quadric form to represent a cone 18
Conditions for quadric form to represent two planes . . . 19
Conditions for quadric form to represent a repeated plane . . 20
General properties of a quadric given by its equation . . . 20—26
Tangent cone, or enveloping cone, of a quadric 26
Polar plane, and tangent plane, descriptively defined . . . 27
Polar line of a line in regard to a quadric 28
Polar point of a plane in regard to a quadric 29, 30
Polar point of a plane in regard to a quadric, expressed by the symbols 31
Examples of the general properties of quadrics (Exx. 1—19) . 31—56
Ex. 1. *The self-dual character of a quadric, in particular form* . 31
Ex. 2. *The same in general* 32
Ex. 3. *Two conjugate sections have tangent lines at a common point harmonic in regard to the generators; the dual of this* . . 32, 33
Ex. 4. *Self-polar tetrad in regard to a quadric* 33, 34
Ex. 5. *Tetrad of points whose opposite joins are conjugate lines; self-conjugate pentad; construction from two tetrads in perspective; analytical treatment; expression of a quadric by five squares* 34—40
Ex. 6. *A general self-polar figure in space of any number of dimensions* 40, 41

a 5

PAGES

Ex. 7. *Joins of two reciprocal tetrads are generators of a quadric* 41, 42

Ex. 8. *Symmetry of two particular quadrics arising in preceding example* . . . . 42—44

Ex. 9. *Dandelin's figure of generators; its application to Steiner points in Pascal's figure* . . . . 44—47

Ex. 10. *Construction of a self-conjugate hexad. Expression of a quadric by six squares* . . . . 47—49

Ex. 11. *Construction of an incomplete tetrad, or pentad, or hexad, of points of a quadric* 49, 50

Ex. 12. *Condition for one quadric to be outpolar to another* . . 50—52

Ex. 13. *A property of two self-polar tetrads* 52

Ex. 14. *Quadric for which two proper tetrads are reciprocal* . 53

Ex. 15. *A theorem of Chasles for the intersections of a quadric with the joins of four points* 53, 54

Ex. 16. *A further theorem for the intersections of a quadric with the joins of four points* 54

Ex. 17. *Bipunctual quadric, the harmonic conjugate of two planes* 54

Ex. 18. *The equation of a quadric touching the four planes of reference* 55

Ex. 19. *A birational transformation of a quadric into itself. Its geometrical meaning* 55, 56

The coordinates and equations of a line in three dimensions. Elements of the theory of a linear complex . . . . 56—69

Ex. 1. *The analytical conditions for a plane to contain a line* . 57

Ex. 2. *Common element of a line and point, or of a line and plane* 57, 58

Ex. 3. *The condition of intersection of two lines* 58

Ex. 4. *Lines of a quadric as a linear system* 58

Ex. 5. *The tangent planes from a line to a quadric* . . . 58

Ex. 6. *Coordinates of the polar line of a line in regard to a quadric* 58, 59

Ex. 7. *Condition a line should touch a quadric* 59

Ex. 8. *Change of line coordinates by change of reference points* . 59, 60

Ex. 9. *Generators of a quadric, of one system, belong to three linear complexes* 60

Ex. 10. *First properties of a focal system and linear complex. Analytical definition. Derivation from generators of a quadric. Sylvester's derivation. Polar lines. Linear complex consists of those lines of a focal system which intersect, and coincide with, their polars. Invariant of two linear complexes* . . . 60—66

Ex. 11. *Pole of a plane in a focal system* 66

Exx. 12—14. *Geometrical theorems. A theorem of Sylvester's* . 66

Ex. 15. *Chasles' generation of a linear complex* 66, 67

Exx. 16—22. *The focal system and Moebius tetrads* . . . 67, 68

Ex. 23. *The two lines common to a linear complex and a quadric* . 68

Ex. 26. *A skew pentagon determines a focal system* . . . 68
Ex. 27. *The polar line of a line in regard to a general quadric* . 69
Ex. 28. *The tangent lines of the curve of intersection of two quadrics; eight of these meet an arbitrary line* 69

CHAPTER II. RELATIONS WITH A FIXED CONIC. SPHERES, CONFOCAL SURFACES; QUADRICS THROUGH THE INTERSECTION OF TWO GENERAL QUADRICS

Parallel lines and planes. Middle points. Lines and planes at right angles 70, 71
Exx. 1—3 71
Spheres and Circles 72, 73
Exx. 1—5. *Plane sections of a sphere* 73
Relations of two spheres. Coaxial spheres . . . . . . 74—76
Ex. 1. *Two circles with two common points lie on a sphere* . . 77
Ex. 2. *The radical planes of the pairs of three spheres meet in a line* 77
Ex. 3. *Any three circles are met in two points by another properly taken circle* 77
Ex. 4. *Analytic treatment of the relations of two spheres. Centres of similitude* 77, 78
Ex. 5. *A sphere can be constructed of given centre to pass through a given point* 78
Ex. 6. *Sphere determined by perpendiculars from a fixed point to planes through another point* 78
Ex. 7. *Theorems for an orthogonal tetrad* 78
Relations of a quadric in general with the absolute conic. The circular sections 79
Umbilici of a quadric. Generators through these 80
Relations of a quadric cone with the absolute conic. Cone of revolution; or right circular cone 81
Ex. *Analytical conditions for a right circular cone* . . . 82
Quadric touching the absolute plane 82, 83
Ex. 1. *Umbilici of a paraboloid* 83
Ex. 2. *Two circular sections of a quadric not in parallel planes lie on a sphere* 83
Ex. 3. *Condition a plane should give a circular section* . . 83
Ex. 4. *Centres of plane sections of a quadric* 83, 84
Ex. 5. *Locus of line of intersection of two perpendicular tangent planes of a quadric* 84
Ex. 6. *Locus of normals of a quadric at points of a generator* . 84

CHAPTER I

INTRODUCTION TO THE THEORY OF QUADRIC SURFACES

Preliminary remark. We have, in previous volumes, given trouble to emphasizing the view that the use of the algebraic symbols is not necessary to the geometrical theory; and that the use of symbols of any particular system is equivalent to the adoption of definite geometrical restrictions.

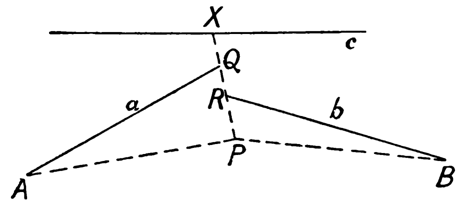
It is, however, often conducive to clearness and brevity, to employ symbols; and it is usual to suppose that the symbols have the same laws of operation as the numbers of ordinary Analysis. Accordingly in the present volume we shall employ such symbols, whenever it seems desirable. The arithmetic notion of the *magnitude* of the symbols, and especially of *infinite* values, remains excluded—as indeed it is in a logical theory of Analysis; and, as heretofore, the *length* and *congruence* of geometrical lines are not employed, save in the conventional sense explained in Volume II (Chap. V).

It will be seen that the utility of the symbols arises chiefly from the use of the *equation of a quadric* (or other) *surface*. We here deduce this from the geometrical definition of the surface. It becomes therefore an interesting problem to replace proofs depending on this equation by direct geometrical deductions from the definition.

Not much space is given in this Volume to the proof, which has already been given in Volume II, p. 191, that a plane is represented by a single equation which is linear in the coordinates; that this is so will be readily understood from the explanation given of the equation of a line, in a plane, in Volume II. A line, in this chapter, is generally given as the join of two points, or the intersection of two planes. The theory of the coordinates of a line is discussed at length in a subsequent section (pp. 56 ff.).

Definition of a quadric surface by means of its lines. We may define a quadric surface, or, as we shall often briefly say, a quadric, in several ways.

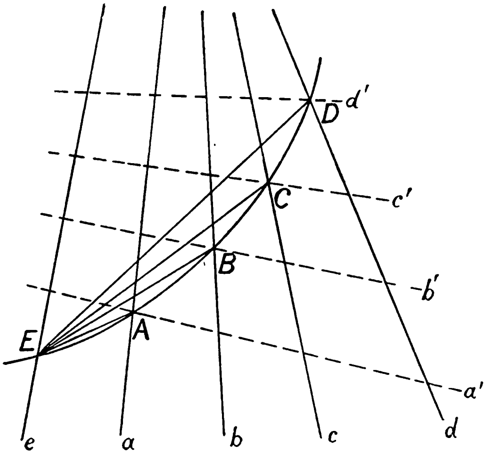
Take three arbitrary lines, in space of three dimensions, of which no two intersect. From any point of one of these can be drawn a transversal to meet both the other lines. Consider the aggregate of all the points on all the transversals so drawn. This does not include all points of space, since it is not in general possible to draw from an arbitrary point a transversal to meet three given lines.



The points of the aggregate which lie in an arbitrary plane lie on a conic. For denote the given lines by a, b, c; let an arbitrary plane meet the lines a, b, respectively, in A and B, and let the transversal drawn from an arbitrary point, X, of the third line, c, meet the lines a, b, respectively, in Q and R, and meet the arbitrary plane in P. Then the two axial pencils of planes, having, respectively, a and b as axes, given by the planes $a(X)$ and $b(X)$ as X varies on c, are related. On the arbitrary plane these give therefore the two related pencils of lines, $A(P)$ and $B(P)$. The locus of P is therefore a conic, passing through A and B; this conic equally passes through the point, say C, where the line c meets the arbitrary plane, for evidently a transversal of a and b can be drawn from this point.

If the points A, B, C are in line, the ray AC of the pencil $A(P)$ is AB, and coincides with the ray BC of the pencil $B(P)$. Then the locus of P consists, beside the line ABC, of a straight line. In other words, the aggregate now being considered, of points lying on all transversals of the three lines a, b, c, contains, in a plane which contains a transversal ABC of a, b, c, beside the points of this line, also the points of another line, say d, which does not meet a or b or c. Every point of this new line, d, is thus a point from which a transversal can be drawn to meet the given lines a, b and c. It is thus clear that the aggregate of points under consideration consists of the points of a system of lines a, b, c, d, ..., infinite in number, of which no two intersect, together with the points of another system of lines, every one of which meets all those of the first system, but of which no two intersect.

This aggregate of points constitutes a quadric. We see that through every point of the locus there pass two lines, consisting of points belonging to the locus, and the plane of these two lines contains no other points of the locus. But a general plane meets the quadric in the points of a conic. Through points $E, A, B, C, D, \ldots$ of this conic will pass lines e, a, b, c, d, ..., no two of which meet, of which the points are points of the quadric, and also lines e', a', b', c', d', ..., also skew to one another, of which every one meets all those of the first system. On the conic, the flat pencil of lines, $E(A, B, C, D)$, is a section of the axial pencil of planes ea', eb', ec', ed', which is met, by any particular one of the lines a, b, c, d, in the points where this line meets the lines a', b', c', d'. Thus we see that these lines a', b', c', d' meet the lines of the other system in related ranges, which are also related to the range, on the conic in a plane section, determined by the points where these lines a', b', c', d' meet the conic. Similarly the lines a, b, c, d determine, on any of the lines e', a', b', c', d', a range related to that of A, B, C, D on the conic.



Conversely, if, on two lines, a, b, which do not intersect one another, we have two related ranges, the joins of corresponding points of these ranges are lines which are all met by an infinite number of other lines; the points of these lines are, therefore, those of a quadric surface. For, if P, Q, R be points of the line a, to which correspond the points P', Q', R', respectively, of the line b, and a transversal, c, be drawn from any point of the line PP' to meet QQ' and RR', it follows at once, from what we have seen, that a line drawn from any point of c, to meet a and b, meets these in corresponding points of the two given related ranges thereon. The construction assumes, by hypothesis, that the lines, a, b, of the two related ranges, are not in one plane; if they are, the joins of corresponding points of the two ranges are, as we have seen in Volume II, the tangents of a conic lying in that plane, having the two given lines also as two tangents. The points of a plane, regarded as lying on the tangents of a conic in that plane, may thus be regarded as the points of a degenerate quadric, each tangent line of the conic being taken twice over as a line of the quadric, as a line of each of the systems lying on the quadric.

This account has been obtained by considering the aggregate of the points lying on all the lines which meet three given skew lines. But, in three dimensions, a line is self-dual, and two lines which have a point in common lie also in a common plane; it is proper to consider, then, also the aggregate of all the planes which pass through all the transversals of three given lines. As we have found that through any point of the quadric there pass two lines lying entirely thereon, so we have incidentally found that in any plane passing through a transversal of three given skew lines, *a*, *b*, *c*, there is another line, *d*, not meeting *a*, *b*, *c*, which meets all transversals of these.

To describe the dual correspondence in further detail it is necessary to speak first of what is meant by a quadric cone. We have seen that the quadric surface is the locus of points on lines joining corresponding points of two related ranges on skew lines, these joining lines degenerating into the tangents of a conic when the skew ranges are replaced by ranges on two intersecting lines. Similarly the aggregate of planes we are now considering, as the dual of the aggregate of points of a quadric, may be obtained by taking two skew lines as axes of two related axial pencils of planes; a line of intersection of a plane of one pencil, with the corresponding plane of the other pencil, is then a line meeting both the axes, and, as may easily be seen, in points of two related ranges thereon. The planes of the aggregate are the planes through such lines of intersection. But, now, if we take two intersecting lines, and have two related axial pencils of planes with these as axes, the line of intersection of a plane of one pencil with the corresponding plane of the other pencil, is a line through the point of intersection of the axes; the aggregate of these lines, passing through a point, constitutes what is called a quadric cone, and is the dual of the aggregate of lines in a plane which touch a conic. As two tangents of the conic meet in a point, so two of the lines forming the cone lie in a plane; as the point of intersection of two tangents of the conic becomes a point of the conic when the two tangents coincide (Vol. II, p. 25), so, if the two lines of the cone coincide, the plane containing them is replaced by a definite plane, called a tangent plane of the cone. The section of a cone by an arbitrary plane is evidently a conic, of which one point is determined by a line of the cone, and a tangent line by a tangent plane of the cone; conversely from any conic we obtain a quadric cone by projection from an arbitrary point not lying in the plane of the conic.

This being understood, consider the dual of the statement that a plane section of a quadric is a conic, through every point of which there passes a line of each of the two systems lying on the quadric. Let an arbitrary point of space be joined to every line of one system of lines lying on the quadric, by a plane. Each of these planes will, as we have seen, contain another line lying on the quadric, of the other system. The aggregate of these planes is then that of the tangent planes of a quadric cone. This is obvious from the fundamental duality of the figure. But it is clear, too, by considering that a variable line, a', of one system, of the quadric surface, meets two lines, a, b, of the other system, in related ranges of points. The plane Oa', joining the line a' to a fixed point O, thus meets the planes Oa, Ob in two related flat pencils of lines, with O as common centre. By taking a section by an arbitrary plane, the planes Oa' give rise to lines in this plane meeting two fixed lines, which are the sections of the arbitrary plane by the planes Oa and Ob, in two related ranges. These lines, therefore, are tangents of a conic in that plane; and the planes Oa' are tangent planes of a quadric cone of which all the lines pass through O. This point O is called the *vertex* of the cone, and its lines are called its *generators*; the lines of a quadric surface are also called the *generators* of the quadric.

A particular consequence is that, as there are two points of the quadric locus lying on an arbitrary line, so there are two of the aggregate of planes, passing through an arbitrary line. These may be obtained, directly from the definition, as the two common corresponding planes of two related axial pencils, just as in the case of the locus of points.

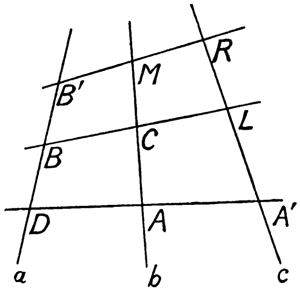
Ex. 1. If A, B, C, D, O be five general points in space, the pairs of planes joining O to the opposite pairs of joins of A, B, C, D, such as OAD, OBC, meet an arbitrary line in three pairs of points which are in involution.

Ex. 2. If an axial pencil of planes be drawn through a line, l, and a related axial pencil of planes be drawn through another line, m, which does not meet l, the lines of intersection, of a plane of the first pencil with the corresponding plane of the second pencil, define a quadric surface, upon which the lines l and m also lie.

Ex. 3. A line l meets the planes BCD, CAD, ABD, ABC, which contain the triads of four arbitrary points A, B, C, D, respectively in P, Q, R, S; another line, l', meets these planes, respectively, in P', Q', R', S'; and the four lines PP', QQ', RR', SS' all lie on the same quadric surface. Prove that the four transversals drawn from A, B, C, D, each to meet both the lines l and l', all lie on a quadric surface. (Cf. Vol. I, p. 30.)

Ex. 4. Let D, P, Q, R be four points in line, and A, B, C be three points whose plane does not contain the line. Let the transversal, l, be drawn from A to meet the lines BQ, CR; the transversal, m, be drawn from B to meet the lines CR, AP; and the transversal, n, be drawn from C to meet the lines AP, BQ. Prove that a line can be drawn from D to meet all of l, m, n.

The representation of this definition by means of the algebraic symbols. We may represent the matter very simply by means of the algebraic symbols. Let a, b, c be three skew lines, of which DAA', BCL, $B'MR$ are any three transversals. Taking D, A, C, B, which do not lie in a plane, as fundamental points, we



can choose the symbols of the points A, A', relatively to that of D, so that $A' = D + A$, and, similarly, the symbols of C, L, relatively to that of B, so that $L = B + C$. Then the symbol of R may be supposed to be

$$R = A' + \mu L = D + A + \mu(B + C)$$
$$= D + \mu B + A + \mu C,$$

where $D + \mu B$ is the symbol of some point on the line a, and $A + \mu C$ of some point on the line b. Hence we infer, for the symbols of B' and M, which lie on a line through R, respectively,

$$B' = D + \mu B, \quad M = A + \mu C.$$

Any other point of the transversal $B'M$ has thus a symbol $B' + \lambda M$, namely

$$\lambda A + \mu B + \lambda\mu C + D,$$

which, then, for different symbols λ, μ, is the general point of the general transversal of the fundamental lines a, b, c. It is thus the general point of the quadric surface under consideration. The symbol can also be written

$$D + \lambda A + \mu(B + \lambda C),$$

and the point lies on a transversal of the lines DA, BC, this transversal meeting these, respectively, in the points $D + \lambda A$, $B + \lambda C$.

We see that every point of the quadric is characterised by two particular algebraic symbols, λ and μ; and further that all points of the quadric for which λ is the same are on a line, not intersecting a, or b, or c; and all points for which μ is the same are on a line, meeting a, b, c but not meeting DA, BC, $B'M$.

The two points of the quadric which lie on an arbitrary line, say on the line joining the points whose symbols are

$$a_1A + b_1B + c_1C + D, \quad a_2A + b_2B + c_2C + D,$$

would then be found by choosing σ, so that the point of this line given by

$$(a_1 + \sigma a_2)A + (b_1 + \sigma b_2)B + (c_1 + \sigma c_2)C + (1 + \sigma)D$$

is the same, for proper values of λ and μ, as the point

$$\lambda A + \mu B + \lambda\mu C + D;$$

this requires

$$(1 + \sigma)(c_1 + \sigma c_2) = (a_1 + \sigma a_2)(b_1 + \sigma b_2).$$

We can express the character of the quadric also by representing any point of it by a symbol

$$XA + YB + ZC + TD,$$

so that X, Y, Z, T are the *coordinates* of this point relatively to the points A, B, C, D; then the sole condition for X, Y, Z, T, is that

$$XY = ZT;$$

this is called the *equation of the quadric*. If we take new points of reference A_1, B_1, C_1, D_1, such that

$$A_1 = C - D, \quad B_1 = A + B, \quad C_1 = A - B, \quad D_1 = C + D,$$

any point of space given by

$$xA_1 + yB_1 + zC_1 + tD_1,$$

is $$x(C - D) + y(A + B) + z(A - B) + t(C + D),$$

and is a point of the quadric if

$$X = y + z, \quad Y = y - z, \quad Z = t + x, \quad T = t - x,$$

that is, if $$x^2 + y^2 - z^2 = t^2.$$

This, then, is another form for the equation of the quadric. Whatever θ may be, this equation is satisfied by

$$y + z = \theta^{-1}(t + x), \quad y - z = \theta(t - x);$$

also, whatever ϕ may be, it is satisfied by

$$y + z = -\phi^{-1}(t - x), \quad y - z = -\phi(t + x).$$

It is, however, easy to see that a single *linear* equation connecting the coordinates, (x, y, z, t), of a point, implies that this point lies on a certain plane; for instance, an equation $t = lx + my + nz$ shews that the point, $xA_1 + yB_1 + zC_1 + (lx + my + nz)D_1$ is on the plane through the three points $A_1 + lD_1$, $B_1 + mD_1$, $C_1 + nD_1$. Thus the points for which $y + z = \theta^{-1}(t + x)$, $y - z = \theta(t - x)$ are those of a line; and, by taking different values of θ, we thus obtain a system of lines lying on the quadric surface; it is easy to see that no two of these have a point in common. Another system of mutually non-intersecting lines is given by the equations $y + z = -\phi^{-1}(t - x)$, $y - z = -\phi(t + x)$, for different values of ϕ. It is easily verified that, whatever θ and ϕ may be, the θ-line, of the first system, has a point in common with the ϕ-line, of the second system, this being, in fact, that given by

$$x = \theta + \phi, \quad y = 1 - \theta\phi, \quad z = 1 + \theta\phi, \quad t = \theta - \phi.$$

These expressions then satisfy identically the equation

$$x^2 + y^2 - z^2 - t^2 = 0.$$

Quadric surface defined by two conics in space having two points in common, and a line which meets these conics. We have seen that the points of a quadric which are on a plane lie on a conic. If two points, A, B, of the quadric be taken, and two planes be drawn through these two points, we thus obtain two conics lying on the quadric. Considering only the lines of the quadric belonging to one system of generators, there will be one line of this system through an arbitrary point, P, of one of these conics; this line will meet the plane of the other conic in a point, say P', which, as the line lies entirely on the quadric, will be on the other conic. There is thus a (1, 1) correspondence between the points of the two conics, whereby to every point, P, of one of these conics, there corresponds a definite point, P', of the other, while P' equally determines P. By what has been proved above, the range of points, P', on one conic, is related to the range of points, P, on the other.

Conversely, let two arbitrary conics be given, lying in different planes, but having two points, A, B, in common; let a further arbitrary fixed point, C, be taken on one conic, and a point, C', on the other; then, we can, to any variable point, P, of the former conic, make correspond a definite point, P', of the latter conic, by the condition that the range of points, A, B, C, P, of the former conic is related to the range of points, A, B, C', P', of the latter. The aggregate of all the points lying on all the lines PP' is then a quadric surface. And when the conics only are given, there is an infinite number of quadrics so obtainable, since we can choose the point C', which is to correspond to C, in an infinite number of ways. A definite quadric is determined by the two conics together with the line CC'. In particular, if the tangents of one conic at the points A, B meet in the point T, and the tangents of the other conic at the points A, B meet in the point U, and the line CC' intersect the line TU, say in O, it can be shewn that the conics are in perspective from the point O. For if the lines which join the point O to the points, P', of one of the two given conics, σ', be allowed to meet the plane of the other conic, σ, in points, Q, it follows, because the pencils of lines, $A(P')$, $B(P')$, are related, that the pencils of lines, $A(Q)$, $B(Q)$, are also related, so that Q describes a conic, τ, in the plane of the conic σ. As O, A, T, U are in one plane, the conic τ will touch the conic σ at A; similarly it will touch it at B; and the point C, lying on OC', will be common to the conics τ and σ. Two conics which touch at two points, and have another point in common, are however coincident. Thus the lines, PP', joining corresponding points of the two conics, all pass through O. The quadric determined by this particular correspondence of C' to C thus reduces to a quadric cone, of vertex O.

In symbols, referred to A, B, T, U, the corresponding points P, P' of the two conics may be taken to be

$$P = \theta^2 A + \theta T + B, \quad P' = \phi^2 A + \phi U + B,$$

where θ, ϕ, by their variation, are to give two related ranges on the two conics, with the condition that the values $\theta^{-1} = 0$, $\theta = 0$, at

A, B, are to correspond to the values $\phi^{-1}=0$, $\phi=0$; thus ϕ is of the form θa^{-1}, where a is the same for all points P, P', but depends upon the initial correspondence adopted, of C' to C. A general point $\rho P+aP'$, of the line PP', is then

$$\theta^2(\rho+a^{-1})A+\theta\rho T+\theta U+(\rho+a)B,$$

or, say, $xA+tT+zU+yB$, so that

$$x=\theta^2(\rho+a^{-1}),\quad t=\theta\rho,\quad z=\theta,\quad y=\rho+a;$$

eliminating ρ we have, for the equation satisfied by the coordinates of any point of the line PP',

$$xy=z^2+(a+a^{-1})zt+t^2;$$

if we put

$$\xi=x+y,\quad \eta=x-y,\quad \zeta=(a^{\frac{1}{2}}+a^{-\frac{1}{2}})(z+t),\quad \tau=(a^{\frac{1}{2}}-a^{-\frac{1}{2}})(z-t),$$

this equation is the same as

$$\xi^2-\eta^2-\zeta^2+\tau^2=0,$$

which is another form of the equation of the quadric.

But, without assigning the correspondence of the two points C, C', we may suppose the two conics to be given, respectively, with the coordinates here used, by the equations

$$z=0,\ xy-t^2=0,\quad \text{and}\quad t=0,\ xy-z^2=0;$$

then, whatever k may be, the equation

$$xy=z^2+2kzt+t^2,$$

is evidently that of a locus containing both the given conics. And k can be chosen so that the locus contains an arbitrary point of space which does not lie in the plane of either of the two conics. A plane drawn through such an arbitrary point, say O, will meet each of the two conics in two points; through the four points so found, and the point O, a definite conic can be drawn. The points of all such conics, obtained by drawing different planes through the same point O, do in fact constitute a quadric determined by the two conics and the point O. To prove this, it is sufficient, after what has preceded, to shew that a quadric can be found to contain two conics which have two points in common, and to contain also an arbitrary point not lying on the plane of either of the two conics; and this follows from the equation just put down. But we can deduce the result at once without the symbols, from the preceding theory, by remarking that a line (two lines, indeed) can be drawn from the arbitrary point to meet the given conics, say in C and C' respectively, and these points C, C' can then be used to establish a (1, 1) relation of points of the two conics. That such a transversal of the two conics can be drawn from the arbitrary point, is clear by projecting one of the conics, from the point, on to the plane of the other conic; thereby a conic is obtained having, beside A and B, two points of intersection with the given conic on that plane. Thereby two such transversals are obtained; but these lead to the same quadric, being the generators of the two systems of the quadric which pass through the arbitrary point.

When k is real, in the quadric given by the equation

$$xy = z^2 + 2kzt + t^2,$$

there is a difference according to the value of k, that is, according to the position of the arbitrary point, which is given in addition to the two conics. When $k^2 > 1$, there exists a *real* number a such that $2k = a + a^{-1}$; then the quadric contains real lines, as we have seen. When $k^2 < 1$, the lines are imaginary. When $k^2 = 1$, the equation of the quadric surface is one of the two represented by

$$xy = (z+t)^2, \quad xy = (z-t)^2,$$

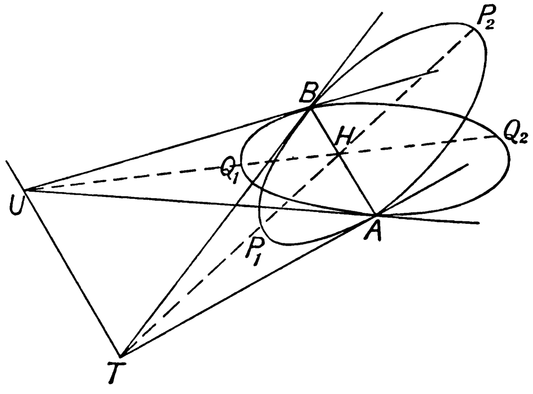
and the surface is, in fact, a cone. In this case the corresponding points, P, P', of the two conics, are

$$P = \theta^2 A + \theta T + B, \quad P' = \theta^2 A \pm \theta U + B,$$

and the line PP' contains one of the two points $T \mp U$, whatever P and P' may be.

An interesting simple result follows from what we have said; *if we have three conics in space of which every two have two points in common, then a quadric surface exists containing all these conics.* This remark is made by Poncelet, *Traité des propriétés projectives des figures*, 1865, I, p. 378, § 606.

Ex. 1. There are in fact just two quadric cones which can be constructed to contain two conics in space which have two points in common, as will appear also in another way. We may construct these, if T, U be, as above, the intersections of the tangents of the



two conics, respectively, at their common points A, B, by taking an arbitrary point, say H, upon the line AB, then joining TH, to meet the conic of the plane TAB in P_1 and P_2, and joining UH, to meet the conic of the plane UAB in Q_1 and Q_2. It is then clear that the lines P_1Q_1, P_2Q_2 meet in a point, say O, of the line TU; and the lines P_1Q_2, P_2Q_1 meet in another point, say O', of this line. The lines joining O to the points of one of the conics meet the plane of the other conic in this conic itself, and constitute one of the two quadric cones, with O as vertex; and O' is the vertex of the other cone. The same points, O and O', are found whatever be the point H taken on AB.

Ex. 2. Shew that the equations of three conics in space of which every two have two points in common, can be taken to be, respectively,

$$x = 0,\ y^2 + 2fyz + z^2 = t^2; \quad y = 0,\ z^2 + 2gzx + x^2 = t^2;$$
$$z = 0,\ x^2 + 2hxy + y^2 = t^2.$$

All these then lie on the locus represented by the equation

$$x^2 + y^2 + z^2 + 2fyz + 2gzx + 2hxy = t^2.$$

Definition of a quadric by two related central systems of lines and planes. We have in Vol. I (pp. 148, 149) explained what is meant by two related plane systems of points and lines, of which the correspondence is determined by assigning four points of one plane to correspond respectively to four points of the other, no three of the four points being in line. In this relation, to any point of one plane corresponds a point of the other, the points of a range, on a line of one plane, corresponding to the points of a related range on a corresponding line of the other plane; and, consequently, to a pencil of lines through a point in one plane, corresponds a related pencil of lines through the corresponding point of the other plane. We may, however, have two dually related plane systems, in which to a point of one plane corresponds a line of the other plane, and, to the points of a range of the former plane, correspond the lines of a pencil of lines through the corresponding point of the latter plane; then to the lines of a pencil in the former plane will correspond the points of a range in the latter plane. As we have established the theory of related ranges and pencils, in Vol. I, by means of incidences, coupled with Pappus' theorem, which is a self-dual theorem, it follows at once that when a range in the former plane corresponds to a pencil in the latter plane, these will be related to one another; and, hence, that when a pencil of lines in the former plane corresponds to a range of points in the latter plane, these will also be related.

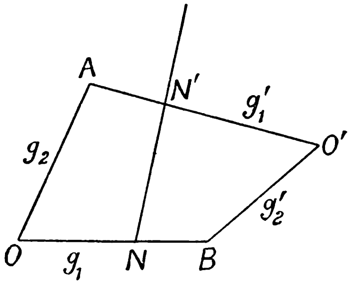
When we have, in space of three dimensions, two related plane systems, ϖ and ϖ', and, also, two points, O and O', of which O does not lie in the plane ϖ, and O' does not lie in the plane ϖ', we may join the points and lines of ϖ to O, by lines and planes, respectively, and the points and lines of ϖ' to O', by lines and planes, respectively. Thereby we obtain two systems of lines and planes, passing respectively through O and O', which we may call ***star systems***, or ***central systems***. When the plane systems ϖ and ϖ' are related, we may speak of these central systems as being related.

But then, equally, if we have two dually related plane systems, ϖ and σ', and two points, O and O', of which O is not in the plane of ϖ, and O' is not in the plane of σ', we may join the points and lines of ϖ to O by lines and planes, respectively, and the lines and points of σ' to O' by planes and lines, respectively. Then we obtain two central systems which are dually related. To a line of the system of centre O, will correspond a plane of the system of centre O'; to a plane through O, containing two lines of the system O, will correspond the line through O', which is the intersection of the planes through O' corresponding to the lines through O; to a pencil of lines through O, lying in a plane through O, will correspond an axial pencil of planes through O', all passing through the line, through O', which corresponds to the plane of the flat pencil through O; and this axial pencil of planes will be related to the flat pencil of lines. And the same may be said of the correspondence, of planes and lines through O', to the lines and planes through O.

Taking now two such dually related central systems, of centres O and O', we consider the locus of the intersection of any line of the system O with the corresponding plane of the system O'. It is the fact that this locus is a quadric surface containing O and O'; conversely, on a given quadric surface we may take two points O and O', arbitrarily, and, in an infinite number of ways, regard the surface as the locus of the intersection of lines of a central system of centre O, with the corresponding planes of a dually related system of centre O'. The theory arises naturally in a later section, devoted to the $(1, 1)$ correspondence of two spaces, and we shall limit ourselves here to the proof of the first part of the statement we have made. To every line, l, through O, there corresponds a plane, λ', through O'; and to every line in the plane λ', passing through O', there corresponds a plane λ, passing through the line l, and through O; and the same for O' and O as for O and O'. In particular, to the line $O'O$, of the system O', there corresponds a plane τ, through O; to every line, l, through O, in this plane τ, there corresponds then a plane through the line $O'O$. This plane, which corresponds to the line l, will meet the plane τ in a line, say m, passing through O. We shall thus have two related pencils of lines, l and m, in the plane τ, all passing through O. These two related pencils will, in the case we regard as general, have two common corresponding rays.

There are, therefore, two lines l, through O, in the plane τ, such that the corresponding planes of the central system O', respectively, contain them; we may call these lines g_1 and g_2, the planes through O' to which they correspond being called, respectively, γ_1' and γ_2'. As every point of the line g_1 lies in the corresponding plane γ_1', every point of g_1 is a point of the locus; and, similarly, so is every point of g_2. Then, to every plane through g_1 (and hence, through O), will correspond a line through O' lying in the plane γ_1'; in particular, to the plane g_1O', will correspond a line g_2', through O', which, as it lies in this plane g_1O', will meet g_1. And there will, similarly, be a line g_1', through O', in the plane g_2O', and, therefore, meeting g_2. The lines g_2', g_1' will be the lines through O' which lie, respectively, in the planes through O which correspond to them.

Now consider a line meeting g_1, say in N, and meeting g_1', say in N'. Then, to the lines through O in the plane NON', correspond planes through O', all passing through a line, and forming an axial pencil related to the pencil of lines through O. The lines in question, and these planes, will meet the line NN' in two related ranges; in the most general case these ranges will have two corresponding points in common; these are the points N, N', and no other point of the locus lies on the line NN'. The locus, however, contains a point on any line drawn through O; let P be such a point, not lying on g_1 or g_1'; let PNN' be the transversal from P to g_1 and g_1'. Then, upon this line, there are two related ranges, as explained, which now have three common corresponding points, and therefore coincide entirely. The line PNN' thus lies entirely on the locus. By taking various points P we can thus obtain an infinite number of lines such as PNN', lying entirely on the locus. If three such lines be taken, it can be proved that any transversal of these lies entirely on the locus, each of these transversals containing three corresponding points of two related ranges in common.



The locus is thus identified with that of all points on all the transversals of three skew lines, namely as a quadric.

Quadric as representing a plane on which two fundamental points are given. The expression above given of the points of a quadric by means of two parameters

$$x = \theta + \phi, \quad y = 1 - \theta\phi, \quad z = 1 + \theta\phi, \quad t = \theta - \phi,$$

is capable of being regarded from a point of view to which brief reference may now be made. We have already, in Vol. II (p. 191), come to regard the points of a plane on which two absolute points are given as arising from the points of a quadric. Without repeating what is there said, we refer here to a general point of view.

If for the parameters θ, ϕ, in the formulae just cited, we write, respectively, ξ/ζ and η/ζ, we may suppose the points of the quadric to be given by

$$x = \zeta(\xi + \eta), \quad y = \zeta^2 - \xi\eta, \quad z = \zeta^2 + \xi\eta, \quad t = \zeta(\xi - \eta);$$

if we regard ξ, η, ζ as homogeneous coordinates in a plane, there will correspond, in this plane, to a condition $Ax + By + Cz + Dt = 0$ for the points of the quadric, the equation

$$A\zeta(\xi + \eta) + B(\zeta^2 - \xi\eta) + C(\zeta^2 + \xi\eta) + D\zeta(\xi - \eta) = 0;$$

this is easily seen to be that of the general conic, in the plane of ξ, η, ζ, which passes through the two points $(1, 0, 0)$, $(0, 1, 0)$. The condition $Ax + \ldots + Dt = 0$ expresses, as we have remarked above, that the point (x, y, z, t) lies on a certain plane; the section of the quadric by this plane, then, corresponds to a particular conic in the plane ξ, η, ζ, passing through two definite points, which are the same for all such plane sections. More generally, take two absolute points in the plane of ξ, η, ζ, and let S_1, S_2, S_3, S_4 be any four homogeneous quadratic functions of ξ, η, ζ, such that the general conic passing through these two absolute points has an equation of the form

$$AS_1 + BS_2 + CS_3 + DS_4 = 0;$$

then, to any point (ξ, η, ζ) of the plane, determine a point in three-fold space whose coordinates are given by

$$\frac{x}{S_1} = \frac{y}{S_2} = \frac{z}{S_3} = \frac{t}{S_4};$$

the coordinates x, y, z, t will then be connected by a rational homogeneous equation, obtainable by elimination of the two ratios ξ/ζ, η/ζ from the three equations by which the ratios of x, y, z, t are defined. This equation may be regarded as the equation of a locus. Any general line will meet this locus in two points; for such a line consists of points, whose coordinates satisfy the equations of two planes, $Ax + \ldots + Dt = 0$, and $A'x + \ldots + D't = 0$; and these correspond to points (ξ, η, ζ) lying on two conics $AS_1 + \ldots + DS_4 = 0$, $A'S_1 + \ldots + D'S_4 = 0$; as these conics have two points in common, which are independent of $A, \ldots, D, A', \ldots, D'$, they will have two other points in common. It is in fact the case that this locus is a quadric surface, as will appear abundantly below. To any point of this, which lies on an infinite number of planes, will correspond a single point of the plane (ξ, η, ζ).

Consideration of the most general homogeneous equation of the second order connecting the space coordinates. It will add considerably to clearness to prove at once that the most general homogeneous quadratic equation connecting x, y, z, t implies that the point x, y, z, t lies upon a quadric surface, or upon a locus which we may regard as a particular case of this.

Write this equation in the form

$$ax^2 + by^2 + cz^2 + dt^2 + 2fyz + 2gzx + 2hxy + 2uxt + 2vyt + 2wzt = 0,$$

which we may abbreviate into either of the forms

$$(a, b, c, d, f, g, h, u, v, w \between x, y, z, t)^2 = 0, \quad (x, y, z, t)^2 = 0\,;$$

we prove, first, that, in an infinite number of ways, this can be put into the form

$$A_1(a_1x + b_1y + c_1z + d_1t)^2 + A_2(a_2x + b_2y + c_2z + d_2t)^2$$
$$+ A_3(a_3x + b_3y + c_3z + d_3t)^2 + A_4(a_4x + b_4y + c_4z + d_4t)^2 = 0,$$

wherein $A_1, A_2, A_3, A_4, a_1, b_1, c_1, d_1, \ldots, a_4, b_4, c_4, d_4$ are all rational real functions of the coefficients, $a, b, c, d, \ldots, w$, which occur in the original equation.

1°. A quadratic form in two variables, x and y, say $ax^2+2hxy+by^2$, if the coefficient b be not zero, is

$$b^{-1}(ab - h^2)\,x^2 + b^{-1}(hx + by)^2\,;$$

and similarly if a be not zero. If a and b be both zero it is

$$\tfrac{1}{2}h\,[(x+y)^2 - (x-y)^2].$$

In any case, therefore, it is of the form $A\xi^2 + B\eta^2$, where A, B are rational real functions of a, b, h, and ξ, η are linear functions of x, y with coefficients which are real rational functions of a, b, h.

2°. A quadratic form in three variables, x, y, z, say

$$ax^2 + by^2 + cz^2 + 2fyz + 2gzx + 2hxy,$$

if one of the coefficients a, b, c be not zero, for example, if c be not zero, can be written

$$c^{-1}(gx + fy + cz)^2 + c^{-1}[(ca - g^2)\,x^2 - 2\,(fg - ch)\,xy + (bc - f^2)\,y^2],$$

wherein the terms after the square constitute a quadratic form in the variables x, y only; if a, b, c be all zero, and none of f, g, h be zero, the form is

$$\tfrac{1}{2}fg^{-1}h^{-1}(gz + hy + 2f^{-1}ghx)^2 - 2f^{-1}ghx^2 - \tfrac{1}{2}fg^{-1}h^{-1}(gz - hy)^2\,;$$

if a, b, c be all zero, and one of f, g, h be zero, or two of these, for example either $f = 0$, or $f = g = 0$, the form is, respectively, $2x\,(gz + hy)$ or $2hxy$, that is, respectively,

$$\tfrac{1}{2}\,[(x + gz + hy)^2 - (x - gz - hy)^2], \quad \tfrac{1}{2}\,h\,[(x+y)^2 - (x-y)^2].$$

In any case then the form can be written as $A\xi^2+B\eta^2+C\zeta^2$, where A, B, C are real rational functions of the original coefficients $a, b, \ldots, h$, of which one, or two, may be zero, and ξ, η, ζ are independent linear functions of x, y, z, with coefficients which are rational real functions of $a, b, \ldots, h$.

3°. The quadratic form in four variables,

$$ax^2+by^2+cz^2+dt^2+2fyz+2gzx+2hxy+2uxt+2vyt+2wzt,$$

(i) if not all of a, b, c, d be zero, for example if d be not zero, is

$$d^{-1}(ux+vy+wz+dt)^2+\phi,$$

where ϕ is a quadratic form in x, y, z only, whose coefficients are rational real functions of the original coefficients $a, b, \ldots, w$.

(ii) if all of a, b, c, d be zero, but none of f, g, h be zero, we can choose l, m, n so that

$$hm+gn+u=0, \quad hl+fn+v=0, \quad gl+fm+w=0,$$

namely

$$l=\tfrac{1}{2}g^{-1}h^{-1}(fu-gv-hw), \quad m=\tfrac{1}{2}h^{-1}f^{-1}(-fu+gv-hw),$$
$$n=\tfrac{1}{2}f^{-1}g^{-1}(-fu-gv+hw);$$

then, substituting in the quadratic form, for x, y, z, respectively,

$$x=x'+lt, \quad y=y'+mt, \quad z=z'+nt,$$

this form reduces to

$$2fy'z'+2gz'x'+2hx'y'+2t^2(mnf+nlg+lmh+ul+vm+wn),$$

wherein the first part is a quadratic form in x', y', z' only, and the last part contains only the term in t^2.

(iii) if all of a, b, c, d be zero, and f be zero, but not both of g and h, the form is

$$2(hy+gz)x+2(ux+vy+wz)t;$$

here it may happen that $ux+vy+wz$ is of the form $ux+\lambda(hy+gz)$, namely that $v/h=w/g$, $(=\lambda)$; then the form is

$$2(hy+gz)x+2[ux+\lambda(hy+gz)]t,$$

and is a quadratic form in the *three* variables $x, t, hy+gz$; if $ux+vy+wz$ is not of the form in question, taking ξ, η, ζ, τ so that

$$hy+gz=\eta+\zeta, \quad ux+vy+wz=\tau+\xi,$$
$$x=\eta-\zeta, \qquad t=\tau-\xi,$$

we can, from these, determine x, y, z, t as linear functions of ξ, η, ζ, τ, with coefficients which are real and rational in the coefficients of the original form, which then is

$$2(\eta^2-\zeta^2)+2(\tau^2-\xi^2).$$

(iv) if all of a, b, c, d be zero, and all of f, g, h be zero, the form is

$$2(ux + vy + wz)\, t,$$

and is a quadratic form in the *two* variables $ux + vy + wz$, t.

Thus in all cases the reduction is possible, to the form

$$A_1(a_1x + b_1y + c_1z + d_1t)^2 + \dots + A_4(a_4x + b_4y + c_4z + d_4t)^2,$$

wherein the four linear forms are linearly independent.

Consideration of particular cases. The case of a cone. We regard the case in which none of the coefficients A_1, A_2, A_3, A_4 is zero as the general case. Before coming to this we consider the particular cases, and, first, the case in which one of these coefficients, and only one, say A_4, is zero. Then if we put

$$\xi = a_1x + b_1y + c_1z + d_1t, \quad \eta = a_2x + b_2y + c_2z + d_2t,$$
$$\zeta = a_3x + b_3y + c_3z + d_3t, \quad \tau = a_4x + b_4y + c_4z + d_4t,$$

which is equivalent to choosing for the points of reference, for the space, the four points of intersection of the four planes which are represented by the equations $\xi = 0$, $\eta = 0$, $\zeta = 0$ and $\tau = 0$, the fundamental quadratic form becomes $A_1\xi^2 + A_2\eta^2 + A_3\zeta^2$. We consider then what is represented by the equation

$$A_1\xi^2 + A_2\eta^2 + A_3\zeta^2 = 0.$$

Let $(\xi, \eta, \zeta, 1)$ be any point which satisfies this equation; the general point on the line which joins this to the point $\xi = 0$, $\eta = 0$, $\zeta = 0$, $\tau = 1$, has coordinates of the form $(\xi, \eta, \zeta, 1 + \lambda)$; this point then, also, satisfies the equation. The equation is then satisfied by all the points of an aggregate of lines passing through the point $(0, 0, 0, 1)$. These lines evidently meet the plane $\tau = 0$ in the points of a conic, of which the equations are $\tau = 0$, $A_1\xi^2 + A_2\eta^2 + A_3\zeta^2 = 0$. The equation therefore represents what we have called a quadric cone. Conversely, from the definition of such a cone given above, it follows that its equation must be capable of this form.

Thus we see that the necessary and sufficient condition that the general quadratic polynomial, in the space coordinates x, y, z, t, should represent a quadric cone, when equated to zero, is that this polynomial should be capable of being expressed as a function of only three linear functions of x, y, z, t.

We can hence obtain the condition for this in terms of the coefficients in the original form. For, if this be $f(x, y, z, t)$, and be capable of being expressed in terms of the three linear functions, ξ, η, ζ, of x, y, z, t, in the form $f(x, y, z, t) = F(\xi, \eta, \zeta)$, we have four identities such as

$$\frac{\partial f}{\partial x} = \frac{\partial \xi}{\partial x} \cdot \frac{\partial F}{\partial \xi} + \frac{\partial \eta}{\partial x} \cdot \frac{\partial F}{\partial \eta} + \frac{\partial \zeta}{\partial x} \cdot \frac{\partial F}{\partial \zeta},$$

wherein the factors $\partial\xi/\partial x$, $\partial\eta/\partial x$, etc., are functions of the original coefficients alone, and do not depend on x, y, z, t. Thus the four linear functions of x, y, z, t given by $\partial f/\partial x$, $\partial f/\partial y$, etc., are all expressible as linear functions of the three forms $\partial F/\partial\xi$, $\partial F/\partial\eta$, etc. which are linear in ξ, η, ζ and therefore, also, in x, y, z, t. There exist, however, values of x, y, z, t reducing to zero these three linear forms $\partial F/\partial\xi$, etc. There exist, therefore, values of x, y, z, t reducing to zero the four forms $\partial f/\partial x$, etc. These forms are, respectively,

$$2(ax+hy+gz+ut), \quad 2(hx+by+fz+vt),$$
$$2(gx+fy+cz+wt), \quad 2(ux+vy+wz+dt),$$

and the condition necessary and sufficient that there should be values of x, y, z, t for which these all vanish is that the determinant

$$\Delta, = \begin{vmatrix} a, & h, & g, & u \\ h, & b, & f, & v \\ g, & f, & c, & w \\ u, & v, & w, & d \end{vmatrix},$$

should be zero.

Conversely, if this determinant is zero, and (x_0, y_0, z_0, t_0) be values, then existing, for which all of $\partial f/\partial x$, $\partial f/\partial y$, etc., vanish, while (x, y, z, t) are any values for which $f(x, y, z, t) = 0$, then every point on the line joining the point (x_0, y_0, z_0, t_0) to (x, y, z, t) is a point for which $f(x, y, z, t) = 0$. For such a point has coordinates of the form $(x_0 + \lambda x, y_0 + \lambda y, z_0 + \lambda z, t_0 + \lambda t)$, and we have

$$f(x_0 + \lambda x, \ldots) = f(x_0, y_0, z_0, t_0)$$
$$+ \lambda\left(x\frac{\partial f}{\partial x_0} + y\frac{\partial f}{\partial y_0} + z\frac{\partial f}{\partial z_0} + t\frac{\partial f}{\partial t_0}\right) + \lambda^2 f(x, y, z, t);$$

now, by hypothesis, $f(x, y, z, t) = 0$; and $\partial f/\partial x_0 = 0$, $\partial f/\partial y_0 = 0$, etc., and, therefore, also $f(x_0, y_0, z_0, t_0) = 0$, since

$$f(x_0, y_0, z_0, t_0) = \frac{1}{2}\left(x_0\frac{\partial f}{\partial x_0} + \ldots + t_0\frac{\partial f}{\partial t_0}\right).$$

It follows from this that the equation $f(x, y, z, t) = 0$ is satisfied by all points of an aggregate of lines passing through the point (x_0, y_0, z_0, t_0). It is also easy to see directly that, with the hypothesis made, namely that the four forms $\partial f/\partial x$, $\partial f/\partial y$, etc., are all annulled by the values $x = x_0$, $y = y_0$, etc., the quadratic form $f(x, y, z, t)$ is a function of three forms, linear in x, y, z, t; which, when t_0 is not zero, may be taken to be $xt_0 - x_0t$, $yt_0 - y_0t$, $zt_0 - z_0t$. We find at once, indeed, when we utilise this hypothesis, that

$$a(xt_0 - x_0t)^2 + b(yt_0 - y_0t)^2 + c(zt_0 - z_0t)^2 + 2f(yt_0 - y_0t)(zt_0 - z_0t)$$
$$+ 2g(zt_0 - z_0t)(xt_0 - x_0t) + 2h(xt_0 - x_0t)(yt_0 - y_0t)$$

is equal to $t_0^2 f(x, y, z, t)$. This supposes that t_0 is not zero; but we can suppose that one at least of x_0, y_0, z_0, t_0 is not zero, and so, in any case, obtain a similar formula.

The case of two planes. Consider now the more particular case when the quadratic form in x, y, z, t, $f(x, y, z, t)$, reduces to only two squares,

$$A_1(a_1x + b_1y + c_1z + d_1t)^2 + A_2(a_2x + b_2y + c_2z + d_2t)^2,$$

say to $A_1\xi^2 + A_2\eta^2$. The equation $f(x, y, z, t) = 0$ is then equivalent to

$$(\sqrt{A_1}\,\xi + \sqrt{-A_2}\,\eta)(\sqrt{A_1}\,\xi - \sqrt{-A_2}\,\eta) = 0,$$

so that, as ξ and η are linear in x, y, z, t, it represents two planes. These are imaginary when A_1 and A_2 are real and both positive, or negative. In this case, by identities such as those used in the last case, the four linear forms $\partial f/\partial x$, $\partial f/\partial y$, etc., are linearly expressible by *two* linear forms; thus every first minor, of three rows and columns, in the determinant

$$\Delta, = \begin{vmatrix} a, & h, & g, & u \\ h, & b, & f, & v \\ g, & f, & c, & w \\ u, & v, & w, & d \end{vmatrix},$$

vanishes. Conversely, denote respectively by U, V, W, P the linear forms in x, y, z, t, $\frac{1}{2}\partial f/\partial x$, $\frac{1}{2}\partial f/\partial y$, $\frac{1}{2}\partial f/\partial z$, $\frac{1}{2}\partial f/\partial t$, and assume that the three particular first minors of this determinant which are the cofactors respectively of c, d and w, are all zero (from which, as will appear, all the first minors are zero), and that the second minor $ab - h^2$ is not zero; then it is easy to verify that, for all values of x, y, z, t, the forms W and P are expressible in terms of U and V, by means of the equations

$$-(ab - h^2)W = (hf - bg)U + (gh - af)V,$$
$$-(ab - h^2)P = (hv - bu)U + (hu - av)V;$$

from these it follows that $(ab - h^2)f(x, y, z, t)$, which is equal to

$$(ab - h^2)(xU + yV + zW + tP),$$

is equal to $U[(ab - h^2)x + (bg - hf)z + (bu - hv)t]$
$+ V[(ab - h^2)y + (af - gh)z + (av - hu)t]$

and hence to $\quad U(bU - hV) + V(aV - hU)$,

or to $\quad aV^2 - 2hUV + bU^2$.

Wherefore, $f(x, y, z, t)$ is expressible in the form $A_1\xi^2 + A_2\eta^2$, where ξ, η are linear in x, y, z, t. This same conclusion follows, in a similar way, whenever all the first minors of the determinant Δ are zero, if there be one second minor which is not zero.

The case of two coincident planes. For the last particular case suppose that $f(x, y, z, t)$ reduces to the single term

$$A_1(a_1x + b_1y + c_1z + d_1t)^2.$$

Then, we see, as in the preceding cases, that the four linear forms $\partial f/\partial x$, $\partial f/\partial y$, etc., are identical save for a factor independent of x, y, z, t. When this is so, every second minor of the determinant Δ vanishes. Conversely suppose that this is so, but $f(x, y, z, t)$ does not vanish identically. The forms U, V, W, P, with the notation just employed, are then the same, save for a factor independent of x, y, z, t. The coefficients a, b, c, d, respectively of x^2, y^2, z^2, t^2, in $f(x, y, z, t)$, cannot all vanish, since then, from $bc - f^2 = 0$, $ad - u^2 = 0$, would follow $f = 0$, $u = 0$, and similarly all other coefficients in $f(x, y, z, t)$ would vanish. Suppose then, for example, that a is not zero; then from the equivalence of the forms U, V, W, P, it follows that $U/a = V/h = W/g = P/u$, and hence

$$f(x, y, z, t) = xU + yV + zW + tP = a^{-1}U(ax + hy + gz + ut) = a^{-1}U^2,$$

so that $f(x, y, z, t)$ is the square of a single linear form, and the equation $f(x, y, z, t) = 0$ represents a plane taken twice over.

After Sylvester (*Coll. Papers*, I, p. 147), the vanishing of six, suitably chosen, second minors of Δ, is sufficient to ensure that they all vanish.

General properties of a quadric given by its equation. After what we have seen we may agree to understand by a quadric the locus determined by the vanishing of any homogeneous quadratic form, $f(x, y, z, t)$, in x, y, z, t. When the contrary is not referred to, we suppose that the determinant Δ does not vanish, so that $f(x, y, z, t)$ can be expressed in the form $A\xi^2 + B\eta^2 + C\zeta^2 + D\tau^2$, where A, B, C, D are rational real functions of the original coefficients, all different from zero, and ξ, η, ζ, τ are linear functions of x, y, z, t, with coefficients which are equally rational real functions of the original coefficients. The coefficients A, B, C, D, if real, may be all positive, or all negative; then, clearly, there is no point, of which the coordinates are all real, for which $f(x, y, z, t)$ vanishes; it is, then, usual, as in the case of a conic (Vol. II, p. 163), to speak of $f(x, y, z, t) = 0$ as representing an imaginary quadric. Or, the coefficients A, B, C, D may consist of two which are positive and two which are negative. In this case, as appears from what we have seen above (p. 7), there are two systems of real lines of which every point is a point of the quadric $f(x, y, z, t) = 0$. Or, finally, three of the coefficients A, B, C, D may be of one sign, and the remaining one of the opposite sign. In this case, the locus $f(x, y, z, t) = 0$ contains real points; for example, if A, B, C be of one sign and D be of the opposite sign, two real points are given by $\eta = 0$, $\zeta = 0$, $A\xi^2 + D\tau^2 = 0$. But the locus does not contain any real lines. For example, with the particular signs just taken, a real line of the locus would contain a real point lying on the plane represented by $\tau = 0$; but $\tau = 0$ involves, for points of the locus, $A\xi^2 + B\eta^2 + C\zeta^2 = 0$, and, as A, B, C are of the same sign, there is no set of real values of ξ, η, ζ for which this can be satisfied. We see thus that the three cases are distinct, if we take account of the reality of the points of the locus; and, though the reduction to a sum of four squares can be made in an infinite number of ways, yet, when made by rational real substitutions only, as here, the number of positive and negative signs obtained for the coefficients A, B, C, D will be the same, for any particular form $f(x, y, z, t)$ of *real* coefficients, in whatever way the reduction is made.

Certain general properties of the quadric locus may now be enumerated: (1) If a linear transformation be made, from variables x, y, z, t to variables ξ, η, ζ, τ, by equations of the forms

$$\xi = a_1x + b_1y + c_1z + d_1t, \quad \eta = a_2x + b_2y + c_2z + d_2t,$$
$$\zeta = a_3x + \dots, \quad \tau = a_4x + \dots,$$

whereby a function $f(x, y, z, t)$ becomes $F(\xi, \eta, \zeta, \tau)$, and if $\xi', \eta', \zeta', \tau'$ be the same linear functions of variables x', y', z', t' as are ξ, η, ζ, τ of x, y, z, t, then

$$\xi'\frac{\partial F}{\partial \xi} + \eta'\frac{\partial F}{\partial \eta} + \zeta'\frac{\partial F}{\partial \zeta} + \tau'\frac{\partial F}{\partial \tau} = x'\frac{\partial f}{\partial x} + y'\frac{\partial f}{\partial y} + z'\frac{\partial f}{\partial z} + t'\frac{\partial f}{\partial t}.$$

For we have
$$\frac{\partial f}{\partial x} = a_1\frac{\partial F}{\partial \xi} + a_2\frac{\partial F}{\partial \eta} + a_3\frac{\partial F}{\partial \zeta} + a_4\frac{\partial F}{\partial \tau},$$
$$\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots$$
$$\frac{\partial f}{\partial t} = d_1\frac{\partial F}{\partial \xi} + d_2\frac{\partial F}{\partial \eta} + d_3\frac{\partial F}{\partial \zeta} + d_4\frac{\partial F}{\partial \tau};$$

if these equations be multiplied in turn by x', y', z', t', and then added, the result follows at once.

It is often convenient to represent the original equations of transformation by

$$(\xi, \eta, \zeta, \tau) = \left|\begin{matrix} a_1, & b_1, & c_1, & d_1 \\ a_2, & b_2, & c_2, & d_2 \\ a_3, & b_3, & c_3, & d_3 \\ a_4, & b_4, & c_4, & d_4 \end{matrix}\right| (x, y, z, t);$$

the array of coefficients is then called a *matrix*. The matrix obtained from this, by writing as columns what are here written as rows, is then called the *transposed* matrix. Denoting the original matrix by M, and the transposed matrix by $\bar{M}$, we have

$$(\xi, \eta, \zeta, \tau) = M(x, y, z, t),$$

and $$\left(\frac{\partial f}{\partial x}, \frac{\partial f}{\partial y}, \frac{\partial f}{\partial z}, \frac{\partial f}{\partial t}\right) = \overline{M}\left(\frac{\partial F}{\partial \xi}, \frac{\partial F}{\partial \eta}, \frac{\partial F}{\partial \zeta}, \frac{\partial F}{\partial \tau}\right),$$

where the new variables, ξ, η, ζ, τ, occur on the left in the first equation, but the new differential coefficients $\partial F/\partial \xi$, $\partial F/\partial \eta$, etc., occur on the right in the second equation. This is often expressed by saying that the differential coefficients $\partial f/\partial x$, $\partial f/\partial y$, etc., are transformed *contragrediently* from the variables x, y, z, t.

(2) A general quadric, expressed by the equation $f(x, y, z, t) = 0$, is met in two points by the line joining any two given points $(x, y, z,$ and (x', y', z', t'). The necessary and sufficient condition that the two points of meeting should be harmonic conjugates of one another in regard to the given points (x, y, z, t), (x', y', z', t'), is

$$x'\frac{\partial f}{\partial x} + y'\frac{\partial f}{\partial y} + z'\frac{\partial f}{\partial z} + t'\frac{\partial f}{\partial t} = 0\,;$$

this equation, when $f(x, y, z, t)$ is a quadratic function, is symmetrical in regard to the two points (x, y, z, t), (x', y', z', t'); with the notation originally suggested for the coefficients in $f(x, y, z, t)$, it is (after division by 2)

$$\begin{aligned} &axx' + byy' + czz' + dtt' + f(yz' + y'z) + g(zx' + z'x) \\ &\qquad + h(xy' + x'y) + u(xt' + x't) + v(yt' + y't) + w(zt' + z't). \end{aligned}$$

For the point $(x+\lambda x', y+\lambda y', z+\lambda z', t+\lambda t')$ lies on $f(x, y, z, t) = 0$ if

$$f(x, y, z, t) + \lambda\left(x'\frac{\partial f}{\partial x} + y'\frac{\partial f}{\partial y} + z'\frac{\partial f}{\partial z} + t'\frac{\partial f}{\partial t}\right) + \lambda^2 f(x', y', z', t') = 0;$$

this equation in λ has two roots, and they are equal, and of opposite sign, only if the coefficient of λ vanish.

(3) Particular applications of the result in (2) may be referred to: It appears that if, from an arbitrary point, (x', y', z', t'), or O, variable lines be drawn to meet the quadric, each in two points, P and Q, the locus of a point, R, which is the harmonic conjugate of O in regard to P and Q, is a plane, with the equation

$$x'\frac{\partial f}{\partial x} + y'\frac{\partial f}{\partial y} + z'\frac{\partial f}{\partial z} + t'\frac{\partial f}{\partial t} = 0.$$

This plane is called the *polar plane* of O in regard to the quadric.

In the particular case in which the quadric is a cone, and all the differential coefficients $\partial f/\partial x$, $\partial f/\partial y$, etc., vanish at the point which is the vertex of this cone, this polar plane passes through the vertex. In the still more particular case when the quadric is a pair of planes, the polar plane passes through the line in which these two planes intersect. Finally, when the quadric is a pair of coincident planes, the polar plane coincides with these.

It appears, also, that if (x', y', z', t') be a point of the quadric $f(x, y, z, t) = 0$, which we now suppose not to be a cone or a particular case of this, so that one of the two roots of the above quadratic equation for λ^{-1} is zero, and if (x, y, z, t) be taken on the polar plane of (x', y', z', t'), but not on $f(x, y, z, t) = 0$, then the second value of λ^{-1} is also zero, so that the two points, where the line joining the points (x', y', z', t'), (x, y, z, t) meets the quadric, both coincide with (x', y', z', t'); while if, with (x', y', z', t') on the quadric, the point (x, y, z, t) be both on the polar plane of (x', y', z', t'), and also such that $f(x, y, z, t) = 0$, then the quadratic equation for λ is satisfied for every value of λ, namely every point of the line joining (x', y', z', t') to (x, y, z, t) lies on the quadric. In general the intersection of the quadric surface with a plane is a conic, being a locus met by a line of the plane in two points; in the case spoken of, when the plane is the polar plane of a point of the quadric, this conic, we see, contains a line, and, therefore, also another line, as part of itself, and consists of these two lines. Thus for a general quadric, the polar plane of any point lying on the quadric, which for such a point is called the *tangent plane* of the quadric at the point, meets the quadric in two lines intersecting at the point; any other line, in the tangent plane through this point, has two coincident intersections with the quadric, lying at this point. The point itself is called the *point of contact* of the tangent plane with the quadric. When the quadric considered is a cone, the tangent plane at any point passes through the vertex of the cone, and the two lines in which the tangent plane meets the cone coincide, in the line joining the vertex to the point of contact, as is easy to see; at the vertex itself there is no proper tangent plane. When the quadric considered consists of two planes, the tangent plane at any point, not on the line of intersection of the two planes, coincides with one of these.

(4) The condition that a plane, represented, suppose, by the equation

$$lx + my + nz + pt = 0,$$

should be a tangent plane of the quadric $f(x, y, z, t) = 0$, is that its equation should be capable, for values of x', y', z', t' which satisfy the two equations

$$f(x', y', z', t') = 0, \quad lx' + my' + nz' + pt' = 0,$$

of being written in the form appropriate to that of the tangent plane at (x', y', z', t'), which is

$$x(ax' + hy' + gz' + ut') + \ldots + t(ux' + vy' + wz' + dt') = 0.$$

For this it is necessary and sufficient that the coefficients of x, y, z, t, in the last equation, should be proportional to those in the given equation, namely that there should be a value of σ for which we have the four equations

$$ax' + hy' + gz' + ut' + \sigma l = 0,$$

$$\dots\dots\dots\dots\dots\dots\dots\dots$$

$$ux' + vy' + wz' + dt' + \sigma p = 0,$$

while, also, $$lx' + my' + nz' + pt' \qquad = 0.$$

These equations, as we see by adding the first four, after multiplication, respectively, by x', y', z', t', involve $f(x', y', z', t') = 0$. Thus the necessary and sufficient condition, for the given plane to be a tangent plane of the given quadric, is that l, m, n, p should satisfy the equation

$$\begin{vmatrix} a, & h, & g, & u, & l \\ h, & b, & f, & v, & m \\ g, & f, & c, & w, & n \\ u, & v, & w, & d, & p \\ l, & m, & n, & p, & 0 \end{vmatrix} = 0;$$

if the cofactors of a, b, c, etc., in the determinant Δ, of four rows and columns, which is obtained by omitting the last row and column of this determinant, be denoted, respectively, by A, B, C, etc., this condition is

$$Al^2 + Bm^2 + Cn^2 + Dp^2 + 2Fmn + 2Gnl + 2Hlm$$
$$+ 2Ulp + 2Vmp + 2Wnp = 0.$$

As the equation $f(x, y, z, t) = 0$ is the condition that the point (x, y, z, t) should be a point of the quadric, so the condition just obtained is the condition that the plane (l, m, n, p) should be a tangent plane of the quadric. Thus it appears that, as the quadric is the aggregate of points satisfying the most general homogeneous quadratic relation connecting the point coordinates x, y, z, t, so the aggregate of the tangent planes of a quadric is obtained by subjecting the coefficients, l, m, n, p, in the equation of a plane, to the most general homogeneous quadratic relation. For, supposing the determinant Δ not to be zero, we may regard, not the coefficients a, b, c, etc., as fundamental, but the coefficients A, B, C, etc., as fundamental; taking the determinant

$$\begin{matrix} A, & H, & G, & U \\ H, & B, & F, & V \\ G, & F, & C, & W \\ U, & V, & W, & D \end{matrix}$$

the coefficients a, b, c, etc., each multiplied by Δ^2, are the cofactors of A, B, C, etc., in this last determinant. The case of $\Delta = 0$ will be considered immediately below.

The equation $Al^2 + Bm^2 + \ldots + 2Wnp = 0$, may then be spoken of as the *tangential equation* of the quadric, and l, m, n, p as the *coordinates* of a plane, the whole being analogous to the case of a conic dealt with in Chap. III of Vol. II.

In particular, if $F(l, m, n, p) = 0$ be the tangential equation of a quadric, the point of contact of a particular tangent plane, whose coordinates are l_0, m_0, n_0, p_0, has for its equation

$$l_0 \frac{\partial F}{\partial l} + m_0 \frac{\partial F}{\partial m} + n_0 \frac{\partial F}{\partial n} + p_0 \frac{\partial F}{\partial p} = 0,$$

so that, if $F(l_0, m_0, n_0, p_0)$ be denoted by F_0, the coordinates of the point of contact are $\partial F_0/\partial l_0$, $\partial F_0/\partial m_0$, etc.

When the determinant Δ vanishes, the tangential equation above written, regarded as deduced from the point equation, is not general, being in fact a perfect square. For, by the theorem of reciprocal determinants referred to above, the determinants of two rows and columns such as

$$BC - F^2, \quad AD - U^2, \quad GH - AF, \quad HU - AV,$$

which are equal respectively to $ad - u^2$, $bc - f^2$, $fd - vw$, $fw - vc$, multiplied by Δ, all vanish; thus, when A is not zero, the tangential equation is the same as

$$(Al + Hm + Gn + Up)^2 = 0,$$

and so in other cases.

Taking, however, the general tangential equation, we may shew, as for the point equation above, that it can be written in the form

$$A_1(a_1 l + b_1 m + c_1 n + d_1 p)^2 + \ldots + A_4(a_4 l + b_4 m + c_4 n + d_4 p)^2 = 0.$$

In the most general case none of A_1, A_2, A_3, A_4 vanishes. When one of these vanishes, the planes conditioned by this equation are all those which pass through the tangent lines of a certain conic. When two of the coefficients $A_1, \ldots, A_4$ vanish, the planes conditioned by this equation are all those which pass through one of two particular points. Finally, when only one of the coefficients is present, the planes are all those passing through a particular point. This follows from the principle of duality, the tangential *equation of a point*, of the form

$$x_0 l + y_0 m + z_0 n + t_0 p = 0,$$

being exactly analogous to the equation of a plane. The matter has been explained in detail for a plane, in Chap. III of Vol. II.

(5) Denoting $f(x, y, z, t)$ by $f(x)$, and $f(x', y', z', t')$ by $f(x')$ and

$$\frac{1}{2}\left(x' \frac{\partial f}{\partial x} + y' \frac{\partial f}{\partial y} + z' \frac{\partial f}{\partial z} + t' \frac{\partial f}{\partial t}\right)$$

by $f(x, x')$, we have remarked above that the points

$$(x+\lambda x', \quad y+\lambda y', \quad z+\lambda z', \quad t+\lambda t'),$$

of the line joining (x', y', z', t') to (x, y, z, t), which lie on the quadric $f(x, y, z, t) = 0$, are given by the quadratic equation

$$f(x) + 2\lambda f(x, x') + \lambda^2 f(x') = 0.$$

The line will then meet the quadric in two coincident points if, for an assigned point (x', y', z', t'), the point (x, y, z, t) be such that

$$f(x) f(x') - [f(x, x')]^2 = 0.$$

Regarded as a condition for (x, y, z, t), this equation represents a quadric. It is, however, evidently satisfied by any point of the line joining (x', y', z', t') to (x, y, z, t). Thus all the lines from (x', y', z', t') which meet the quadric in two coincident points lie on a quadric cone. This is called the *tangent cone*, or the *enveloping cone*, to the given quadric, from the point, and the lines are said to *touch* the quadric. It can in fact be directly verified, (a), that the equation represents a cone; (b), that every one of its tangent planes is equally a tangent plane of the given quadric.

(6) As the general equation $f(x, y, z, t) = 0$ contains ten, homogeneously entering, coefficients, and the condition that the quadric should contain an assigned point is a single linear condition for these coefficients, it follows that a quadric can be found containing nine points arbitrarily chosen. For instance, if three non-intersecting lines be given, a quadric can be found containing three points on each of these lines; and then, as each line meets this quadric in more than two points, the line lies entirely upon the quadric. Or again, if three conics be given in space, of which every two have two points in common, by taking another point upon each of the conics, we have nine points in all; the quadric through these nine points will meet the plane of any one of the three given conics in a conic having five points lying thereon, and, therefore, coinciding with it. The quadric thus contains the three given conics.

It has seemed desirable to give the preceding analysis in order to make clear the general conception of a quadric surface; the notion of the equation of a quadric is undoubtedly of great power, and as we have deduced this from the geometrical definition of the surface, it would be pedantic to avoid the use of it. The descriptive theory, however, often gives a better insight into the geometrical figure under consideration. This theory we now resume.

The polar plane of a point in regard to a quadric. Given any quadric, take an arbitrary point, O, not lying thereon. Draw an arbitrary plane through O, meeting this quadric in a conic. Let a line, passing through O, lying in this plane, meet this conic in the points A and B, and let P be the harmonic conjugate of O

in regard to A and B. As the line varies in this plane, passing through O, the locus of P is a line, the polar line of O in regard to this conic. Now let another plane be drawn through O, meeting the former plane in a line l, passing through O, and let the points in which the line l meets the quadric be U and V. If W be the harmonic conjugate of O in regard to U and V, the point W is on the polar lines of O in regard to both the conics, in which the quadric is met by the two planes drawn through O; these two polar lines, therefore, intersect one another. Hence, if a third plane, not containing the line l, be drawn through O, the polar line of O, in regard to the conic in which this third plane cuts the quadric, will intersect the polar lines of O taken in regard to the two former conics, and not pass through the point of intersection of these lines, which is on l. The third polar line will thus lie in the plane of the first two. From this it is clear that, if an arbitrary line be drawn through O, to meet the quadric in the points Q and R, and P be the point which is the harmonic conjugate of O in regard to Q and R, then the locus of P is a plane. This is called the *polar plane* of O in regard to the quadric. From the definition it is manifest that if the polar plane of O pass through P, the polar plane of P passes through O.

The tangent plane of the quadric at any point. The polar plane of O meets the quadric in a conic. Let H be any point of this. Then the second point, H', in which the line OH meets the quadric, coincides with H; for H is the harmonic conjugate of O in regard to H and H'. We therefore say that the line OH *touches* the quadric at the point H. Any plane drawn through OH meets the quadric in a conic; this conic is met by OH in two points which coincide at H, that is, HO is the tangent at H of this conic. Again, the conic, also passing through H, in which the quadric is met by the polar plane of O, has a tangent at H, say t, unless this conic consists of two lines. This line, t, meets the conic in two points which coincide at H, and, therefore, meets the quadric in two points which coincide at H. Consider now the conic in which the quadric is met by the plane containing the two lines HO and t; this conic is met in two points coinciding at H, both by the line HO and by the line t. It cannot, therefore, be a proper conic, but must consist of two lines meeting at H. The plane of these lines is called the *tangent plane* of the quadric at H. It is to be regarded as the polar plane of the point H; it passes through O, and the polar plane of O passes through H. By choosing O suitably, H may be supposed to be any general point of the quadric. But there may be exception if the polar plane of O meets the quadric in two lines, as happens when the quadric degenerates into a cone, or into two planes; the polar plane of O then passes, respectively, through the vertex of the cone, or through the line of intersection of the two planes; in the former case it meets the cone in lines, in the latter case it meets the planes only in their line of intersection; in the former case there is still a tangent plane of the cone, which passes through the vertex, unless H be actually the vertex.

The polar line of any line in regard to a quadric. Let O_1, O_2 be any two points, not lying on the quadric. Their polar planes will meet in a line, say m. Draw through the line O_1O_2 any plane, meeting the line m in a point K. As the polar planes of O_1 and O_2 both pass through K, it follows that the polar plane of K passes through both O_1 and O_2, and therefore contains any point, O_3, of the line O_1O_2. The polar plane of O_3, therefore, passes through K. The lines O_1O_2 and m are thus in reciprocal relation, the polar plane of any point of either of these containing every point of the other, and, therefore, containing the other. Either of these lines is called the polar line of the other in regard to the quadric. A plane drawn through one of these lines will meet the quadric in a conic and meet the polar line in a point; in regard to this conic, this point is the pole of the first line, as follows from the harmonic relation for points on a transversal. The polar planes, in regard to the quadric, of any range of points on one of the lines, form an axial pencil, of which the polar line is the axis, and, as follows from what has just been remarked, and the theory of conics, this axial pencil of planes is related to the range of points.

Let one of these two lines meet the quadric in the two points F and G; then, as the polar plane of any point, O, of the other line, contains the line FG, and hence contains F and G, it follows, as we have seen above, that the tangent plane of the quadric at F, as also the tangent plane at G, both contain O. In other words, as O is any point of the second line, the tangent planes of the quadric at F and G intersect in this line, the polar line of FG. From this it follows, also, that the lines, lying on the quadric, which pass through F, being in the tangent plane of the quadric at F, both meet the polar line of FG. The points of meeting, being points on lines which lie on the quadric, are themselves on the quadric; they are, therefore, the two points in which the quadric is intersected by the polar line of FG. The lines on the quadric which pass through G must, similarly, pass through these two points. Calling these points F' and G', the two lines, on the quadric, which meet at F', determine the tangent plane of the quadric at F', and this, we see, contains FG; similarly the two lines, on the quadric, which meet at G', determine the tangent plane of the quadric at G', and this plane also passes through the line FG. When the quadric is a cone, the lines on the cone, at any point F, coincide in a line which passes through the vertex; the tangent plane of the cone at any point of this line is the same plane as the tangent plane at any other point of this line, and passes through the vertex. The polar line of a line FG, where F, G are points of the cone other than the vertex, is thus a line through the vertex.

Employing a symbolism introduced in connexion with the original definition of a quadric (above, p. 6), we may suppose, in general, that the points F, G are, respectively, of symbols

$$\lambda A + \mu B + \lambda\mu C + D, \quad \lambda' A + \mu' B + \lambda'\mu' C + D,$$

so that the parameters λ, μ are associated, respectively, with the two lines of the quadric which pass through F, and the parameters λ', μ' with those through G. The parameters associated with the two lines through F' may, therefore, be taken to be (λ, μ'), and those for G' to be (λ', μ); thus the symbols for F' and G' will, respectively, be

$$\lambda A + \mu' B + \lambda\mu' C + D, \quad \lambda' A + \mu B + \lambda'\mu C + D.$$

The coordinates of the points F, G, F', G', relatively to A, B, C, D, will thus be, respectively,

$$(\lambda, \mu, \lambda\mu, 1); \quad (\lambda', \mu', \lambda'\mu', 1); \quad (\lambda, \mu', \lambda\mu', 1); \quad (\lambda', \mu, \lambda'\mu, 1).$$

The coordinates of the three points F, F', G', thus, all satisfy the equation

$$x\mu + y\lambda = z + t\lambda\mu;$$

by the theory we have just given this is, therefore, the equation of the tangent plane of the quadric at F. If we put

$$x_0 = \lambda, \quad y_0 = \mu, \quad z_0 = \lambda\mu, \quad t_0 = 1,$$

for the coordinates of F, this is the same as

$$xy_0 + yx_0 - zt_0 - tz_0 = 0,$$

or
$$\left(x_0 \frac{\partial}{\partial x} + y_0 \frac{\partial}{\partial y} + z_0 \frac{\partial}{\partial z} + t_0 \frac{\partial}{\partial t}\right)(xy - zt) = 0,$$

which is in accordance with preceding results, the equation of the quadric being $xy - zt = 0$.

The polar point, or pole, of a plane in regard to a quadric. There are two senses in which we may very naturally speak of the pole of a plane in regard to a quadric; we shew here that these lead to the same point.

(*a*) Given any plane ϖ, if any three points of this be A, B and C, and we take their polar planes in regard to the quadric, meeting, suppose, in the point O; then, as the polar plane of A passes through O, therefore the polar plane of O passes through A, and this plane similarly passes through B and C; it is, thus, the plane ϖ. The polar plane of any other point of the plane ϖ, since this point lies in the polar plane of O, also passes through O. The pole of the plane ϖ, in this sense, is thus the point common to the polar planes of all points of ϖ; and the plane is the polar plane of this point.

(*b*) As, however, we defined the polar plane of a point when the quadric is regarded as a locus of points, so we may define the pole of a plane, in a dual way, when the quadric is generated by an aggregate of planes. When regarded in the former way, the quadric is the aggregate of points lying on all transversals of three non-intersecting lines. We may, however, consider the aggregate of all planes passing through the transversals of three given non-intersecting lines. We have proved above that these planes are in fact the tangent planes of a quadric defined as a locus of points, each plane containing points of the quadric lying on two lines. As we defined the polar plane of a point, O, in regard to the quadric locus of points, by drawing a line through O, and taking the points Q, R of this line which are points of the quadric, and then the locus of the point P of this line which is the harmonic conjugate of O in regard to Q and R, so we may proceed for the aggregate of planes: given a plane ϖ, let l be a line on this plane; through this line l two planes of the aggregate can be drawn, which are in fact tangent planes of the quadric locus; we may take the plane, through the line l, which is the harmonic conjugate of ϖ in regard to these two planes. All these fourth harmonic planes, when l takes different positions on the plane ϖ, have a point, O', in common. This is the point which we might naturally call the pole of the plane ϖ, when the figure is regarded in this dual way. We shew that this point O' is the same as the point O obtained above, of which ϖ is the polar plane.

For the polar line of l, containing all points whose polar planes pass through l, passes through O; and, as we have seen above, this polar line meets the quadric locus in two points, Q and R, whereat the tangent planes of the quadric are such as to pass through l; as the point in which this line meets the plane ϖ is the harmonic conjugate of O, in regard to Q and R, it follows that the plane ϖ is the harmonic conjugate of the plane Ol in regard to the tangent planes Ql and Rl. This being so for every line l of the plane ϖ, the result follows, that O' coincides with O.

Alternative deduction of the polar point of a plane with the help of the symbols. If we are given three arbitrary non-intersecting lines, we have seen that two points of a transversal of these may, by taking suitable points of reference, be supposed to be of coordinates

$$(\lambda, \mu, \lambda\mu, 1), \quad (\lambda, \mu', \lambda\mu', 1),$$

respectively, where λ refers to the particular transversal chosen, and μ, μ' belong to the generators of the opposite system which determine the two points of this. The conditions that a plane, of equation $lx + my + nz + pt = 0$, should contain these two points, are

$$l\lambda + p + \mu(m + \lambda n) = 0, \quad l\lambda + p + \mu'(m + \lambda n) = 0;$$

the conditions that the plane should contain the transversal λ are, therefore,

$$l\lambda + p = 0, \quad m + \lambda n = 0;$$

these are the only conditions for the coordinates (l, m, n, p) of a plane containing a transversal of the three given lines, which may thus be expressed in terms of λ and another variable parameter, σ, in the forms

$$l = -\frac{1}{\lambda}, \quad m = -\frac{1}{\sigma}, \quad n = \frac{1}{\lambda\sigma}, \quad p = 1,$$

which are of the same forms as are the coordinates $(\lambda, \mu, \lambda\mu, 1)$ of a point of the locus. They satisfy the equation $lm - np = 0$; and the pole of an arbitrary plane, $Lx + My + Nz + Pt = 0$, in regard to the aggregate of planes whose coordinates satisfy this relation, calculated in the precisely dual way, will be the point whose equation is

$$\left(L\frac{\partial}{\partial l} + M\frac{\partial}{\partial m} + N\frac{\partial}{\partial n} + P\frac{\partial}{\partial p}\right)(lm - np) = 0,$$

or

$$Lm + Ml - Np - Pn = 0,$$

that is, the point whose coordinates are $(M, L, -P, -N)$. The polar plane of this point in regard to the quadric locus, of which the points satisfy the equation, $xy - zt = 0$, is the plane whose equation is

$$\left(M\frac{\partial}{\partial x} + L\frac{\partial}{\partial y} - P\frac{\partial}{\partial z} - N\frac{\partial}{\partial t}\right)(xy - zt) = 0;$$

this is exactly the original plane $Lx + My + Nz + Pt = 0$.

Examples of some general properties of quadrics. *Examples* 1—19. We may now usefully apply these ideas to deduce some general properties of a quadric.

Ex. 1. The plane, whose equation is

$$-\frac{x}{\lambda} - \frac{y}{\mu} + \frac{z}{\lambda\mu} + t = 0,$$

is at once verified to contain the three points

$$(\lambda, \mu, \lambda\mu, 1), \quad (\lambda, \mu', \lambda\mu', 1), \quad (\lambda', \mu, \lambda'\mu, 1),$$

whatever λ' and μ' may be, that is, it contains the two intersecting generators λ and μ. Correspondingly, if this plane be called $[\lambda, \mu]$, it is at once verified that the point $(\lambda, \mu, \lambda\mu, 1)$ lies on the three planes $[\lambda, \mu]$, $[\lambda, \mu']$, $[\lambda', \mu]$. The plane $[\lambda, \mu]$ is, in fact, the tangent plane of the quadric $xy - zt = 0$ at the point (λ, μ).

Ex. 2. The pole of the plane $Lx + My + Nz + Pt = 0$ in regard to the plane-aggregate which is represented by the general equation $(A, B, C, D, F, G, H, U, V, W \between l, m, n, p)^2 = 0$, has a tangential equation

$$L(Al + Hm + Gn + Up) + \dots + P(Ul + Vm + Wn + Dp) = 0,$$

and this point, therefore, has the coordinates

$$AL + HM + GN + UP, \dots, UL + VM + WN + DP.$$

The polar plane of this point in regard to the locus represented by $(a, b, c, d, f, g, h, u, v, w \between x, y, z, t)^2 = 0$ has the equation

$$(AL + HM + GN + UP)(ax + hy + gz + ut) + \dots$$
$$+ (UL + VM + WN + DP)(ux + vy + wz + dt) = 0.$$

If A, B, C, etc., be the cofactors of a, b, c, etc. in the determinant Δ, as before, this equation can be verified to reduce to

$$\Delta(Lx + My + Nz + Pt) = 0.$$

Ex. 3. Two points are said to be *conjugate* to one another in regard to a quadric when the polar plane of either point contains the other point. Two planes are said to be *conjugate* to one another in regard to a quadric when the pole of either plane lies on the other plane.

Now, supposing the quadric not to be a cone, consider any two planes, α, β, whose line of intersection meets the quadric in the points F and G; let the polar line of FG, which is the line joining the poles, say A and B, respectively, of the planes α, β, meet the quadric in F' and G'. We have seen that the lines, lying on the quadric, which intersect in F, pass through F' and G', as do the lines, lying on the quadric, which intersect in G. If the planes α, β be conjugate to one another, the point A, the pole of the plane α, lies on the plane β, and similarly B on α; so that the planes α, β meet the line $F'G'$, which is the line AB, in points which are harmonic conjugates of one another in regard to F' and G'. The tangent lines at F, of the conics in which the quadric is met by the planes α, β, meet the line $F'G'$, however, in the same two points as do the planes α, β; for these tangent lines lie in the tangent plane of the quadric at F, which, we have seen, contains the generators of the quadric at F, and contains the line $F'G'$. Thus we have the result: *if two conic sections of a quadric be made by planes which are conjugate to one another in regard to the quadric, the tangent lines of these sections, at either one of the two points of the quadric at which the conics intersect, are harmonic conjugates of one another in regard to the two generators of the quadric at this point.*

The fact which corresponds dually to this may be remarked; it will be seen that, incidentally, it has been established by the argument given. To the points of the quadric which lie in a plane, correspond dually the tangent planes of the quadric which pass through a point; as the points lie on a conic, so these planes are the tangent planes of a quadric cone. As the conics in which two planes meet the quadric have two points in common, these being the points of intersection, with the quadric, of the line of intersection of the two planes, so the tangent cones drawn to the quadric, from two points, have two tangent planes in common, these being the tangent planes drawn to the quadric from the line joining the vertices of the two cones. To the tangent line of a plane conic section of the quadric, at any point of this, corresponds a generator of a tangent cone. To the tangent lines of two plane sections, at a common point, which both lie in the tangent plane of the quadric at this point, correspond, then, two generators of two cones of contact of the quadric, lying in a common tangent plane of these cones, and intersecting in the point where this plane touches the quadric. If A and B be the vertices of these cones, and F be one of the two points of the quadric for which the tangent plane contains the line AB, this plane is one of the tangent planes of the quadric which pass through A, and, therefore, a tangent plane of the cone of contact whose vertex is A; and is, similarly, a tangent plane of the cone of vertex B. The lines AF, BF are the two generators of the cones which correspond to the tangents at a common point of the plane sections. By what we have seen above, if A and B be conjugate points in regard to the quadric, so that they are harmonic conjugates of one another in regard to the two points, F' and G' say, in which the line AB meets the quadric, then, the lines FA, FB are harmonic conjugates in regard to the two generators of the quadric which meet in F.

Ex. 4. We can, in an infinite number of ways, find four points, A, B, C, D, such that each is the pole of the plane containing the other three. Let D be an arbitrary point, and A an arbitrary point lying in the polar plane of D. The polar plane of A will, then, pass through D; and it will meet the polar plane of D in a line. On this line take an arbitrary point, B; the polar plane of B will then pass through A and D, and meet this line in a point C; as C is in the polar plane of D and A and B, its polar plane contains D, A, B. The four points A, B, C, D are, therefore, four such points as were desired.

When referred to A, B, C, D as points of reference, the equation of the quadric must reduce to

$$ax^2 + by^2 + cz^2 + dt^2 = 0,$$

containing only squares of the coordinates. For, if the point D be joined to any point, $xA + yB + zC$, of the plane ABC, the joining line meets the quadric in two points which are harmonic conjugates in regard to D and the point, $xA + yB + zC$, where this line meets the plane ABC. Two such points will be of symbols

$$xA + yB + zC + tD \text{ and } xA + yB + zC - tD;$$

namely, to any point (x, y, z, t) of the quadric is associated a point $(x, y, z, -t)$. Thus the equation of the quadric, $f(x, y, z, t) = 0$, must be such as to be the same as $f(x, y, z, -t) = 0$, for all values of x, y, z. It is similarly unaffected by change of the sign of x only, or y only, or z only; and thus has the form in question. Or the same result may be obtained by remarking that the polar plane of D, of which the equation is $ux + vy + wz + dt = 0$, must reduce to $t = 0$, so that $u = v = w = 0$; and similarly for A, B, C.

It follows that if $a_rx + b_ry + c_rz + d_rt = 0$ be the equations, for $r = 1, 2, 3, 4$, of four planes such that any three intersect in the pole of the remaining one, the equation of the quadric is capable of the form

$$\sum_{r=1}^{4} A_r (a_rx + b_ry + c_rz + d_rt)^2 = 0.$$

Further, the tangential equation of the quadric

$$ax^2 + by^2 + cz^2 + dt^2 = 0 \text{ is } a^{-1}l^2 + b^{-1}m^2 + c^{-1}n^2 + d^{-1}p^2 = 0.$$

And, if (x_r, y_r, z_r, t_r) be four points, for $r = 1, 2, 3, 4$, such that any one is the pole of the plane containing the other three, the tangential equation of the quadric is capable of the form

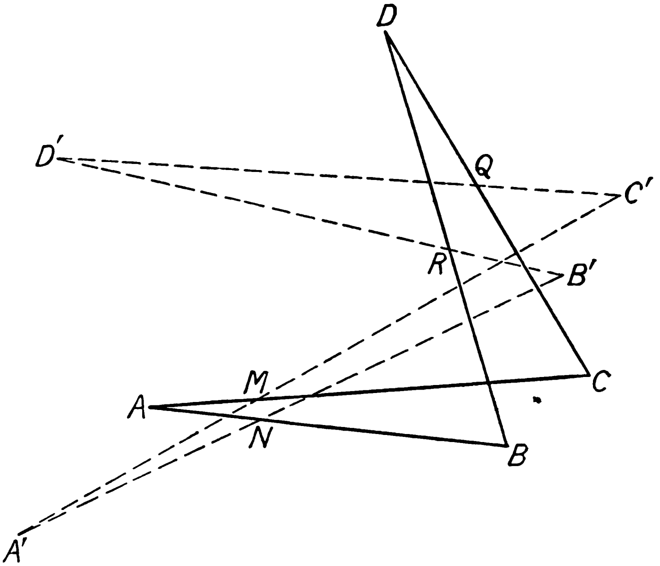
$$\sum_{r=1}^{4} (lx_r + my_r + nz_r + pt_r)^2 = 0.$$

For a cone, one of the four points, say D, must be at the vertex; the equation then is $ax^2 + by^2 + cz^2 = 0$; the polar plane of *any* point of the line DA is then the plane DBC, and so for DB and DC; the plane $t = 0$ is then arbitrary.

Four points A, B, C, D, of which each is the pole of the plane containing the other three, are said to form a self-polar tetrad in regard to the quadric.

Ex. 5. When two lines, l, m, are such that the polar line, l', of l, in regard to a quadric, intersects the other line m, it can be shewn that the polar line, m', of m intersects l. For, if M be the point where l' meets m, the polar plane of M, a point of l', contains the line l; but as M is on m, this polar plane also contains the line m'. Thus l and m' meet. Two such lines, l, m, are said to be *conjugate* in regard to the quadric.

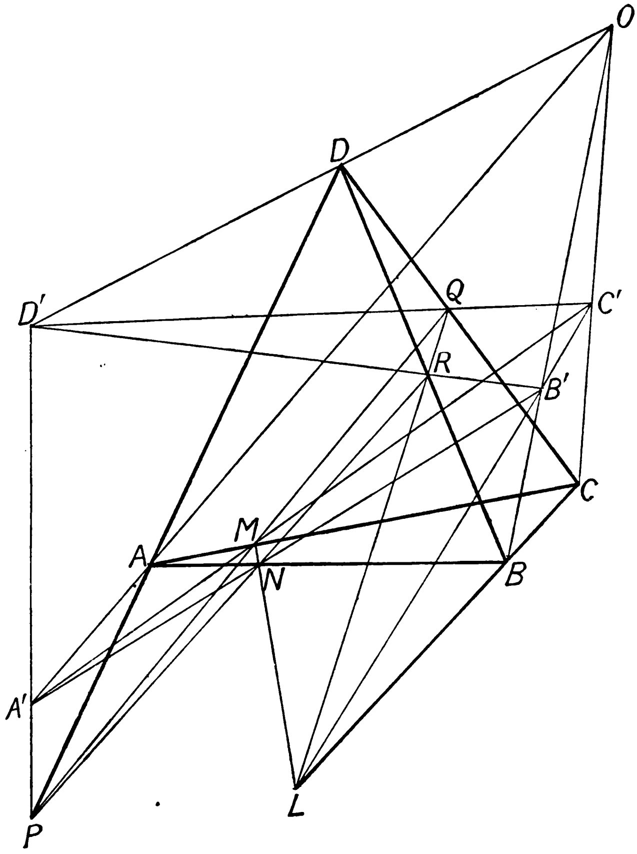
It can be shewn that, if A, B, C, D be four points such that two pairs of opposite joining lines of these be conjugate, say CA conjugate to BD and AB conjugate to CD, then also the third pair of joins, BC and AD, are conjugate lines. Let D', A', B', C' be the poles, respectively, of the planes ABC, BCD, CAD, ABD, so



that $C'D'$, which is the polar line of AB, intersects CD, say in Q; and similarly, $B'D'$, $C'A'$, $B'A'$, the respective polar lines of AC, BD, CD, meet the joins BD, AC, AB, say in the points R, M, N.

Considering the section, of the quadric and of the planes DBC, DCA, DAB, by the plane $A'B'C'$, we obtain a conic, and three lines, which, in virtue of the definition of a polar plane by a harmonic range, are the polar lines, with respect to this conic, respectively of the points A', B', C'. The three intersections of these lines respectively with $B'C'$, $C'A'$, $A'B'$ are thus in line (Vol. II, p. 31). Thus, the line $B'C'$ intersects the line MN in a point lying on the plane DBC, which is, therefore, on the line BC. By considering the section by the plane $D'B'C'$, we similarly prove that QR and $B'C'$ intersect on BC. Let this point of intersection of $B'C'$, QR, MN, BC be called L. A similar argument will shew that QM, RN, AD and $A'D'$ meet in a point, say P. It is then easy to prove that any two of the four lines AA', BB', CC', DD' meet one another, so that these four lines all meet in one point, say O, and the two tetrads A, B, C, D and A', B', C', D' are in perspective from O, corresponding lines and planes, belonging to these, intersecting the plane $QMNR$ in the same point or line. The consequence that BC, being met by $B'C'$, is conjugate to AD, is contained in this statement.

The complete figure so obtained is one in which there are fifteen points, twenty lines and fifteen planes, each point lying on four of these lines and on six of these planes, each line containing three of the points and lying in three of the planes, each plane containing six of the points, and four of the lines. So that the structure of the figure may be indicated by the scheme



$$15\,(\,\cdot\,, 4, 6)\ 20\,(3, \cdot\,, 3)\ 15\,(6, 4, \cdot\,)\,;$$

the figure is in fact the same as that which is used in the proof of Desargues' theorem for two triangles lying in the same plane (of which a diagram is given as frontispiece to Vol. I).

In this figure the points A', B', C', D' are introduced as the poles of certain planes, and these are in perspective with A, B, C, D

from the point O. It can however be shewn that the points of the figure are symmetrical in their relations to the quadric. For first, the line AA', joining the poles of the planes $B'C'D'$, BCD, is the polar line of the intersection of these, that is, of the line QR; and, similarly, the lines BB', CC', DD' are, respectively, the polars of the lines MQ, NR, MN, so that the point O is the pole of the plane, $MQRN$, containing these four lines; and also, the point P, where MQ, NR intersect, is the pole of the plane OBC, containing the lines BB', CC'; and, similarly, L, M, N, Q, R are, respectively, the poles of the planes OAD, OBD, OCD, OAB, OCA. Thus the six points in which the polar plane of O meets the joins of A, B, C, D (which are also the points in which this plane meets the joins of A', B', C', D'), are the poles of the planes joining O to the respectively opposite joins of A, B, C, D (which are the same as the planes joining O to the corresponding joins of A', B', C', D'). Every one of the fifteen points of the figure is, however, the centre of perspective of two tetrads of points, of which the respective sets of six joins occur in the figure; the remaining six points of the figure are then on the polar plane of the centre of perspective, and are the poles of the six planes of the figure passing through this centre. For each of the two tetrads, a join, l', is conjugate to the opposite join, l, the polar line of l being a join in the second tetrad, meeting l'. Either tetrad consists of the poles of the planes containing three points of the other tetrad. The point O and A, B, C, D together form a pentad of points, with the property that the pole of the plane containing any three of these lies on the line joining the other two; the same statement is true of the pentad O, A', B', C', D'. For each of the fifteen points of the figure a similar pair of pentads exists. Such a pentad may be called a *self-conjugate pentad*. It may be regarded as a generalisation of a self-polar tetrad, just as, in a plane, a set of four points, of which every pair of opposite joins consists of conjugate lines in regard to a conic (Vol. II, p. 33), may be regarded as a generalisation of a self-polar triad.

Conversely given two tetrads of points which are in perspective, there is a definite quadric in regard to which the completed figure has the reciprocal properties which have been announced.

The whole may be discussed with the symbols; and it appears that the quadric can be expressed, in point coordinates, or in tangential coordinates, by an equation involving five squares, for each of the ways in which the figure may be regarded. Let A, B, C, D be four points such that the lines AC, BD are conjugate, and, also, the lines AB, CD are conjugate, in regard to a certain quadric surface. Let the equation of this surface, in point coordinates referred to A, B, C, D, be $(a, b, c, d, f, g, h, u, v, w \between x, y, z, t)^2 = 0$, and A', B', C', D' be, as before, the poles of the planes BCD, CAD, ABD, ABC; then the planes $A'B'D'$, $B'C'D'$, which are the polar planes of C and A respectively, have the respective equations

$$gx + fy + cz + wt = 0, \quad ax + hy + gz + ut = 0;$$

in order that $B'D'$, the line of intersection of these planes, should intersect BD, the points, given by $fy + wt = 0$, $hy + ut = 0$, where these planes meet BD, must be the same, so that $fu = hw$. In order that $C'D'$ may intersect CD, the results of putting $x = 0$, $y = 0$ in the equations $ax + hy + gz + ut = 0$, $hx + by + fz + vt = 0$, namely $gz + ut = 0$, $fz + vt = 0$, must be the same, so that $fu = gv$. From $gv = hw$ it then follows at once that the joins BC, AD are conjugate. It follows also, writing σ in place of any one of the equal expressions vw/f, wu/g, uv/h, that the equation of the quadric is capable of the form

$$(a - \sigma^{-1}u^2)x^2 + (b - \sigma^{-1}v^2)y^2 + (c - \sigma^{-1}w^2)z^2 + (d - \sigma)t^2 \\ + \sigma^{-1}(ux + vy + wz + \sigma t)^2 = 0;$$

here $x = 0$, $y = 0$, $z = 0$, $t = 0$ are the equations of the planes BCD, ..., ABC; and it can be shewn that $ux + vy + wz + \sigma t = 0$ is the equation of the plane containing the six points of intersection of corresponding joins of the two tetrads A, B, C, D and A', B', C', D'. This plane is the polar of the point, O, in which the lines AA', BB', CC', DD' meet. It will appear that, if the cofactors of a, b, c, ... in the determinant Δ, formed by the coefficients in the equation of the quadric, be, as above (p. 24), denoted by A, B, C, ..., then there exist also the relations $FU = GV = HW$, and that, if λ denote any one of the equal expressions VW/F, WU/G, UV/H, then the coordinates of O are (U, V, W, λ). That the polar plane of this point should have the equation above given involves identities which are reducible to those given.

We may investigate the theorem with the tangential equation of the quadric, supposed of the form

$$(A, B, C, D, F, G, H, U, V, W \between l, m, n, p)^2 = 0.$$

The condition that the line $B'D'$ should meet the line BD is that a plane with equation of the form $x = mz$ should contain the points B', D', whose coordinates are, respectively, (H, B, F, V) and (U, V, W, D); this requires that $HW = FU$. The condition that the line $C'D'$ should meet the line CD, similarly, requires that the points (G, F, C, W), (U, V, W, D) should lie in a plane with equation of the form $x = ny$; and this involves that $GV = FU$. The consequence $GV = HW$, of these equations, is easily seen to secure that the joins BC, AD are conjugate in regard to the quadric. Denoting the equal quantities VWF^{-1}, etc., as just said, by λ, these identities allow the tangential equation of the quadric to be put into the form

$$(A-\lambda^{-1}U)\,l^2+(B-\lambda^{-1}V)\,m^2+(C-\lambda^{-1}W)\,n^2+(D-\lambda)\,p^2$$
$$+\lambda^{-1}(Ul+Vm+Wn+\lambda p)^2=0,$$

where $l=0$, $m=0$, $n=0$, $p=0$, $Ul+Vm+Wn+\lambda p=0$, are, respectively, the tangential equations of the points A, B, C, D, O.

In general, we may determine the tangential equation of a quadric whose point equation is

$$Ex^2+Qy^2+Rz^2+Kt^2+(ex+qy+rz+kt)^2=0.$$

For this, we have to express that, for a point (x', y', z', t') satisfying this equation, and the equation $lx'+my'+nz'+pt'=0$, the equation

$$Exx'+Qyy'+Rzz'+Ktt'+(ex'+qy'+rz'+kt')\,(ex+qy+rz+kt)=0$$

is the same as $lx+my+nz+pt=0$; namely that, with M' written for $ex'+qy'+rz'+kt'$, we have

$$\frac{Ex'+M'e}{l}=\frac{Qy'+M'q}{m}=\frac{Rz'+M'r}{n}=\frac{Kt'+M'k}{p}.$$

These equations, if $lx'+my'+nz'+pt'=0$, involve that (x', y', z', t') lies on the quadric. Denoting these equal fractions by θ, we have

$$Ex'+M'e-\theta l=0,\quad \ldots,\quad Kt'+M'k-\theta p=0,$$

from which we infer

$$M'+M'\,(e^2E^{-1}+\ldots+k^2K^{-1})-\theta\,(elE^{-1}+\ldots+kpK^{-1})=0\,;$$

if $1+e^2E^{-1}+\ldots+k^2K^{-1}$ be denoted by ω, and $elE^{-1}+\ldots+kpK^{-1}$ by L, this equation is $M'=\omega^{-1}\theta L$. We, therefore, have

$$Ex'+\theta\,(e\omega^{-1}L-l)=0,\ \ldots,\ Kt'+\theta\,(k\omega^{-1}L-p)=0,$$

so that, by $lx'+\ldots+pt'=0$, we deduce

$$E^{-1}l^2+\ldots+K^{-1}p^2-\omega^{-1}L^2=0\,;$$

this is the tangential equation sought. More explicitly it is

$$\left(1+\frac{e^2}{E}+\ldots+\frac{k^2}{K}\right)\left(\frac{l^2}{E}+\ldots+\frac{p^2}{K}\right)-\left(\frac{e}{E}\,l+\ldots+\frac{k}{K}\,p\right)^2=0.$$

It is easily seen that a special form of self-conjugate pentad is constituted by a self-polar tetrad and an arbitrary point.

A particular case of a tetrad, of which each pair of opposite joins are conjugate lines in regard to a quadric, arises when the quadric, regarded as the aggregate of its tangent planes, reduces to all the planes passing through the tangent lines of a conic. This degeneration of a quadric is that which is the dual of the case when the quadric, regarded as the locus of its points, reduces to all the points on the generating lines of a quadric cone. In the latter case, the polar plane of any point passes through the vertex of the cone. In the former case, which we consider here, the pole of any plane is a point in the plane of the conic, being the pole, in regard to the conic, of the line in which the plane meets the plane of the conic; the polar line of any line, which does not lie in the plane of the conic, is the line, in this plane, which is the polar line, in regard to the conic, of the point in which the former line meets this plane. Two lines, of which neither lies in the plane of the conic, are then conjugate lines if they meet in this plane in two points which are conjugate points in regard to this conic. This being understood, we still have the result that, if the joins AC, BD, of four points A, B, C, D, be conjugate lines in regard to this degenerate quadric, and also the joins AB, CD be conjugate lines, then the remaining pair of joins BC, AD are conjugate lines. And we have the further result that the lines joining A, B, C, D, respectively to the poles A', B', C', D', of the planes BCD, CAD, ABD, ABC, all of which are in the plane of the conic, are four lines which meet in a point. In this case the points L, M, N, P, Q, R, are the points where the joins of A, B, C, D meet the plane of the conic.

Ex. 6. The unsymmetrical algebra of Ex. 5 may be replaced by symmetrical algebra, which suggests itself naturally if we regard the figure as arising by projection of a figure in four dimensions. The theorem so suggested is one for which there is an analogue in space of any number of dimensions; for instance we may have, in a plane, a set of four points such that the join of any two is conjugate to the join of the other two, with respect to a conic in that plane. This is analogous to the self-conjugate pentad. By taking the poles of these joins we obtain six other points, lying by threes on four lines. Thereby we have a figure of ten points and ten lines, of which three points lie on each line, and three lines pass through each point. This is analogous to the complete figure obtained above, and is self-polar in regard to the conic; as the figure obtained in Ex. 5 may be regarded as consisting of two tetrads in perspective from a point, together with the six points of intersection of the corresponding joins of the two tetrads, so the figure of which we speak, in a plane, may be regarded as consisting, in ten ways, of two triads in perspective from a point, together with the three points of intersection of corresponding joins of the two triads, these lying in line. The centre of perspective is the pole of this line. The conic in regard to which the polarity has place may have its equation expressed as a sum of four squares, in terms of the three joins of one of the triads which are in perspective, and of the axis of perspective corresponding, and this mode of expression arises in as many ways as the relation in question. But the analytical expression is suggested most naturally by regarding the figure as arising from a figure in three dimensions, that namely of the complete intersection of five planes. This figure is also self-polar, in a particular way, in regard to a quadric cone.

The existence of this polarity may be regarded as a generalisation of the theorem that if we take four arbitrary lines in a plane, and an arbitrary point O of the plane, the pair of lines joining O to two opposite pairs of intersection of the four lines, are harmonic conjugates in regard to a certain pair of lines drawn through O. This is the dual of the Greek theorem that the joins of four points of a plane cut an arbitrary line in pairs of points in involution.

The general theorem to which reference is here made will be understood from the Examples on p. 218 of Vol. II.

Ex. 7. Consider now a tetrad of points in three dimensions, and a fixed quadric, Σ, such that no one of the three pairs of opposite joins of these points consists of lines which are conjugate in regard to Σ. We prove that, if A', B', C', D' be the poles of the planes BCD, CAD, ABD, ABC, respectively, then the four lines, AA', BB', CC', DD', are such that they have an infinite number of transversals, and that they may be regarded as lines belonging to one system of lines of a quadric surface.

The condition that no two opposite joins, such as AB, CD, are conjugate lines, involves that no two of the lines AA', BB', CC', DD' intersect. For, if AA' meets BB', then $A'B'$ meets AB; but $A'B'$ is the polar line of CD, and only meets AB when AB, CD are conjugate.

Now consider the plane $A'B'C'$; let it meet the lines DA, DB, DC respectively in A_1, B_1, C_1. Then, in virtue of the definition of the polar plane of a point in regard to a quadric, by means of ranges of four harmonic points, it follows that the lines B_1C_1, C_1A_1, A_1B_1 are the polar lines, respectively of A', B', C', in regard to the conic in which the plane $A'B'C'$ meets the quadric Σ. Thus, by a theorem for two triads which arise by taking polars in regard to a conic (Vol. II, p. 31), the triads A', B', C' and A_1, B_1, C_1 are in perspective, and the lines $A'A_1$, $B'B_1$, $C'C_1$ meet in a point. Thus the planes DAA', DBB', DCC' meet in a line; and this line meets AA', BB' and CC'; it evidently also meets DD', at D. By a similar argument there is a line through each of the points A, B, C which meets all the lines AA', BB', CC', DD'. The three lines AA', BB', CC', of which, as we have seen, no two intersect, determine a quadric surface, containing all the points of all the transversals of these three lines; the line DD' contains four points of this quadric surface, namely the points where it is met by the four transversals of AA', BB', CC', DD' which are found above. Thus DD' lies entirely on this quadric surface.

Let the tangential equation of the given quadric surface, Σ, referred to the points A, B, C, D, be, as before,

$$(A, B, C, D, F, G, H, U, V, W \between l, m, n, p)^2 = 0.$$

Then, as the poles of the planes ABC, BCD, etc., are (U, V, W, D), (A, H, G, U), etc., the planes DAA', DBB', DCC' are at once seen to intersect in the line, through the point D, whose equations are $Fx = Gy = Hz$; and the planes ABB', ACC', ADD' similarly intersect in the line whose equations are $V^{-1}y = W^{-1}z = FV^{-1}W^{-1}t$. These two lines are at once verified to lie entirely upon the quadric surface whose equation is

$$(GV - HW)(Fxt + Uyz) + (HW - FU)(Gyt + Vzx) \\ + (FU - GV)(Hzt + Wxy) = 0,$$

and, as this equation is symmetrical, it is that containing the four lines AA', BB', CC', DD'. This equation is independent of the coefficients A, B, C, D.

Let this quadric be denoted by $\Phi(A, B, C, D)$, and let E be any point lying thereon. We may similarly form, with poles of the planes ABC, BCE, CAE, ABE, taken in regard to the same quadric Σ, a quadric $\Phi(A, B, C, E)$. One common point of these quadrics is the point D', which is the pole of the plane ABC in regard to the quadric Σ, and the lines $D'D$, $D'E$ lie, by construction, respectively on the quadrics $\Phi(A, B, C, D)$ and $\Phi(A, B, C, E)$; through D' there passes another generator of each of these quadrics. This other generator is, in fact, the same for both. For, if P, Q, R be the poles, in regard to Σ, respectively of the planes BCE, CAE, ABE, the three points D', A', P, being poles of planes which intersect in the line BC, are on a line, the polar line of BC in regard to Σ; therefore the plane $D'AA'$, containing $D'A'$, equally contains $D'P$. The generator of $\Phi(A, B, C, D)$ of which we are speaking is a line through D' meeting the lines AA', BB', CC'; thus the planes $D'AA'$, $D'BB'$, $D'CC'$ meet in a line, and, of these, the plane $D'AA'$ contains $D'P$, as we have seen; this common line, then, equally meets the lines AP, BQ, CR, and is the generator spoken of, drawn through D', of the quadric $\Phi(A, B, C, E)$.

It can be further shewn that the quadric $\Phi(A, B, C, E)$ passes through the point D. But this result follows from the less particular result given in the following example (8).

Ex. 8. Let A, B, C and P, Q, R be any six points, in three dimensions; suppose that the polar lines of the lines QR, RP, PQ, in regard to any quadric, Σ, which will be lines passing through the pole, say O, of the plane PQR in regard to the quadric Σ, meet the plane ABC in points A', B', C', respectively, such that the lines AA', BB', CC' meet in a point. Then, if the polar lines, in regard to Σ, of the lines BC, CA, AB, which will be lines passing through the pole, say D, of the plane ABC, meet the plane PQR, respectively, in points P', Q', R', the lines PP', QQ', RR' also meet in a point.

For, by the hypothesis made, the planes $AA'O$, $BB'O$, $CC'O$ meet in a line. Now A is the intersection of the lines AB, AC, and is thus the pole of the plane containing the polar lines of these, DR', DQ', respectively, namely, A is the pole of the plane $DQ'R'$; and $A'O$ is the polar line of QR. Thus, the plane joining A to the line $A'O$ is the polar of the point in which the plane $DQ'R'$ is met by the line QR; in other words, the plane $AA'O$ is the polar of the point of intersection of the lines $Q'R'$ and QR. Similarly the planes $BB'O$ and $CC'O$ are, respectively, the polar planes of the points $(R'P', RP)$ and $(P'Q', PQ)$. As these three planes meet in a line, it follows that the points $(Q'R', QR)$, $(R'P', RP)$, $(P'Q', PQ)$ are in line, so that the triads P', Q', R' and P, Q, R are in perspective, as was to be shewn.

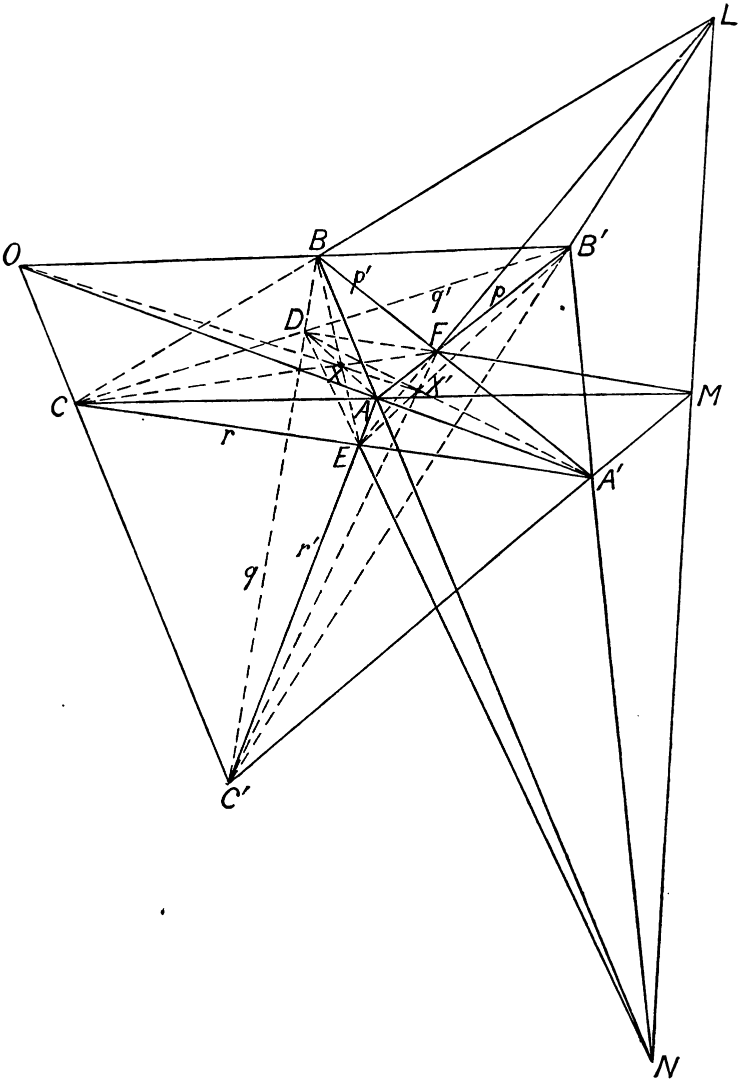
The proposition dual to the above may also be enunciated; but first it may be well to remark that three planes, α, β, γ, are said to be in perspective with three planes, α', β', γ', whose point of intersection is the same as the point of intersection of α, β, γ, when the plane containing the lines $\beta\gamma$, $\beta'\gamma'$, the plane containing the lines $\gamma\alpha$, $\gamma'\alpha'$, and the plane containing the lines $\alpha\beta$, $\alpha'\beta'$, are three planes which meet in a line. When this is so, the line of intersection of the planes α, α', the line β, β' and the line γ, γ', are three lines which lie in a plane. This being clear, the dual of the result above given is this: let α, β, γ be three planes, meeting in a point (α, β, γ), and (λ, μ, ν) be three other planes, meeting in a point (λ, μ, ν). Consider the polar lines of the lines (μ, ν), (ν, λ) and (λ, μ); these polars are lines lying in the polar plane of the point (λ, μ, ν). Suppose that the planes joining the point (α, β, γ) to these polar lines are in perspective with the planes α, β, γ. Then, also, the polar lines of the lines (β, γ), (γ, α), (α, β)—which polars are lines lying in the polar plane of the point (α, β, γ)—when joined by planes to the point (λ, μ, ν), give three planes in perspective with the planes λ, μ, ν.

A particular case of this is the result referred to in the preceding example. Let DBC, DCA, DAB, or λ, μ, ν, be three planes, whose respective poles are A', B', C', with reference to a quadric Σ. Let E be a point from which can be drawn a line to meet the lines AA', BB', CC', so that the planes EAA', EBB', ECC' meet in a line. From this it follows that if the planes EBC, ECA, EAB be called, respectively, α, β, γ, the planes joining E to the polar lines, respectively $B'C'$, $C'A'$, $A'B'$, of λ, μ, ν, are in perspective with the planes α, β, γ. Now let P, Q, R, respectively, be the poles of the planes EBC, ECA, EAB, so that the planes joining D to the polars of the lines EA, EB, EC are, respectively, the planes DQR, DRP, DPQ. By what we have seen above, these planes are in perspective with the planes λ, μ, ν, respectively. Therefore the planes DAP, DBQ, DCR meet in a line. Hence, a line can be drawn from D to meet the lines AP, BQ, CR. That is, as stated in the last example, when E is a point of the quadric $\Phi(A, B, C, D)$, then D is a point of the quadric $\Phi(A, B, C, E)$.

Ex. 9. It has been remarked, in Ex. 5, that when two tetrads of points, in three dimensions, are in perspective, there is a definite quadric, in regard to which each point of either tetrad is the pole of the plane containing three points of the other tetrad. A particular case is that when three of the points of either tetrad lie upon their corresponding planes, which are thus tangent planes of the quadric. This case arises when we consider a skew hexagon, formed with three generators of a quadric of one system, and three generators of the other system (Dandelin, *Gergonne's Annales de Math.* xv (1824, 5), p. 387; Hesse, *Crelle*, xxiv (1842), p. 40); and the figure leads to a proof of the concurrence, in a Steiner point, of three of the Pascal lines of six points of a conic, and to the theorem that two of these Steiner points are conjugate points in regard to the conic (Vol. II, Note II, p. 231).

It will be simplest, first, to describe the figure which is obtained: let O, A, B, C be four points of which no three are in line; let A', B', C' be any points lying respectively on OA, OB, OC, the lines BC', $B'C$ meeting in D, the lines CA', $C'A$ meeting in E, and the lines AB', $A'B$ meeting in F. The lines BC, EF then meet on $B'C'$ at the point, L, where the planes $OB'C'$, $A'BC$, AEF meet; so CA, FD, $C'A'$ meet, say in M, and the lines AB, DE, $A'B'$ meet, say in N; the points L, M, N are in the line in which the planes ABC, $A'B'C'$, DEF meet. Further, the lines AD, BE, CF meet in a point, say X; also the lines $A'D$, $B'E$, $C'F$ meet in a point, say X'; and the points O, X, X' are in line. The two tetrads A, B, C, X and A', B', C', X' are, thus, in perspective from O, the plane of perspective being D, E, F, L, M, N; but A' lies on the plane BCX, as A lies on the plane $B'C'X'$, and, similarly, B, B', C, C' lie each on their corresponding planes; the figure is thus a particular case of one often considered, of which the scheme of the indices of structure is $15(\cdot, 4, 6)\ 20(3, \cdot, 3)\ 15(6, 4, \cdot)$. If we take, for the symbols of A, B, C, in regard to A', B', C', O, $A = O + A'$, etc., we have $D = O + B' + C'$, etc.; $X = 2O + A' + B' + C'$; $X' = O + A' + B' + C'$.

We may initiate the figure by taking six generators, AB', $B'C$, CA', $A'B$, BC', $C'A$, which we shall call, respectively, p, q', r, p', q, r', of a quadric surface. The point A, where the generators AB', AC' intersect, is then the pole of the plane $B'C'X'$, and so on; the line



AD is the polar line of the line $B'C'$, etc., and X is the pole of the plane $A'B'C'$; so the line $A'D$ is the polar line of the line BC, etc., and X' is the pole of the plane ABC; the line AA' is the polar line of the line EF, etc.; hence the line AXX' is the polar line of the line LMN.

It can be proved that the equation of the quadric, referred to A, B, C, X, is capable of the form

$$x^2+y^2+z^2-t^2-(x+y+z-t)^2=0,$$

this being the particular case of the equation

$$(a+b+c+d+1)(ax^2+by^2+cz^2+dt^2)-(ax+by+cz+dt)^2=0,$$

which arises when $a=b=c=-1$, $d=1$; this last is that of the quadric in regard to which the two tetrads,

$$(1, 0, 0, 0), (0, 1, 0, 0), (0, 0, 1, 0), (0, 0, 0, 1),$$

and

$$(a^{-1}+1, 1, 1, 1), (1, b^{-1}+1, 1, 1), (1, 1, c^{-1}+1, 1), (1, 1, 1, d^{-1}+1),$$

are obtained from one another by reciprocation.

Now consider the section of the quadric by an arbitrary plane. The generators p, q', ... will meet this plane in six points, say P, Q', ..., lying on a conic; the plane of two consecutive generators, p, q', will meet this plane in the line PQ'; the intersection of the opposite joins, PQ', $P'Q$, of the six points, P, Q', etc., of the plane, will be the point in which the plane is met by the line of intersection of the opposite planes, p, q' and p', q, of the skew hexagon formed by the generators. Taking the generators in a definite order, p, q', r, p', q, r', the three lines of intersection of the three pairs of opposite planes, each plane defined by two consecutive generators, namely of the planes pq', $p'q$; qr', $q'r$; rp', $r'p$, are in one plane. This plane meets an arbitrary plane in a line. This is then the Pascal line of the six points, P, Q', R, P', Q, R', in the plane. By taking the generators in a different order we obtain other Pascal lines in this plane, corresponding to different orders of the same six points P, Q', ... We consider in particular the six orders obtained by interchanging the alternate generators p', q', r' among themselves, leaving p, q, r unaltered. We find that the three Pascal lines corresponding to the three cyclically different orders p', q', r'; q', r', p'; r', p', q', meet in a point, one of the Steiner points, the three planes in the space figure which give these Pascal lines, by their intersection with the arbitrary plane, being planes which meet in a line, say l; and, then, that the three planes corresponding to the other three orders r', q', p'; q', p', r'; p', r', q' meet in another line, say l', which is the polar line of l in regard to the quadric. Wherefore these latter give rise to a Steiner point, for the conic, which is conjugate to the former Steiner point in regard thereto. The details may be tabulated thus:

the orders of the generators

$$p, p', r, r', q, q';\quad p, r', r, q', q, p';\quad p, q', r, p', q, r';$$
$$p, q', r, r', q, p';\quad p, p', r, q', q, r';\quad p, r', r, p', q, q',$$

correspond respectively to the skew hexagons

$$B', F, A', E, C', D;\quad F, A, E, C, D, B;\quad A, B', C, A', B, C';$$
$$F, B', C, E, C', B;\quad A, F, A', C, D, C';\quad B', A, E, A', B, D;$$

the pairs of opposite planes of these, each plane containing two consecutive sides of the skew hexagon, meet on three lines which are the joins, respectively, of the three points

$$A, B, C;\quad A', B', C';\quad D, E, F;\quad A, A', D;\quad B, B', E;\quad C, C', F;$$

the planes determined by the first three triads of points meet in the line LMN; the planes determined by the second three triads of points meet in the line OXX'. We have seen that this line is the polar line of the line LMN.

This proves the statement made.

Ex. 10. We have considered above, in Ex. 5, a set of five points which are such that the pole of the plane containing any three of them, taken in regard to a quadric, lies on the join of the other two, calling it a self-conjugate pentad. We consider now a set of six points which are such that the pole of the plane containing any three of them, taken in regard to a quadric, lies on the plane containing the other three. The pentad was such that the tetrad, constituted by any four of its points, had each of its three pairs of opposite joins as conjugate lines, in regard to the quadric. For a hexad, we take any four arbitrary points A, B, C, D, and consider the quadric, $\Phi(A, B, C, D)$, of which four generators are the lines joining A, B, C, D, respectively, to the poles, A', B', C', D', of the planes BCD, CAD, ABD, ABC, taken in regard to the fixed quadric, Σ. If E and F form, with A, B, C, D, such a hexad as is desired, the plane EFD must contain the pole, D, of the plane ABC, so that the line EF must meet DD'; and it must similarly meet AA', BB', CC'. Thus EF must be a generator of $\Phi(A, B, C, D)$, of the opposite system from the lines AA', etc. Again, the plane ADF must contain the pole, P, of the plane BCE, or DF must meet AP; similarly, DF must meet BQ and CR, where Q and R are, respectively, the poles of the planes CAE and ABE. Thus DF must be a generator of the quadric $\Phi(A, B, C, E)$, of the opposite system from the lines AP, etc. We therefore proceed as follows: we take E to be any point of $\Phi(A, B, C, D)$, and on the generator of this through E, of the opposite system from the lines AA', etc., we take the point F, in which the quadric $\Phi(A, B, C, E)$, which passes through E, meets this generator again. Then as EF meets DD', the line ED', which lies on $\Phi(A, B, C, E)$, meets DF; we have shewn (above, Ex. 8) that $\Phi(A, B, C, E)$ contains D; thus the line DF contains three points of $\Phi(A, B, C, E)$, and is a generator of this, through D, meeting ED', and, thus, of the opposite system from the lines AP, etc. We can now shew that the hexad A, B, C, D, E, F, so constructed, is such a self-conjugate hexad as is desired, in regard to the quadric Σ.

For first, as EF meets DD', the plane DFF' contains the pole, D', of the plane ABC; for a similar reason, the planes AEF, BEF, CEF, are, respectively, conjugate to the opposite planes of the hexad, BCD, CAD, ABD. Again, as DF is a generator of $\Phi(A, B, C, E)$, of the opposite system from the lines AP, etc., it follows that AP meets DF, and the plane ADF contains the pole, P, of the opposite plane, BCE, of the hexad; similarly, the planes, BDF, CDF are conjugate to the respectively opposite planes, CAE, ABE, of the hexad. Finally, we proved (Ex. 8, above), that if E be on $\Phi(A,B,C,D)$, then D is on $\Phi(A, B, C, E)$; by a similar argument, since F is on $\Phi(A, B, C, E)$, it follows that E is on $\Phi(A, B, C, F)$, and the point E may be constructed from F, just as was F from E. Wherefore it follows that DE is a generator of $\Phi(A, B, C, F)$, and that the planes ADE, BDE, CDE are conjugate to the respectively opposite planes, BCF, CAF, ABF, of the hexad. The proof of the property is thus complete, for each of the ten pairs of opposite planes of the hexad. In the particular case when E is so taken that EF contains the pole, D', of the plane ABC, it may be shewn that A, B, C, E, F constitute a self-conjugate pentad.

It has been remarked that the equation of the quadric $\Phi(A,B,C,D)$, referred to A, B, C, D, if the tangential equation of the fixed quadric, Σ, be $(A, B, C, D, F, G, H, U, V, W \between l, m, n, p)^2 = 0$, is

$$(GV - HW)(Fxt + Uyz) + (HW - FU)(Gyt + Vzx) + (FU - GV)(Hzt + Wxy) = 0.$$

If the point E be (ξ, η, ζ, τ), it can be shewn that the point F, or $(\xi', \eta', \zeta', \tau')$, is given by

$$\frac{\xi'}{\tau'} = \frac{G\eta - H\zeta}{\eta W - \zeta V}, \quad \frac{\eta'}{\tau'} = \frac{H\zeta - F\xi}{\zeta U - \xi W}, \quad \frac{\zeta'}{\tau'} = \frac{F\xi - G\eta}{\xi V - \eta U}.$$

Further, it can be shewn that these values secure that all the determinants, of three rows and columns, of the array

$$\left\| \begin{array}{cccccc} F, & G, & H, & U, & V, & W \\ \eta\zeta, & \zeta\xi, & \xi\eta, & \xi\tau, & \eta\tau, & \zeta\tau \\ \eta'\zeta', & \zeta'\xi', & \xi'\eta', & \xi'\tau', & \eta'\tau', & \zeta'\tau' \end{array} \right\|,$$

are zero. It follows thence that the quadric Σ is capable of being written, tangentially, in the form

$$Pl^2 + Qm^2 + Rn^2 + Kp^2 + (l\xi + m\eta + n\zeta + p\tau)^2 + (l\xi' + m\eta' + n\zeta' + p\tau')^2 = 0;$$

this form shews at once that the plane containing any three of the points A, B, C, D, E, F is conjugate, in regard to this quadric, to the plane containing the other three points.

To find the point equation of the quadric represented by this equation, say $\Psi = 0$, we have to find the locus of a point (x, y, z, t), where x is $\partial\Psi/\partial l$, etc., and $lx + my + nz + pt = 0$; that is, writing L for $l\xi + \ldots + p\tau$, and L' for $l\xi' + \ldots + p\tau'$, we have to eliminate l, m, n, p, and ρ, from the equations

$$Pl + \xi L + \xi' L' + \rho x = 0, \text{ etc.,} \quad lx + my + nz + pt = 0.$$

These equations give, if we write

$$U = \frac{x\xi}{P} + \ldots + \frac{t\tau}{K}, \quad U' = \frac{x\xi'}{P} + \ldots + \frac{t\tau'}{K}, \quad S = \frac{x^2}{P} + \ldots + \frac{t^2}{K},$$

$$\omega = 1 + \frac{\xi^2}{P} + \ldots + \frac{\tau^2}{K}, \quad \phi = \frac{\xi\xi'}{P} + \ldots + \frac{\tau\tau'}{K}, \quad \omega' = 1 + \frac{\xi'^2}{P} + \ldots + \frac{\tau'^2}{K},$$

the following equations

$$\begin{aligned} UL + U'L' + \rho S &= 0, \\ \omega L + \phi L' + \rho U &= 0, \\ \phi L + \omega' L' + \rho U' &= 0, \end{aligned}$$

and hence

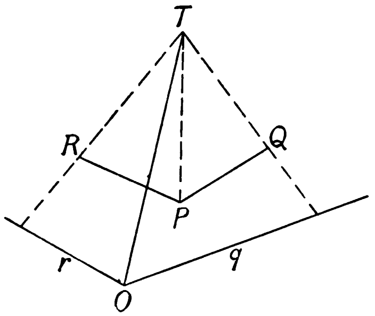
$$\begin{vmatrix} U, & U', & S \\ \omega, & \phi, & U \\ \phi, & \omega', & U' \end{vmatrix} = 0,$$

or
$$S(\omega\omega' - \phi^2) - U^2\omega' + 2UU'\phi - U'^2\omega = 0.$$

The expression of the equation of a quadric, referred to a self-polar tetrad, by four squares, has been considered above. The expression of a quadric by five, or more, squares, is considered by Paul Serret, *Géométrie de direction*, Paris, 1869, pp. 265, etc. The theory of the self-conjugate pentads and hexads has been much developed by Reye; see *Crelle's Journal*, Vols. LXXVII (1874), LXXXII (1877), etc.

Ex. 11. Given two arbitrary quadrics, S and Σ, it is possible to find three points of S of which every two are conjugate in regard to Σ, in an infinite number of ways; or, four points of S, forming a tetrad of which every pair of opposite joins consists of conjugate lines in regard to Σ, so that (Ex. 5, above) a fifth point can be found, not necessarily lying on S, such that the five form a self-conjugate pentad, in an infinite number of ways; or, lastly, five points of S, forming five points of a self-conjugate hexad, also in an infinite number of ways. We consider these cases in turn.

In regard to the first case, take an arbitrary point P, on S; then a point Q of S, lying anywhere on the conic in which S is met by the polar plane of P taken in regard to Σ; the polar plane of Q in regard to Σ will pass through P, and will meet the conic spoken of in two points. If R be one of these, then P, Q, R are three points of S of which every two are conjugate to one another, in regard to the quadric Σ. The pole of the plane PQR, say T, which does not necessarily lie on S, will then form, with P, Q, R, a tetrad which is self-polar in regard to Σ.



For the self-conjugate pentad, take three arbitrary points P, Q, R lying on S, and the polar lines, in regard to Σ, of the joins QR, RP, PQ; these lines, respectively p, q, r, will then meet in the point, O, which is the pole, in regard to Σ, of the plane PQR. The two planes Qq, Rr will meet in a line, passing through O; and this line will meet the quadric S in two points; let T be one of these. The four points P, Q, R, T, of the quadric S, are then such that the join TQ intersects the polar line, q, in regard to Σ, of the opposite join RP, so that TQ, RP are conjugate lines in regard to Σ. The opposite joins TR, PQ are equally conjugate lines in regard to Σ. Thus (by Ex. 5, above), the remaining pair of opposite joins, TP, RQ, are also conjugate. Wherefore, as has been shewn, the tetrad of points formed by the poles, in regard to Σ, of the planes PQR, TQR, TRP, TPQ, is in perspective with T, P, Q, R, and the centre of perspective, say U, forms, with T, P, Q, R, a self-conjugate pentad in regard to Σ. But U does not necessarily lie upon the quadric S.

For the self-conjugate hexad, take four arbitrary points, P, Q, R, T, of S: then form the quadric $\Phi\,(P, Q, R, T)$ in regard to Σ, as above explained (Ex. 7); on the curve of intersection, of this quadric Φ, with S, we can then take an arbitrary point E, and from this determine, as above explained, a point F, such that P, Q, R, T, E, F form a self-conjugate hexad, of which the points P, Q, R, T, E, but not necessarily F, are upon S.

Ex. 12. It is very easy now to prove with help of the equation to a quadric, that if upon a quadric S there be, either a self-polar tetrad, or a self-conjugate pentad, or a self-conjugate hexad, in regard to another quadric Σ, then an infinite number, of either of these figures, can be found whose points lie upon S. And though it is desirable, also, to establish this result without help of the symbols, the symbolical proof retains its interest. It depends on the facts we have remarked, that in regard to a self-polar tetrad, or a self-conjugate pentad, or a self-conjugate hexad, the tangential equation of Σ is capable of expression as a sum of squares, respectively four, five, or six in these respective cases.

For brevity let us call a set of h points, (x_r, y_r, z_r, t_r), for $r=1, \ldots, h$, which are so related to the quadric Σ, that the tangential equation of this is capable of a form

$$\sum_{r=1}^{h} A_r (lx_r + my_r + nz_r + pt_r)^2 = 0,$$

involving the squares of the left sides of the equations of these points, a self-conjugate h-ad in regard to Σ. Suppose, then, that a quadric S contains the points of a self-conjugate h-ad in regard to Σ. Suppose further that it has been shewn that $k-1$ points can be taken on S, so related to Σ that they can be completed by another point, not necessarily lying on S, to form a self-conjugate k-ad in regard to Σ; this has been proved, in the preceding example 11, for the cases of $k=4$, 5, 6. It can then be shewn that this remaining point of the k-ad equally lies on S. For if $(\xi_s, \eta_s, \zeta_s, \tau_s)$ be the points of the k-ad, for $s=1, \ldots, k$, we have, by identifying the two forms of which the tangential equation of Σ is capable, an identity, in regard to l, m, n, p, of the form

$$\sum_{r=1}^{h} A_r (lx_r + my_r + nz_r + pt_r)^2 + \sum_{s=1}^{k} P_s (l\xi_s + m\eta_s + n\zeta_s + p\tau_s)^2 = 0;$$

namely, we have the equations of forms such as

$$\sum_r A_r x_r^2 + \sum_s P_s \xi_s^2 = 0, \quad \sum_r A_r y_r z_r + \sum_s P_s \eta_s \zeta_s = 0.$$

If however the point equation of the quadric S be $f(x)=0$, where $f(x) = (a, b, c, d, f, g, h, u, v, w \between x, y, z, t)^2$, these equations lead to

$$\sum_r A_r f(x_r) + \sum_s P_s f(\xi_s) = 0,$$

and we are given that the $h+k-1$ equations, $f(x_r)=0, f(\xi_\sigma)=0$, hold, where $\sigma = 1, \ldots, k-1$. It follows then, supposing that P_k is not zero, that is, supposing that the $k-1$ points of the k-ad which have been taken on S do not form a $(k-1)$-ad, that we also have $f(\xi_k)=0$. So that the quadric S contains the point completing the k-ad, as was to be shewn.

But we see that the condition that there exists upon S a h-ad in regard to Σ may be replaced by another, in order to prove that all the points of the k-ad lie on S. For suppose that the tangential equation of Σ is $(A, B, C, D, F, G, H, U, V, W \between l, m, n, p)^2 = 0$, and, as before, that $k-1$ points of a k-ad in regard to Σ have been taken on S. By identifying the two forms of which the tangential equation of Σ is capable, we have again ten equations of forms such as

$$-A + \sum_s P_s \xi_s^2 = 0, \quad -F + \sum_s P_s \eta_s \zeta_s = 0,$$

and, therefore,

$$-\Theta + \sum_s P_s f(\xi_s) = 0,$$

where

$$\Theta = aA + bB + cC + dD + 2fF + 2gG + 2hH + 2uU + 2vV + 2wW.$$

If then S be so conditioned, relatively to Σ, that $\Theta = 0$, it follows, as before, that all the points of the k-ad lie on S. But, conversely, this same equation shews that, if it be possible to find a k-ad of which all the points lie on the quadric S, then $\Theta = 0$.

When $\Theta = 0$, the quadric S is said to be *outpolar* to Σ.

Ex. 13. If P, P' be two points which are conjugate to one another in regard to a quadric, Σ, and Q, Q' two other such points, and if l, m be the respective polar lines of the lines PP', QQ', in regard to Σ, then a quadric S exists containing the lines l, m and the four points P, P', Q, Q'.

To see this, recall, first, that if planes be drawn through a line, p, the poles of these planes lie on the line, p', which is the polar of p; and the planes through a second line, q, drawn, respectively, conjugate to the former planes, are those which contain these poles; these planes, therefore, form an axial pencil related to that formed by the planes through p.

With the figure we have assumed, the polar plane of the point P' contains both the line l and the point P, namely P' is the pole of the plane lP; thus the planes mP' and lP are conjugate. In this way we see that the planes lP, lP', lQ, lQ' are conjugate, respectively, to the planes mP', mP, mQ', mQ; so that the axial pencil of planes, $l(P, P', Q, Q')$, is related to the axial pencil $m(P', P, Q', Q)$, and, therefore, also to the pencil $m(P, P', Q, Q')$. There is thus (above, p. 4), a quadric surface containing the lines l, m, and the points P, P', Q, Q', of which the transversals, drawn from these four points to meet both l and m, are all generators.

A corollary from this theorem is, that, if P, P', A, A' and Q, Q', B, B' are two tetrads of points, both self-polar in regard to a quadric Σ, then the quadric surface containing the points P, P', A, A', Q, B, B', and the lines AA', BB', passes through the point Q'.

From this can be deduced the theorem proved, with the help of the symbols, in Ex. 12, that every quadric surface containing the seven points P, P', A, A', Q, B, B', contains also the eighth point Q'. But we do not enter into this at present.

Ex. 14. It has been seen (Ex. 7, above) that the lines joining four points A, B, C, D, respectively to the poles of the planes BCD, CAD, ABD, ABC, taken in regard to a quadric with respect to which A, B, C, D have general positions, are generators, of the same system, of another quadric.

Conversely, if four lines, p, q, r, s, of which no two intersect, passing, respectively, through A, B, C, D, be generators of the same system of a quadric, and A', B', C', D' be arbitrary points respectively on p, q, r, s, then there exists a quadric in regard to which the points A', B', C', D' are the poles, respectively, of the planes BCD, CAD, ABD, ABC. In particular, if A', B', C', D' be the points in which these planes are met by p, q, r, s, there exists a quadric touching these planes at these points.

For if the lines p, q, r, s be such generators, a line, s', can be drawn through D to meet all of p, q, r, so that the planes (DA, p), (DB, q) and (DC, r) meet in a line. The condition for this to be so is, that the lines p, q, r should meet the planes BCD, CAD, ABD, respectively, in points whose coordinates, relatively to A, B, C, D, are of the forms $(0, H, G, U)$, $(H, 0, F, V)$, $(G, F, 0, W)$. Considering, similarly, the three lines q, r, s, we see that the line s meets the plane ABC in a point whose coordinates are, with this notation, $(U, V, W, 0)$; the planes (DA, p), (DB, q), (DC, r) meet in a line which meets the plane ABC in the point of coordinates $(F^{-1}, G^{-1}, H^{-1}, 0)$. The quadric whose tangential equation is

$$Fmn + Gnl + Hlm + Ulp + Vmp + Wnp = 0,$$

then touches the planes BCD, etc., in the points where these are met by p, q, r, s; and, if (A, H, G, U), (H, B, F, V), etc., be the coordinates of any points A', B', etc., lying, respectively, on the lines p, q, etc., these points are the poles of the planes BCD, etc., in regard to the quadric whose equation is

$$(A, B, C, D, F, G, H, U, V, W \between l, m, n, p)^2 = 0.$$

We have excluded the consideration of cases in which the lines p, q, etc., lie in the planes ABC, ABD, ACD, BCD.

Dually, if lines l, m, n, k, lying respectively in the planes, BCD, CAD, ABD, ABC, are generators of a quadric, of the same system, and arbitrary planes be drawn through these lines, there is a quadric for which these are the polar planes of A, B, C, D, respectively.

Ex. 15. Consider the twelve points in which the six joins of four points, A, B, C, D, are met by an arbitrary quadric. Three of these, lying on the joins of one of these points, D, to A, B, C, define a plane. We may thus, in thirty-two ways, specify four planes each of which contains three of the points, no two of these planes intersecting in one of the twelve points. If we consider the line in which the plane ABC is met by the plane containing the three points chosen on *DA*, *DB*, *DC*, and the three other lines in which the planes *BCD*, *CAD*, *ABD* are met by the corresponding planes, the four lines so obtained are generators of a quadric, of the same system. (Chasles, *Aperçu historique*, 1837, Note XXXII, p. 400.)

Dually, if we draw the pairs of tangent planes to a quadric from the lines *BC*, *CA*, *AB*, *DA*, *DB*, *DC*, and denote by D' the point of intersection of three planes, one chosen from each of the three pairs of planes drawn from *BC*, *CA*, *AB*, and by A' the point of intersection of three planes drawn from *BC*, *DB*, *DC*, not including the one already taken which is drawn from *BC*, and so on, so as to obtain four points D', A', etc., each the intersection of three of the twelve tangent planes, then the four lines DD', AA', ... are generators of the same system of a quadric.

For, let A' be the intersection of planes β, γ', δ, drawn, respectively, through *DB*, *DC*, *BC*; let B' be the intersection of planes γ, α', ϵ, drawn, respectively, through *DC*, *DA*, *CA*; and let C' be the intersection of planes α, β', ζ, drawn, respectively, through *DA*, *DB*, *AB*. The planes β, γ', γ, α', α, β', being tangent planes of the quadric, are tangent planes of the quadric cone which is drawn from *D* to the quadric. Therefore, by Brianchon's theorem (Vol. II, p. 25), the three planes (DA', DA), (DB', DB), (DC', DC) meet in a line, say k; for DA' is the intersection of the planes β, γ', and *DA* the intersection of the opposite planes α', α; and so on. The lines AA', BB', CC' are, therefore, all met by the line k, which equally meets DD'. These four lines AA', etc., are similarly met by a line through each of the points *A*, *B*, *C*. They are thus such generators as was stated.

Ex. 16. If every intersection of a quadric with a join, such as *AD*, of four points *A*, *B*, *C*, *D*, be joined by a plane to the opposite edge, *BC*, the twelve planes so obtained, touch another quadric. If the point equation of the first quadric be

$$(a, b, c, d, f, g, h, u, v, w \between x, y, z, t)^2 = 0,$$

the tangential equation of the second quadric is

$$\left(\frac{1}{a}, \frac{1}{b}, \frac{1}{c}, \frac{1}{d}, \frac{-f}{bc}, \frac{-g}{ca}, \frac{-h}{ab}, \frac{-u}{ad}, \frac{-v}{bd}, \frac{-w}{cd} \between l, m, n, p\right)^2 = 0.$$

Ex. 17. The transversal is drawn from a point, *O*, to each pair of opposite joins of four points *A*, *B*, *C*, *D*, so giving rise to six points. Six other points, one on each join, are similarly obtained from another point, O'. Shew that the twelve points lie on a quadric. If the points O, O' be, respectively, (ξ, η, ζ, τ), $(\xi', \eta', \zeta', \tau')$, referred to *A*, *B*, *C*, *D*, the quadric has a point equation obtained from

$$\left(\frac{x}{\xi} + \frac{y}{\eta} + \frac{z}{\zeta} + \frac{t}{\tau}\right)\left(\frac{x}{\xi'} + \frac{y}{\eta'} + \frac{z}{\zeta'} + \frac{t}{\tau'}\right) = 0,$$

by changing, in this, the signs of the six terms in yz, zx, ..., yt, zt. The relation itself is a particular case of that of Ex. 16, when the second quadric there referred to becomes a point-pair; but it will be found to be of importance.

Ex. 18. The point equation of the quadric, touching the planes BCD, CAD, ABD, ABC, whose tangential equation is

$$Fmn + \ldots + Ulp = 0,$$

is, by the rule proved above (p. 24),

$$\begin{vmatrix} 0, & H, & G, & U, & x \\ H, & 0, & F, & V, & y \\ G, & F, & 0, & W, & z \\ U, & V, & W, & 0, & t \\ x, & y, & z, & t, & 0 \end{vmatrix}.$$

Prove that, if we put

$$\xi = x(FVW)^{\frac{1}{2}}, \quad \eta = y(GWU)^{\frac{1}{2}}, \quad \zeta = z(HUV)^{\frac{1}{2}}, \quad \tau = t(FGH)^{\frac{1}{2}},$$

this is the same as

$$\xi^2 + \eta^2 + \zeta^2 + \tau^2 - 2(\eta\zeta + \xi\tau)\cos\alpha - 2(\zeta\xi + \eta\tau)\cos\beta - 2(\xi\eta + \zeta\tau)\cos\gamma = 0,$$

where $\alpha + \beta + \gamma = \pi$. In fact

$$\cos\alpha = \tfrac{1}{2}(GV + HW - FU)(GVHW)^{-\frac{1}{2}}, \text{ etc.}$$

Ex. 19. Prove that if (x, y, z, t) be any point of the quadric

$$fyz + gzx + hxy + uxt + vyt + wzt = 0,$$

so also is the point $(Ax^{-1}, By^{-1}, Cz^{-1}, Dt^{-1})$, where $A, = 2fvw$; $B, = 2gwu$; $C, = 2huv$; $D, = 2fgh$, are the minors of the diagonal elements, in the usual determinant of four rows and columns formed with the coefficients of the quadric.

Let P be any point of the quadric, and l, l' be the two generators through P; let the quadric cone be constructed, with vertex at any one, D, of the four points of reference for the coordinates, to contain P, and also the joins, DA, DB, DC, of D to the other three points of reference, and also to contain the generator at D which is of the same system as l; shew that these four cones all meet l again in the same point Q. Making a similar construction for the other system of generators, we obtain a point, Q', on l'. Shew that we can pass from Q to Q' by the above transformation.

Prove that, if the equation of the quadric be put into the form

$$(b - c)(axt + yz) + (c - a)(byt + zx) + (a - b)(czt + xy) = 0,$$

and P be (ξ, η, ζ, τ), one of the lines l, l' is given by

$$x(\eta - \zeta) + y(\zeta - \xi) + z(\xi - \eta) = 0,$$

$$y(\zeta - b\tau) - z(\eta - c\tau) + t(b\eta - c\zeta) = 0,$$

the point Q being given by

$$xt^{-1} = (b\eta - c\zeta)(\eta - \zeta)^{-1}, \quad yt^{-1} = (c\zeta - a\xi)(\zeta - \xi)^{-1},$$
$$zt^{-1} = (a\xi - b\eta)(\xi - \eta)^{-1},$$

and that the other line of l, l' is given by

$$ax(b\eta - c\zeta) + by(c\zeta - a\xi) + cz(a\xi - b\eta) = 0,$$
$$y(\zeta - a\tau) - z(\eta - a\tau) + at(\eta - \zeta) = 0,$$

the point Q' being

$$xt^{-1} = bc(\eta - \zeta)(b\eta - c\zeta)^{-1}, \quad yt^{-1} = ca(\zeta - \xi)(c\zeta - a\xi)^{-1},$$
$$zt^{-1} = ab(\xi - \eta)(a\xi - b\eta)^{-1}.$$

It may also be shewn that, if

$$U = a(b-c)x + b(c-a)y + c(a-b)z,$$
$$V = (a-b)y + (c-a)z + a(b-c)t,$$

the equation of the quadric is capable of the form

$$UV = (by - cz)(y - z)(c - a)(a - b).$$

The coordinates, and equations, of a line, in three dimensions. Elements of the theory of a linear complex. Some elementary results, in regard to lines in space, largely algebraical in character, which it is sometimes convenient to be able to refer to, may be collected here.

Referred to four given points, A, B, C, D, a line may evidently be given in general by the two points in which it meets two, definitely chosen, of the planes BCD, CAD, ABD, ABC. As the position of a point in a plane depends on the two ratios of its three coordinates, we see thus that a line depends upon four parameters, or, in order to avoid the occurrence of infinite parameters, upon the ratios of five parameters. It is desirable to choose these so that the representation shall be valid for all positions of the line; the representation above suggested would fail if the line were entirely contained in one of the two chosen planes. We owe to Cayley (*Coll. Papers*, IV, p. 447, 1860; and VII, p. 66) the discovery that a convenient representation is obtained only by taking the ratios of *six* parameters, which are connected by an equation, reducing them effectively to five.

Let (x_1, y_1, z_1, t_1), (x_2, y_2, z_2, t_2) be the coordinates of any two points of a line. We consider the six quantities

$$l = t_1x_2 - t_2x_1, \quad m = t_1y_2 - t_2y_1, \quad n = t_1z_2 - t_2z_1,$$
$$l' = y_1z_2 - y_2z_1, \quad m' = z_1x_2 - z_2x_1, \quad n' = x_1y_2 - x_2y_1;$$

if, in place of one of the two points, we take any other point of the line, putting, for example, in place of x_2, y_2, z_2, t_2, respectively $\theta x_1 + \phi x_2$, $\theta y_1 + \phi y_2$, etc., it is at once seen that the ratios of l, m, n, l', m', n' remain unaltered. These ratios are therefore given without ambiguity when the line is given. They are evidently connected by the equation

$$ll' + mm' + nn' = 0.$$

Further, it is at once seen that the coordinates, x, y, z, t, of any point of the line, satisfy the four equations $\xi = 0$, $\eta = 0$, $\zeta = 0$, $\tau = 0$, where

$$\xi = l't + mz - ny, \quad \eta = m't + nx - lz,$$
$$\zeta = n't + ly - mx, \quad \tau = -(l'x + m'y + n'z),$$

which, when $ll' + mm' + nn' = 0$, are equivalent only to two equations, since we have

$$l\xi + m\eta + n\zeta = 0, \quad l\tau + m'\zeta - n'\eta = 0.$$

The equation $\xi = 0$ is the equation of the plane which joins the line to the reference point A, and similarly for η, ζ, τ, the equation $\tau = 0$ being that of the plane joining the line to the reference point D. As the line can evidently be determined in all cases by two of these four planes, we see, conversely, that the ratios of any six quantities, l, m, n, l', m', n', which are connected by the equation $ll' + mm' + nn' = 0$, suffice to determine a line. It is these quantities which are called the *coordinates of a line* in threefold space.

These coordinates may also be expressed in terms of the coordinates of any two planes which contain the line. If the equations of two such planes be

$$a_1x + b_1y + c_1z + d_1t = 0, \quad a_2x + b_2y + c_2z + d_2t = 0,$$

the line coordinates are given, as regards their ratios, by

$$l = b_1c_2 - b_2c_1, \quad m = c_1a_2 - c_2a_1, \quad n = a_1b_2 - a_2b_1,$$
$$l' = d_1a_2 - d_2a_1, \quad m' = d_1b_2 - d_2b_1, \quad n' = d_1c_2 - d_2c_1.$$

This is seen at once by obtaining, from the equations of the two planes, the equations of the planes joining the line to the four points of reference, A, B, C, D, and comparing these with the forms above expressed in terms of the line coordinates.

It is easily verified that the line coordinates of the six joins of the points of reference are, for DA, $(1, 0, 0; 0, 0, 0)$, and, for BC, $(0, 0, 0; 1, 0, 0)$, and so on. We may, therefore, symbolically regard any line as represented in terms of these six joins, in the form

$$l(DA) + m(DB) + n(DC) + l'(BC) + m'(CA) + n'(AB).$$

Ex. 1. The conditions that the plane $ax + by + cz + dt = 0$ should contain the line (l, m, n, l', m', n') are two of the following four:

$$ld + m'c - n'b = 0, \quad md + n'a - l'c = 0, \quad nd + l'b - m'a = 0, \quad la + mb + nc = 0.$$

Ex. 2. The plane joining the line (l, m, n, l', m', n') to the point (x, y, z, t) is that whose coordinates are ξ, η, ζ, τ, where, as above, $\xi = l't + mz - ny$, $\tau = -(l'x + m'y + n'z)$, etc. The point of intersection of the line with the plane whose coordinates are (a, b, c, d) is that whose coordinates are

$$ld + m'c - n'b,\ md + n'a - l'c,\ nd + l'b - m'a, \text{ and } -(la + mb + nc).$$

Ex. 3. Expressing the condition that four points, (x_1, y_1, z_1, t_1), (x_2, y_2, z_2, t_2), $(\xi_1, \eta_1, \zeta_1, \tau_1)$ and $(\xi_2, \eta_2, \zeta_2, \tau_2)$, should lie in a plane by the vanishing of a determinant in which the first row consists of x_1, y_1, z_1, t_1, and the third row consists of $(\xi_1, \eta_1, \zeta_1, \tau_1)$, etc., and expanding this determinant as a sum of products of binary determinants formed from the first two rows, and from the third and fourth rows, we see that the condition that the two lines

$$(l_1, m_1, n_1, l_1', m_1', n_1'),\ (l_2, m_2, n_2, l_2', m_2', n_2'),$$

or, say, λ_1 and λ_2, should intersect one another, is $\varpi_{12} = 0$, where

$$\varpi_{12} = l_1 l_2' + l_2 l_1' + m_1 m_2' + m_2 m_1' + n_1 n_2' + n_2 n_1'.$$

When this condition is satisfied, the six quantities such as $\xi l_1 + \eta l_2$, $\xi l_1' + \eta l_2'$, whatever ξ and η may be, satisfy the necessary condition, $\Sigma(\xi l_1 + \eta l_2)(\xi l_1' + \eta l_2') = 0$, that they should be the coordinates of a line. Symbolically, we may say that $\xi\lambda_1 + \eta\lambda_2$ then represents a line. It is easy to see that this is a line passing through the intersection of λ_1 and λ_2, and lying in the plane of these. Similarly, if $\lambda_1, \lambda_2, \lambda_3$ be three lines which meet in a point, not lying in a plane, the line $\xi\lambda_1 + \eta\lambda_2 + \zeta\lambda_3$ is, for proper choice of the ratios $\xi : \eta : \zeta$, any line through this point of intersection.

Ex. 4. If $\lambda_1, \lambda_2, \lambda_3$ be three lines of which no two intersect, the condition that $\xi\lambda_1 + \eta\lambda_2 + \zeta\lambda_3$ should be a line is that ξ, η, ζ should satisfy the condition

$$\varpi_{23}\xi^{-1} + \varpi_{31}\eta^{-1} + \varpi_{12}\zeta^{-1} = 0.$$

There are ∞^1 sets of values of $\xi : \eta : \zeta$ satisfying this condition; they are expressible rationally in terms of a single variable parameter, for instance in the form $\xi = \varpi_{23}$, $\eta = -\varpi_{31}\theta^{-1}$, $\zeta = \varpi_{12}(\theta - 1)^{-1}$. As the condition that two lines should intersect is of the first degree in the coordinates of either line, it follows that any line which intersects $\lambda_1, \lambda_2, \lambda_3$ also intersects $\xi\lambda_1 + \eta\lambda_2 + \zeta\lambda_3$; thus the lines expressed by this last formula are those, of the same system of generators as $\lambda_1, \lambda_2, \lambda_3$, of the quadric determined by these three.

Ex. 5. From Ex. 2, shew that the two tangent planes which can be drawn, from the line (l, m, n, l', m', n'), to touch the quadric whose tangential equation is $f(u, v, w, p) = 0$, where u, v, w, p are the coordinates of a plane, are given by the equation

$$f[l't + mz - ny,\ m't + nx - lz,\ n't + ly - mx,\ -(l'x + m'y + n'z)] = 0.$$

Ex. 6. The polar line of the line (l, m, n, l', m', n'), in regard to the quadric $ax^2 + by^2 + cz^2 + dt^2 = 0$, has the coordinates

$$(bcl',\ cam',\ abn',\ adl,\ bdm,\ cdn).$$

Thus the condition that the polar line of the line λ_1, in regard to the quadric, should meet the line λ_2, is

$$\Sigma\,(adl_1l_2 + bcl_1'l_2') = 0,$$

which is symmetrical in regard to the two lines. Two such lines are said to be *conjugate* in regard to the quadric.

Ex. 7. The condition that the line (l, m, n, l', m', n') should touch the quadric $ax^2 + by^2 + cz^2 + dt^2 = 0$ is

$$\Sigma\,(adl^2 + bcl'^2) = 0, \text{ or } \Sigma\,[l\,(ad)^{\frac{1}{2}} + l'\,(bc)^{\frac{1}{2}}]^2 = 0.$$

This is also the condition that the line should intersect its polar line in regard to the quadric.

Ex. 8. If instead of reference points A, B, C, D, we take other points of reference, X, Y, Z, T, the line coordinates, with reference to X, Y, Z, T, of a line whose coordinates relative to A, B, C, D are (l, m, n, l', m', n'), are certain linear functions of l, m, n, l', m', n'. The coefficients in these linear functions are, in fact, the line coordinates, relative to the original points of reference, A, B, C, D, of the six lines which are the joins of the new points of reference, X, Y, Z, T. We may forecast this result if we remark that, by Ex. 4, the condition that a line (l, m, n, l', m', n') should meet the line DA is $l' = 0$, and the condition that the line should meet BC is $l = 0$; if then (L, M, N, L', M', N') be the coordinates of the line referred to X, Y, Z, T, the condition $L = 0$ will be the condition that the line (l, m, n, l', m', n') should meet the line YZ; denoting the coordinates of YZ by $(\lambda_{23}, \ldots, \lambda_{23}', \ldots)$ we may thence expect that L is proportional to $l\lambda_{23}' + l'\lambda_{23} + \ldots$; and similarly for the others.

In fact, in terms of the symbols of X, Y, Z, T, let the symbols of A, B, C, D be, respectively,

$$A = a_1X + a_2Y + a_3Z + a_4T, \ldots, \; D = d_1X + d_2Y + d_3Z + d_4T,$$

so that, for all values of x, y, z, t,

$$xA + yB + zC + tD = \xi X + \eta Y + \zeta Z + \tau T,$$

where

$$\xi = a_1x + b_1y + c_1z + d_1t, \ldots, \; \tau = a_4x + b_4y + c_4z + d_4t.$$

Then (ξ, η, ζ, τ) are the coordinates, referred to X, Y, Z, T, of a point whose coordinates referred to A, B, C, D, are (x, y, z, t), and the planes $YZT, \ldots, XYZ$, referred to A, B, C, D, have the respective equations $\xi = 0, \ldots, \tau = 0$. The line coordinates of the line YZ, the intersection of $\xi = 0$, $\tau = 0$, are then given by

$$\lambda_{23} = b_4c_1 - b_1c_4, \ldots, \; \lambda_{23}' = d_4a_1 - d_1a_4, \ldots.$$

But, if (x_1, y_1, z_1, t_1), (x_2, y_2, z_2, t_2) be two points of the line (l, m, n, l', m', n'), we have

$$L = \tau_1\xi_2 - \tau_2\xi_1 = \begin{vmatrix} a_4x_1 + b_4y_1 + c_4z_1 + d_4t_1, & a_4x_2 + b_4y_2 + c_4z_2 + d_4t_2 \\ a_1x_1 + b_1y_1 + c_1z_1 + d_1t_1, & a_1x_2 + b_1y_2 + c_1z_2 + d_1t_2 \end{vmatrix}$$

$$= \Sigma \begin{vmatrix} x_1, & t_1 \\ x_2, & t_2 \end{vmatrix} \begin{vmatrix} a_4, & d_4 \\ a_1, & d_1 \end{vmatrix}$$

$$= \Sigma\,(l\lambda_{23}' + l'\lambda_{23}),$$

which is the formula expected. The value of L' is obtained by similar work in which $(a_2, b_2, \ldots)$, $(a_3, b_3, \ldots)$, respectively, replace $(a_4, b_4, \ldots)$ and $(a_1, b_1, \ldots)$. If then the line coordinates of the line TX be denoted by $\lambda_{41}, = b_2c_3 - b_3c_2$, $\lambda_{41}', = d_2a_3 - d_3a_2$, etc., we find

$$L' = \Sigma\,(l\lambda_{41}' + l'\lambda_{41})\,;$$

and so for the others.

Ex. 9. For the quadric surface whose equation is $x^2 + y^2 - z^2 = t^2$, prove that any generating line of one system has coordinates of the form $(p, q, 1, p, q, -1)$, where $p^2 + q^2 = 1$; and any generating line of the other system has coordinates of the form $(p', q', 1, -p', -q', 1)$, where $p'^2 + q'^2 = 1$. The coordinates of a line of the former system thus satisfy the three conditions $l - l' = 0$, $m - m' = 0$, $n + n' = 0$, whereby, from the ∞^4 existing lines of space there are selected the ∞^1 lines forming the system of generators; for the other system the corresponding conditions are $l + l' = 0$, $m + m' = 0$, $n - n' = 0$.

Ex. 10. *The focal system, and linear complex.* In the course of this chapter we have considered a correspondence between a point and a plane, the polar plane of the point in regard to a quadric, in which to the plane also corresponds the point, this correspondence having the property: (*a*), that, if the polar plane, ϖ, of any point, P, contain the point Q, then the polar plane of Q also contains P. From this it follows that the pole of any plane through P must lie on ϖ; for if Q' be this pole, since its polar contains P, the polar, ϖ, of P must contain Q'. It also follows that the polars of three points which are in line, must be planes which intersect in a line; for if P' be any point on the line of intersection of the polar planes of two points P and Q, the polar plane of P' must contain both P and Q, and therefore, also, any other point, R, of the line PQ, from which it follows that the polar plane of R contains P'. From this again it follows that the polar points of three planes which meet in a line are three points in line. The correspondence also had the property: (*b*), that the plane ϖ corresponding to P does not in general contain P, this being so only when the point P is on the quadric of reference. In this relation the coordinates of the plane corresponding to a point, of coordinates (x, y, z, t), are given by formulae of the form

$$ax + hy + gz + ut, \quad hx + by + fz + vt,$$
$$gx + fy + cz + wt, \quad ux + vy + wz + dt,$$

of which the coefficients form a symmetrical system.

We may, however, have a correspondence in which to a point corresponds a plane, and to this plane this point, in which the property (*a*) continues to hold but (*b*) fails, every point lying in the plane which corresponds to it.

Such a correspondence is effected by making correspond to a point (x, y, z, t) the plane whose coordinates are, with any constants a, b, c, a', b', c', the following, respectively,

$$cy - bz - a't, \quad -cx + az - b't, \quad bx - ay - c't, \quad a'x + b'y + c'z,$$

wherein the coefficients form a skew-symmetrical system. The equation of this plane, when X, Y, Z, T are current coordinates, is then

$$X(a't + bz - cy) + Y(b't + cx - az) \\ + Z(c't + ay - bx) - T(a'x + b'y + c'z) = 0,$$

or $$a'(tX - Tx) + b'(tY - Ty) + c'(tZ - Tz) \\ + a(yZ - zY) + b(zX - xZ) + c(xY - yX) = 0,$$

and the correspondence clearly has the properties referred to. It is supposed that, generally, the coefficients $a, b, \dots$ do not satisfy the condition $aa' + bb' + cc' = 0$. If they do, there is a fixed line of coordinates (a, b, c, a', b', c'), and the correspondence is that by which we make correspond, to any point, the plane joining this point to the fixed line; this is a degenerate relation in that, conversely, the point corresponding to a plane, through the fixed line, is not a definite, but is any, point of this plane.

We may agree to speak of the plane corresponding to any point as the polar plane of that point, and of the point as the pole of the plane. The polar planes of the points of any line are planes which intersect in another line, as we have remarked above; and, dually, the poles of the planes through any line lie on another line. We may agree to speak of either of these lines as the polar line of the other. If P be any point on the polar plane of a point O, the polar plane of P passes through O, and through P; thus the line OP is its own polar line. This is then true of every line, through any point O, lying in the polar plane of O; and is therefore also true of every line, in any plane ϖ, which passes through the pole of ϖ. The line coordinates $(l, m, \dots)$ of any such self-polar line evidently satisfy the equation

$$a'l + b'm + c'n + al' + bm' + cn' = 0.$$

The aggregate of such self-polar lines is called a *linear complex*; it consists of ∞^3 lines. The aggregate of points with their polar planes, and of lines of the linear complex, may be called a *focal system*.

The representation of the relation takes a very simple form if the points of reference for the coordinates be taken so that two of these points of reference are on the polar line of the line joining the other two points of reference. Suppose these points, $A, B, C, D,$

are such that D and C have for polar planes, respectively, the planes DAB and CAB; the coordinates, of the polar plane of (x, y, z, t), namely

$$a't + bz - cy, \quad b't + cx - az, \quad c't + ay - bx, \quad -(a'x + b'y + c'z),$$

must then reduce, respectively, to $(0, 0, 1, 0)$ and $(0, 0, 0, 1)$, when for (x, y, z, t) we have $(0, 0, 0, 1)$ and $(0, 0, 1, 0)$. From these two facts in turn we deduce $a' = 0 = b'$, and $a = 0 = b$. The plane corresponding to (x, y, z, t) has then the equation

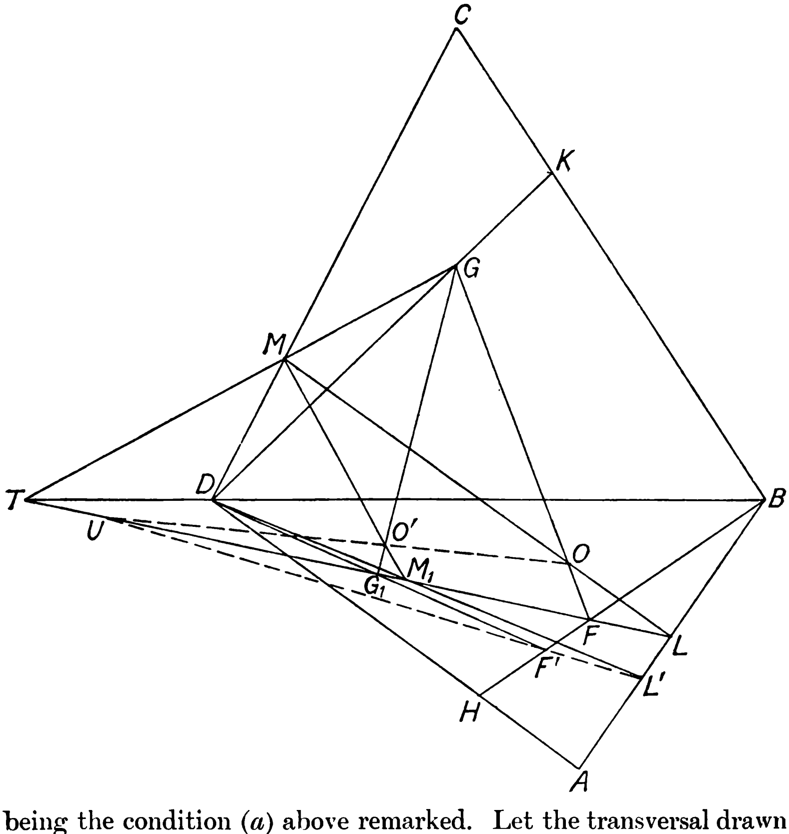
$$c'(tZ - Tz) + c(xY - yX) = 0,$$

and the lines of the linear complex are those for which $c'n + cn' = 0$.

It is clear that the polar plane of any point of a line of the linear complex contains this line. Also that two polar lines do not intersect; for, if they did, the polar plane of any point of one of the lines, as passing through this point and the other line, would contain the first line, which would then be its own polar line and coincide with the other line. Any line which meets two polar lines is evidently a line of the linear complex, since it lies in the polar planes of the two points in which it meets the polar lines.

Now consider any two lines of the linear complex, say λ and λ': the polar plane of any point, P, of λ, is a plane through λ, meeting λ', say, in a point P'. It is clear, or easily verifiable from the equations, that as P describes λ, the range (P'), on λ', described by P', is related to the range (P), on λ, described by (P). Let Q' be the position of P', on λ', corresponding to the position, Q, of P, on λ. Then the polar plane of P contains P', by hypothesis, and contains Q, on the line λ; the polar plane of Q' similarly contains Q and P'. Thus the cross lines PQ' and $P'Q$ are polar lines, one of the other; and therefore, as remarked above, every line meeting PQ' and $P'Q$ is a line of the linear complex. We thus infer that if $A, P, Q, \ldots, D$ and $C, P', Q', \ldots, B$, be related ranges on any two non-intersecting lines in space, the transversal drawn from any point, O, to the lines PQ', $P'Q$, that drawn from O to PR', $P'R$, that drawn from O to QR', $Q'R$, and so on, are in one plane, and are lines of a linear complex in which AB is the polar line of CD. Dually if we join the points in which an arbitrary plane meets PQ' and $P'Q$, all such joins meet in a point of this plane, the pole of the plane in the focal system.

We may thus initiate the theory of the linear complex, as has been remarked in Vol. I, p. 59, without the use of coordinates. Let A, H, D be three points in line, and C, K, B be three points in another line. These are sufficient to determine on the two lines, respectively, two related ranges, $A, H, P, Q, \ldots, D$, and $C, K, P', Q', \ldots, B$; and it is, as there explained, an immediate consequence of the theory of related ranges that the transversals drawn from an arbitrary point, O, to the pairs of cross joins such as (AB, CD), (BH, DK), $(PQ', P'Q)$, lie in a plane through O. This plane is determined by the first two pairs of cross joins, and, therefore, by the points A, H, D and C, K, B alone. In order to establish that the correspondence is that of a focal system, it is necessary to see that if another point, O', be taken in the plane so corresponding to O, then the plane similarly corresponding to O' passes through O, this



being the condition (a) above remarked. Let the transversal drawn from O to AB and CD meet these, respectively, in L and M; and the transversal drawn from O to BH and DK meet these in F and G respectively. Let the plane of these two transversals meet BD in T. Let O' be any other point of this plane. Let MO' meet FL in M_1, and GO' meet FL in G_1; let DM_1 meet AB in L', and DG_1 meet BH in F'. The point L' is in the plane $O'CD$, and is, therefore, the point in which the transversal from O' to AB, CD meets AB. The point F' is in the plane $O'DK$, and is, therefore, the point in which the transversal from O' to BH, DK meets BH. Thus the plane corresponding to O' is the plane $O'F'L'$, and it is desired to shew that this plane contains O. For this it is necessary and sufficient that the lines OO' and $L'F'$ should meet; their point of meeting will then be on FL, which is the line common to the planes LTM and BAD. What we shew, then, is that OO' and $L'F'$ meet the line FL in the same point. Considering, first, the intersections of FL with the pairs of joins of the four points M, O', O, G, we see that OO' meets FL in the point which is conjugate to T in the involution determined by the pairs of points F, M_1 and L, G_1. Considering, next, the intersections with FL of the pairs of joins of the four points F', L', B, D, we see that $F'L'$ meets FL in the point which is the conjugate of T in the involution determined by the same pairs of points F, M_1 and L, G_1. This proves the result required. (Cf. the diagram of p. 61, Vol. I. The tetrads O, M, G, B and D, F', L', O' are Moebius tetrads.) It can easily be seen that, if we take A, B, C, D for points of reference for coordinates, choosing these, as we may, so that H is $(1, 0, 0, 1)$ and K is $(0, 1, 1, 0)$, then the plane, $LFMG$, corresponding to O, has the equation $Tz - Zt = Xy - Yx$, where (x, y, z, t) are the coordinates of O, and (X, Y, Z, T) are current coordinates. This verifies that the linear complex obtained in this way agrees with that originally defined. In the construction used here, the lines of the linear complex passing through O are the transversals of the pairs of cross joins such as PQ', $P'Q$; to obtain these lines it is evidently sufficient to take P and P' always the same, corresponding to one another in the two related ranges, and to vary only the corresponding points Q and Q'. Thus we come back to a construction given by Sylvester, in 1861. (*Math. Papers*, II, p. 237.) In particular when P, P' are taken, respectively, as D and B, we have the result, that, given two related pencils of lines $D(C, K, Q', \ldots, B)$, and $B(A, H, Q, \ldots, D)$, in different planes, with a common corresponding ray, DB, the transversals drawn from any point O to the pairs of corresponding rays DQ', BQ, lie on a plane, which is the polar plane of O in a general focal system.

The line which is the polar of a line (l, m, n, l', m', n'), for the focal system considered, is the intersection of the two planes whose equations are

$$x(a't_1 + bz_1 - cy_1) + \ldots - t(a'x_1 + b'y_1 + c'z_1) = 0,$$
$$x(a't_2 + bz_2 - cy_2) + \ldots - t(a'x_2 + b'y_2 + c'z_2) = 0,$$

where $l = t_1x_2 - t_2x_1$, $l' = y_1z_2 - y_2z_1$, etc. Its line coordinates are thence easily computed to be

$$\Delta l - Ma, \ldots, \quad \Delta l' - Ma', \ldots$$

where $\Delta = aa' + bb' + cc'$, $M = a'l + \ldots + al' + \ldots$.

The condition for the polar lines to intersect would then be $M^2 = 0$, or the original line would be a line of the linear complex, and coincide with its polar. When this is not so, if we write for the computed line coordinates of the polar line, respectively, $-\Delta\lambda$, $-\Delta\lambda'$, etc., we may say that $a = M^{-1}(l+\lambda)$, $a' = M^{-1}(l'+\lambda')$, etc.

In particular when the equation of the linear complex is $n'-kn=0$, the polar line is of coordinates $(l, m, k^{-1}n', l', m', kn)$. Also, the condition, in general, that the polar line of one line, λ_1, should intersect another line, λ_2, is of the form $\Delta\varpi_{12} - M_1M_2 = 0$, which is symmetrical in regard to the lines.

Consider now two linear complexes. It can be shewn that there are in general two lines which are polars of one another in both the corresponding focal systems. Any transversal of these two polar lines is then a line of both linear complexes. The ∞^2 lines so obtained, which are said to form a *linear congruence*, are then the lines common to the two given linear complexes. If the equations for these two complexes be

$$a'l + \ldots + al' + \ldots = 0, \quad A'l + \ldots + Al' + \ldots = 0,$$

any line common to both satisfies, for all values of σ, the equation

$$(A' + \sigma a')\, l + \ldots + (A + \sigma a)\, l' + \ldots = 0\,;$$

herein we may choose σ so that the six quantities given by $\lambda = A + \sigma a$, $\lambda' = A' + \sigma a'$, etc., are the coordinates of a line; this requires only

$$AA' + BB' + CC' + \sigma\,(Aa' + A'a + \ldots) + \sigma^2\,(aa' + bb' + cc') = 0,$$

of which there are two different roots in general. This shews that all the lines common to the two complexes meet both of two definite lines, which are then a pair of common polar lines for these.

Incidentally we infer that the ratios of the functions of the coefficients, in the equations of the two linear complexes, which occur in this quadratic equation for σ, are unaltered by change of the reference points for the coordinates, and that these functions must have a geometrical significance. The first and last of these functions are those which vanish when the linear complexes, respectively, reduce to lines all meeting a given line, as we have seen. The condition that the remaining function should vanish,

$$Aa' + A'a + Bb' + B'b + Cc' + C'c = 0,$$

is that either linear complex should consist of pairs of lines which are polars of one another in regard to the other complex; or also, is that, if we take the polar plane of an arbitrary point, in the first focal system, and then the pole of this plane in the other focal system, we reach the same point independently of the order in which the linear complexes are considered. This is easily verified from the general equations. If the complexes be referred to their common pair of polar lines, however, and take the forms $n' - kn = 0$, $n' - Kn = 0$, the polar line $(l, m, K^{-1}n', l', m', Kn)$, of (l, m, n, l', m', n'), in regard to the second focal system, belongs to the first if $Kn = kK^{-1}n'$, which, when $n' = kn$, becomes $K^2 = k^2$, and leads to $K + k = 0$, the complexes not being identical. This however is the form of the condition in question for these particular equations of the complexes. Again, if (ξ, η, ζ, τ) be the pole in $n' - Kn = 0$ of the polar plane of (x, y, z, t) in $n' - kn = 0$, the planes

$$Xy - Yx - k(Tz - Zt) = 0, \quad X\eta - Y\xi - K(T\zeta - Z\tau) = 0,$$

are identical, so that $\xi = x$, $\eta = y$, $\zeta = kK^{-1}z$, $\tau = kK^{-1}t$; for this to be independent of the order in which the complexes are considered, we again require $k^2 = K^2$.

Two linear complexes for which the function $Aa' + A'a + \ldots$ vanishes are said to be *apolar* to one another.

Ex. 11. A focal system is by definition a self dual construct. In particular the pole of the plane $ux + vy + wz + pt = 0$, corresponding to the linear complex $a'l + al' + \ldots = 0$, has the coordinates

$$ap + b'w - c'v, \quad bp + c'u - a'w, \quad cp + a'v - b'u, \quad -(au + bv + cw).$$

Ex. 12. If $P, Q, R, \ldots, P', Q', R', \ldots$, be related ranges on any two skew lines, any line meeting one pair of cross joins, such as PQ' and $P'Q$, meets an infinite number of other pairs of cross joins, such as RS', $R'S$, one of the four points R, S, R', S' being arbitrary.

Ex. 13. Let A, B, C be three points in a line, A', B', C' three points in another line not intersecting the former, and P, Q, R three points in a third line not meeting either of the other two lines. From P let the transversal be drawn to the lines AB', $A'B$, and also the transversal to the lines AC', $A'C$, and the plane of these two transversals be considered. Similarly the plane containing the transversals from Q, to AB', $A'B$, and to AC', $A'C$; and the plane containing the transversals from R, to AB', $A'B$, and to AC', $A'C$. Prove that these three planes meet in a line.

Ex. 14. Take five arbitrary lines in space of which no two intersect. By omitting each in turn we obtain five sets each of four lines; and these four lines have a common pair of transversals. From an arbitrary point a single line can be drawn to meet the two lines of any such pair of transversals. Prove that the five single lines so obtained lie in a plane (Sylvester, *Math. Papers*, II, p. 237).

In fact, the equation of a linear complex being linear in the line coordinates, there is a definite linear complex containing the five given lines. If a line meet two lines of a linear complex, its polar line, in the associated focal system, also meets these two lines; thus the two common transversals of four skew lines of a linear complex are polar lines one of another, and any line meeting both these transversals is also a line of the linear complex.

Ex. 15. If λ be a transversal of three lines, p, q, r, belonging to a linear complex, of which no two intersect, and λ' be the polar line of λ, then λ' is also a transversal of p, q, r, and every line meeting λ and λ' is a line of the linear complex. Conversely, if t be any line of the complex, the two common transversals of p, q, r and t are polar lines of one another. It is easy to prove that the pairs of polar lines which meet p, q, r determine an involution of pairs of points on any one of these lines. Thus a linear complex appears as an aggregate of lines meeting a quadric surface each on two generators, of one system, which are pairs in an involution of these generators. The involution is determined by the three generators p, q, r of the other system taken in turn with two other generators, say t, u, of that system, and the linear complex by the five lines p, q, r, t, u. (Chasles, *Liouville's J.*, IV (1839), p. 348.)

Ex. 16. By expressing the planes which join an arbitrary line to the four points of reference for the coordinates, in terms of two of these planes, and the points in which the line meets the planes containing three of these points of reference in terms of two of these points, shew that the axial pencil of the planes is related to the range of the points (cf. Vol. I, p. 30).

Ex. 17. Prove that the polar plane, in any focal system, of any one, say, D, of the four reference points for coordinates A, B, C, D, contains the poles in this system, of the three planes DBC, DCA, DAB. So that A, B, C, D, and the poles of the four planes such as these, form two Moebius tetrads (cf. Vol. I, pp. 61, 91). Conversely, any two Moebius tetrads define a focal system.

Ex. 18. For the linear complex $al' + a'l +$ etc. $= 0$, the two tetrads of Ex. 17 are both self-polar in regard to the quadric

$$a'bcx^2 + b'cay^2 + c'abz^2 + a'b'c't^2 = 0.$$

Ex. 19. If any two generators of the same system of a quadric be taken, and from each of the points A, B, C, D, forming a self-polar tetrad in regard to the quadric, there be drawn the transversal to these two generators, meeting the planes BCD, ..., ABC respectively in A', ..., D', prove that A, B, C, D and A', B', C', D' are two Moebius tetrads.

Ex. 20. If, in any focal system, A', B', C', D' are the respective poles of the planes BCD, ..., ABC, and U, U', on AA', are harmonic conjugates in regard to A and A', etc., prove that, if U, V, W are in line, the plane $U'V'W'$ contains DD'; but, if the line UVW meets DD', then U', V', W' are also in a line meeting DD', the lines UVW, $U'V'W'$ then meeting DD' in points harmonically conjugate in regard to D and D'. (Cf. p. 144, below.)

Ex. 21. If A, A', B, B', C, C' be any six points, and U, U', on AA', are harmonic conjugates in regard to A and A', while $BVB'V'$, $CWC'W'$ are, similarly, harmonic ranges, prove that, U, V, W being in line, there is no position of this line for which U', V', W' are in line, unless the quadric containing the lines BC, BC', $B'C$, $B'C'$, and the point A, also contains A'.

Ex. 22. Shew that the equations of any four non-intersecting lines can be put into the forms

$$y = px,\ t = qz; \qquad y = -px,\ t = -qz;$$
$$y = p^{-1}x,\ t = q^{-1}z; \quad y = -p^{-1}x,\ t = -q^{-1}z.$$

Taking, then, the four points of respective coordinates $(1, p, m, mq)$, $(1, -p, m, -mq)$, $(p, 1, mq, m)$, $(-p, 1, -mq, m)$, where m is arbitrary, say P, Q, R, S, and also the points P', Q', R', S', whose coordinates are obtained from those of P, Q, R, S, respectively, by changing the sign of m, prove that these form two Moebius tetrads, both self-polar in regard to the quadric $yz - xt = 0$. Further, that the polar plane of any point of one tetrad, in the focal system given by $yz' - y'z + tx' - t'x = 0$, contains three points of the other tetrad, the polar plane of P containing Q', R', S', etc.

Ex. 23. Prove that two of the lines of any given linear complex are generators of the same system of any given quadric surface.

Ex. 24. If we be given a fixed conic, we may take, for any two lines which do not lie in the plane of the conic, the pole, in regard to the conic, of the line joining the points where the lines meet the plane of the conic; and draw from this pole the transversal to the two lines. Now take three lines, p, q, r, not lying in the plane of the conic; let p', q', r' be the transversals, determined as described, respectively of the pairs (q, r), (r, p) and (p, q); then let p'', q'', r'' be the transversals, similarly determined, respectively of the pairs (p, p'), (q, q') and (r, r'). Shew that the transversals so determined, respectively of the pairs (q'', r''), (r'', p''), (p'', q''), coincide in one line. The proof depends on two triads, of points and lines, which are polar reciprocals of one another in regard to the conic (cf. Vol. II, p. 27).

Ex. 25. Shew that, of points of which the coordinates, in terms of a varying parameter θ, are $(\theta^3, \theta^2, \theta, 1)$, there are three lying on an arbitrary plane. These points are therefore said to lie on a cubic curve. Shew that any plane containing the line which is given by the two equations $x - 2y\theta + z\theta^2 = 0$, $y - 2z\theta + t\theta^2 = 0$, meets the curve in two coincident points at the point θ; this line is called the tangent of the curve at this point. Shew that all the tangents of the curve belong to the linear complex expressed by $l + 3l' = 0$.

Ex. 26. Given five points in three dimensions joined in order by five lines, shew that there is a focal system in which each of the points is the pole of the plane containing the two lines which meet in this point, each of the five joins being a line of the associated linear complex.

Ex. 27. Prove that, in regard to a quadric surface expressed in the general form

$$(a, b, c, d, f, g, h, u, v, w \between x, y, z, t)^2 = 0,$$

the line coordinates, $(\lambda, \mu, \nu, \lambda', \mu', \nu')$, of the polar line of the line (l, m, n, l', m', n'), are such that

$$\begin{vmatrix} 0, & -\nu, & \mu, & \lambda' \\ \nu, & 0, & -\lambda, & \mu' \\ -\mu, & \lambda, & 0, & \nu' \\ -\lambda', & -\mu', & -\nu', & 0 \end{vmatrix} = \begin{vmatrix} a, & h, & g, & u \\ h, & b, & f, & v \\ g, & f, & c, & w \\ u, & v, & w, & d \end{vmatrix} \begin{vmatrix} 0, & -n', & m', & l \\ n', & 0, & -l', & m \\ -m', & l', & 0, & n \\ -l, & -m, & -n, & 0 \end{vmatrix} \begin{vmatrix} a, & h, & g, & u \\ h, & b, & f, & v \\ g, & f, & c, & w \\ u, & v, & w, & d \end{vmatrix},$$

where the matrices are to be multiplied by the rule explained in Vol. I, p. 67, the rows of a multiplying matrix being combined with the columns of that multiplied.

Ex. 28. Prove that the tangent lines of the curve of intersection of two quadrics which meet an arbitrary line are eight in number; and that, if the line be a generator of one of the two quadrics, the eight tangents are also generators of this.

The focal system was first investigated by Moebius, in connexion with the reduction of a system of forces acting on a single rigid body, and called by him a *Null* system, as consisting of lines about which the sum of the moments of the forces of the system vanishes (*Lehrbuch der Statik*, 1837). The relations were also studied by Chasles in connexion with the kinematics of a rigid body (1843; *Aperçu historique*, Sec. Edit., 1875, p. 614). On account of these applications the system is often referred to as a *Screw*. The kinematical relations will be considered at a later stage.

CHAPTER II

RELATIONS WITH A FIXED CONIC

SPHERES, CONFOCAL SURFACES; QUADRICS THROUGH THE INTERSECTION OF TWO GENERAL QUADRICS

In the plane geometry of Vol. II we have seen that the ordinary metrical relations are particular cases of the relation of the figure to two arbitrary Absolute points, or, more generally, to an arbitrary Absolute Conic; the recognition of this adds greatly to the breadth of view obtained, without increasing the difficulty of proof. A similar gain is found in the geometry of three dimensions. Here we consider an arbitrary Absolute Conic. In a later Volume we shall consider an arbitrary Absolute Quadric.

When we use coordinates we shall most generally suppose the points of reference, A, B, C, D, so taken that A, B, C form a self-polar triangle in regard to this Absolute Conic, and suppose, therefore, that the equations of this conic have the forms $t=0$, $x^2+y^2+z^2=0$. This is immaterial; but it will enable the reader easily to make comparison with metrical formulae which may be familiar.

Parallel lines and planes. Middle point. Lines and planes at right angles. Two lines which meet the plane of the absolute conic in the same point, not themselves lying in this plane, may be said to be *parallel*, relatively to this plane; two planes which meet this absolute plane in the same line may similarly be said to be parallel; a line and a plane may be said to be parallel if they have a common point lying on the absolute plane. Thus, for instance, a plane can be drawn through any line, which shall be parallel to any other given line not meeting the former line.

If the line joining two points A, B, which do not lie in the absolute plane, meet this plane in C, and O be the harmonic conjugate of C in regard to A and B, then O may be spoken of as the *middle point* of A and B, in the relative sense employed.

If two lines, not lying in the absolute plane, meet this plane in two points which are conjugate in regard to the absolute conic, then the lines may be said to be *at right angles*, or *perpendicular* to one another. If a plane and a line meet the absolute plane in a line and a point, respectively, of which the point is the pole of the line in regard to the absolute conic, then the plane and the original line may be said to be at right angles. Similarly, two planes which meet the absolute plane in lines which are conjugate in regard to the absolute conic may be said to be at right angles. Immediate consequences are, that, if two lines are at right angles, a plane can be drawn through either line which shall be at right angles to the other; or, that, if a line and a plane are at right angles, any plane drawn through the line is at right angles to the given plane; or again, that a line can be drawn which shall be at right angles to both of two given lines which do not meet one another; this being the common transversal of the lines, drawn from the point, in the absolute plane, which is the pole of the line joining the points in which the given lines meet the absolute plane.

Ex. 1. Prove that coordinates can be chosen so that the equations of the absolute conic have the forms $t=0$, $x^2+y^2+z^2=0$, and at the same time the equations of any two lines, which do not meet one another, and do not lie in the absolute plane, have the forms

$$lx-my=0,\quad z-ct=0,\quad \text{and}\quad lx+my=0,\quad z+ct=0.$$

Ex. 2. Shew that the equations of any three lines, of which no two intersect, can be supposed to be of the respective forms

$$(y-bt=0,\ z+ct=0),\ (z-ct=0,\ x+at=0),\ (x-at=0,\ y+bt=0);$$

and that the quadric generated by the transversals of these three lines has the equation

$$ayz+bzx+cxy+abct^2=0.$$

Ex. 3. If between nine quantities (l_1, m_1, n_1), $(l_2, \ldots)$, $(l_3, \ldots)$, there hold the six relations

$$l_1^2+m_1^2+n_1^2=1,\qquad l_2^2+m_2^2+n_2^2=1,\qquad l_3^2+m_3^2+n_3^2=1,$$
$$l_2l_3+m_2m_3+n_2n_3=0,\quad l_3l_1+m_3m_1+n_3n_1=0,\quad l_1l_2+m_1m_2+n_1n_2=0,$$

then there also hold the six following relations

$$l_1^2+l_2^2+l_3^2=1,\qquad m_1^2+m_2^2+m_3^2=1,\qquad n_1^2+n_2^2+n_3^2=1,$$
$$m_1n_1+m_2n_2+m_3n_3=0,\quad n_1l_1+n_2l_2+n_3l_3=0,\quad l_1m_1+l_2m_2+l_3m_3=0,$$

while the determinant, of three rows and columns, (l_1, m_2, n_3), has its square equal to 1.

This result, which is often utilised, may be obtained at once by elementary algebra; or, if we use the notation of matrices (explained Vol. I, p. 67), putting Δ for the matrix of three rows whose first row consists of the elements l_1, m_1, n_1, the second and third rows consisting, respectively, of the elements l_2, m_2, n_2 and l_3, m_3, n_3, and $\bar{\Delta}$ for the transposed matrix, obtained from Δ by change of rows into columns, the given equations are equivalent to $\Delta\bar{\Delta}=1$; this leads to $\bar{\Delta}=\Delta^{-1}$, and hence to $\bar{\Delta}\Delta=1$, which is equivalent to the deduced relations. Geometrically, the given relations shew that the conic $x^2+y^2+z^2=0$ is the same as

$$(l_1x+l_2y+l_3z)^2+(m_1x+m_2y+m_3z)^2+(n_1x+n_2y+n_3z)^2=0,$$

so that the lines $l_1x+l_2y+l_3z=0$, etc., determine a self-polar triad for this conic. This proves at once that $l_1m_1+l_2m_2+l_3m_3=0$, etc.

Spheres and Circles. A quadric which meets the absolute plane in the absolute conic is called a sphere, relatively to this conic. A degenerate case is when the quadric consists of the absolute plane and any other plane. Another degenerate case is that in which the sphere is the cone formed by the lines which join an arbitrary point to the points of the absolute conic. The pole of the absolute plane in regard to a sphere is called its *centre*. Let this centre be O, and let any line through O meet the sphere in P and P', and meet the absolute plane in Q. Then O and Q are harmonic conjugates in regard to P and P', or O is the middle point of P, P'. Further, the polar planes, in regard to the sphere, of all points of the line PP', meet in a line, which is, therefore, on the absolute plane, and is the polar line of the point Q in regard to the absolute conic. Thus, the tangent planes of the sphere at P and P' are both at right angles to the line PP'; or, the tangent plane of the sphere, at any point not lying on the absolute conic, is at right angles to the line joining this point to the centre. At a point of the sphere which lies on the absolute conic the tangent plane passes through the pole of the absolute plane, that is, through the centre of the sphere, and all such planes are tangent planes of the tangent cone or cone of contact drawn to the sphere from its centre. (Cf. Chap. I, p. 26.) It may be proved easily that, if P, P' be any two points of a sphere, the plane through the middle point of P, P', at right angles to the line PP', passes through the centre of the sphere.

In the second Volume we have defined a circle, in a plane, as a conic containing two particular points chosen in that plane as absolute points. Let us now agree that for any plane of space the two absolute points shall be the two points in which the plane meets the absolute conic. Then a *circle* will be a conic whose two points of intersection with the absolute plane lie upon the absolute conic. This being understood, consider any plane section of a sphere. Any two plane sections of a quadric are conics with two points in common, the two points where the line of intersection, of the planes of the conics, intersects the quadric. Thus any plane section of a sphere is a circle, relatively to the absolute conic. And, incidentally, it appears, as a quadric can (Chap. I, p. 7) be drawn through two conics which have two points in common, to pass through an arbitrary point, that a sphere can be drawn to contain an arbitrary circle and an arbitrary point. And, hence, that a sphere can be drawn through four arbitrary points in general position.

As in the case of a quadric in general, there pass through any point, P, of a sphere two lines, lying entirely on the sphere, contained in the tangent plane of the sphere at P. These lines meet the absolute plane in two points which, as they lie on the sphere, are on the absolute conic. Any two lines through P, in the tangent plane at P, which are harmonic in regard to these two generating lines of the sphere at P, evidently meet the absolute plane in two points which are conjugate in regard to the absolute conic, and are therefore at right angles to one another. Any plane section of the sphere also meets the two generating lines at P; if this section be projected, from P, on to any plane, ϖ, it becomes, evidently, a conic passing through the two points in which the generating lines of the sphere at P meet the plane ϖ; it becomes then a circle, in the sense above adopted, if the plane ϖ be so taken as to meet the absolute conic in points lying on the tangent plane of the sphere at P. In other words, a plane section of the sphere projects, from any point, P, of the sphere, into a circle, if the plane, upon which the projection is made, is parallel to the tangent plane of the sphere at P.

Ex. 1. Prove that the polar plane of any point in regard to a sphere is at right angles to the line joining that point to the centre of the sphere. This joining line is in fact the polar line of the line in which the absolute plane is met by the polar plane.

Ex. 2. Prove that when the section of the sphere by a plane, ϖ, is projected from a point, H, of the sphere, into a circle on a plane, the centre of this circle is the projection of the pole, in regard to the sphere, of the plane ϖ. The line of intersection of the plane ϖ with the tangent plane of the sphere at H is, in fact, the polar line of the line joining H to the pole of the plane ϖ.

Ex. 3. The line joining any point, Q, of the section of a sphere by a plane, ϖ, to the pole, P, of the plane ϖ, is at right angles to the tangent line of the section at Q. For, a line drawn from P, in the tangent plane of the sphere at Q, meets the sphere in two points lying on the generators of the sphere at Q, and meets the plane ϖ, say in P', upon the tangent plane of the sphere at Q; so that P' is on the tangent line at Q of the section ϖ. But P and P' are harmonic in regard to the points in which the line PP' meets the sphere.

Ex. 4. At either common point of the sections of a sphere by two planes which are conjugate to one another, each plane containing the pole of the other in regard to the sphere, the tangent lines of the sections are at right angles.

Ex. 5. When the two sections of the preceding example are projected, from a point H of the sphere, on to a plane parallel to the tangent plane at H, they become two circles which cut at right angles.

Relations of two spheres. Coaxial spheres. Now consider two spheres. In the first place, they have two points of contact, lying on the absolute conic; that is, there are two points, common to both spheres, on the absolute conic, at each of which the tangent planes of the two spheres are the same. For, let O and O' be the centres of the two spheres, let the line OO' meet the absolute plane in T, and let TA, TB be the tangent lines drawn from T to the absolute conic, touching this in A and B. Then the plane AOT, containing the common tangent line, AT, of the spheres at the common point A, is a tangent plane of both the spheres at this point A; and BOT is, similarly, a common tangent plane at the common point B. This plane equally contains the other centre, O'. The points of contact of the spheres are thus the two points in which either sphere is touched by the two planes which can be drawn to touch it, from the line of centres, OO'. In the next place, the two spheres have in common, beside the absolute conic, a further plane section, which is, therefore, a circle. For, an arbitrary plane cuts the two spheres in circles which, beside their common points lying on the absolute conic, have two further common points; thus the spheres have, beside the absolute conic, an infinite number of points common; let P, Q, R be three of these; then, the plane PQR cuts the spheres in two conics which, beside P, Q, R, have two points in common, those namely where the plane meets the absolute conic; but two conics with five points in common coincide with one another. Thus the two spheres have in common the circle in which the plane PQR meets either; and, therefore, no other common points beside those on the absolute conic. At either of the two points common to this circle and the absolute conic, the tangent plane of either sphere contains the tangent lines of both these conics, and is hence the tangent plane of both spheres. The two points of contact of the spheres are thus the points where their common circular section meets the absolute conic. The plane of this common circular section is called the *radical plane* of the spheres. Through this common circular section can be drawn, as we have seen, an infinite number of further spheres, one through any arbitrary point. These form what is known as a *coaxial system of spheres*. There are, in particular (Chap. I, p. 10), two cones which both contain the absolute conic and the common circle of the two spheres. The vertices of these cones are called the *limiting points* of the system of coaxial spheres. The limiting points lie on the line joining the centres, O and O', of the two original spheres, which also contains the centres of all the spheres of the coaxial system. Further, any sphere drawn through the two limiting points has its centre on the radical plane, and cuts at right angles every sphere of the coaxial system; that is, the tangent plane of such a sphere, at any point common to it and one of the coaxial spheres, is at right angles to the tangent plane of the latter sphere at this point. These facts may be proved from what has been said. We proceed however to utilise the algebraic representation.

Taking reference points A, B, C, D, of which D is arbitrary, but not on the absolute plane, while A, B, C form a self-polar triad in regard to the absolute conic, so that the equations of this conic may be taken to be $t=0$, $x^2+y^2+z^2=0$, the equation of a sphere is necessarily of the form

$$a(x^2+y^2+z^2)+2uxt+2vyt+2wzt+dt^2=0.$$

When the coefficient a vanishes this becomes the aggregate of the absolute plane $t=0$ and another plane; in general we suppose that a is not zero. This equation is the same as

$$(ax+ut)^2+(ay+vt)^2+(az+wt)^2=(u^2+v^2+w^2-ad)\,t^2,$$

and the point $(u, v, w, -a)$, having for polar the plane $t=0$, is the centre. The points common to this sphere and any other, of equation

$$a'(x^2+y^2+z^2)+2u'xt+2v'yt+2w'zt+d't^2=0,$$

satisfy the condition

$$[2(au'-a'u)\,x+2(av'-a'v)\,y+2(aw'-a'w)\,z+(ad'-a'd)\,t]\,t=0;$$

thus, beside the points lying on $t=0$, there are common points on the radical plane, whose equation is obtained by equating to zero the first factor of the left side. This plane meets $t=0$ on the line given by $t=0$ and

$$(au'-a'u)\,x+(av'-a'v)\,y+(aw'-a'w)\,z=0,$$

which is the polar line, in regard to the absolute conic, of the point $(au'-a'u,\ av'-a'v,\ aw'-a'w,\ 0)$, in which the line joining the centres of the spheres meets the absolute plane; so that the radical plane is at right angles to this joining line. We may thus take the point of intersection of this plane and the line of centres for the reference point D, and the point A to be on the line of centres, so that the radical plane becomes $x=0$. This choice requires that $v=0$, $w=0$, $v'=0$, $w'=0$, $ad'-a'd=0$. Supposing a and a' not to be zero, we may put $a=1$, $a'=1$; then $d=d'$ and the equations of the spheres become

$$x^2+y^2+z^2+2uxt+dt^2=0, \quad x^2+y^2+z^2+2u'xt+dt^2=0.$$

Any coaxial sphere, being required to meet $x=0$ on the circle $x=0$, $y^2+z^2+dt^2=0$, will then have an equation

$$x^2+y^2+z^2+2Uxt+dt^2=0;$$

in particular when $U^2 = d$ this represents a cone whose vertex is $(-U, 0, 0, 1)$. The two limiting points are then $(d^{\frac{1}{2}}, 0, 0, 1)$ and $(-d^{\frac{1}{2}}, 0, 0, 1)$. If, for a moment, we put $X = x + d^{\frac{1}{2}}t$, $T = x - d^{\frac{1}{2}}t$, $A = \frac{1}{2}(1 + ud^{-\frac{1}{2}})$, $A' = \frac{1}{2}(1 + u'd^{-\frac{1}{2}})$, $B = 1 - A$, $B' = 1 - A'$, the equations of the two spheres become

$$AX^2 + BT^2 + y^2 + z^2 = 0, \quad A'X^2 + B'T^2 + y^2 + z^2 = 0,$$

which shew that the four points of intersection of the four planes $X = 0$, $T = 0$, $y = 0$, $z = 0$, form a self-polar tetrad for both the spheres, and, therefore, for all the spheres of the coaxial system (Chap. I, p. 33). Herein, however, the planes $y = 0$, $z = 0$ are not unique, being any two planes through the line of centres which are at right angles to one another. The equation of any sphere through the two limiting points is at once seen to be of the form

$$x^2 + y^2 + z^2 + 2Vyt + 2Wzt - dt^2 = 0,$$

having its centre on the radical plane $x = 0$. We proceed to verify that this meets all the spheres of the coaxial system at right angles; and for this purpose we prove that the condition that two spheres,

$$a(x^2 + y^2 + z^2) + 2uxt + 2vyt + 2wzt + dt^2 = 0, \quad a'(x^2 + y^2 + z^2) + \text{etc.} = 0,$$

should cut at right angles, is

$$2(uu' + vv' + ww') - ad' - a'd = 0.$$

The condition that two planes, of equations $lx + my + nz + pt = 0$, $l'x + \text{etc.} = 0$, should be at right angles, is that the lines

$$lx + my + nz = 0, \quad l'x + \text{etc.} = 0,$$

in which these planes meet $t = 0$, should be conjugate in regard to the absolute conic; that is, $ll' + mm' + nn' = 0$. If now (ξ, η, ζ, τ) be a common point of the two spheres, the respective tangent planes, of such equations as

$$x(a\xi + u\tau) + y(a\eta + v\tau) + z(a\zeta + w\tau) + t(u\xi + v\eta + w\zeta + d\tau) = 0,$$

will be at right angles if

$$(a\xi + u\tau)(a'\xi + u'\tau) + (a\eta + v\tau)(a'\eta + v'\tau) + (a\zeta + w\tau)(a'\zeta + w'\tau) = 0;$$

this, however, is the same as

$$a'S + aS' + [2(uu' + vv' + ww') - ad' - a'd]\,\tau^2 = 0,$$

where $S = 0$, $S' = 0$ are the equations of the two spheres, with (ξ, η, ζ, τ) written for (x, y, z, t). As the point (ξ, η, ζ, τ) satisfies both equations, and is supposed not to lie on the absolute plane, we see that if the spheres cut at right angles at one point, the specified condition is satisfied, and the spheres then cut at right angles at every point; and conversely. The condition is evidently satisfied for any sphere through the limiting points, taken with any one of the coaxial spheres.

Ex. 1. If two circles, not lying in the same plane, have two points in common, a sphere can be described to contain both of them. For these circles together with the absolute conic form three conics of which every two have two points in common; and we have seen (p. 10) that three such conics lie upon a quadric. In the present case this quadric, as containing the absolute conic, is a sphere.

Ex. 2. Prove that the three radical planes, for each pair of three given spheres, meet in a line.

Ex. 3. Given any three circles, no two in the same plane, prove that there is another circle meeting each of them in two points.

If $S_r = 0$ be the equation of a sphere, where

$$S_r = a_r(x^2 + y^2 + z^2) + 2u_r xt + 2v_r yt + 2w_r zt + d_r t^2,$$

it is at once clear that for any six spheres there exists an identity $\lambda_1 S_1 + \lambda_2 S_2 + \ldots + \lambda_6 S_6 = 0$, where $\lambda_1, \ldots, \lambda_6$ are functions of a_r, u_r, v_r, w_r, d_r $(r = 1, \ldots, 6)$. Now let $S_1 = 0$, $S_2 = 0$ be any two chosen spheres through the first of the three given circles, $S_3 = 0$, $S_4 = 0$ be any two chosen spheres through the second of the three given circles, and $S_5 = 0$, $S_6 = 0$ be any two chosen spheres through the third of the three given circles. The equation $\lambda_1 S_1 + \lambda_2 S_2 = 0$ then represents a sphere through the first circle, and the equation $\lambda_3 S_3 + \lambda_4 S_4 = 0$ represents a sphere through the second circle. In virtue of the identity remarked, any point common to these two spheres equally lies on the sphere $\lambda_5 S_5 + \lambda_6 S_6 = 0$, which contains the third circle. Thus the circle common to the first two spheres equally lies on the third. This circle intersects each of the three given circles in two points, since any two circles on the same sphere meet in the two points in which the line of intersection of their planes cuts the sphere.

It may be remarked at once that a similar argument shews that any three lines in space of four dimensions are met by another line. We shall see later how to pass from a circle in three dimensions to a line in four dimensions, or conversely.

Ex. 4. For any two spheres,

$$a(x^2 + y^2 + z^2) + 2uxt + 2vyt + 2wzt + dt^2 = 0,$$
$$a'(x^2 + y^2 + z^2) + 2u'xt + \text{etc.} = 0,$$

let

$$D = u^2 + v^2 + w^2 - ad, \quad E = 2uu' + 2vv' + 2ww' - ad' - a'd,$$
$$D' = u'^2 + v'^2 + w'^2 - a'd';$$

we have shewn that $E = 0$ is the condition for the two spheres to cut at right angles; prove that the first sphere becomes a cone passing through the absolute conic if $D = 0$; also, that the condition that the two spheres should touch, that is, have the same tangent plane, at a point not lying on the absolute plane $t = 0$, is $E^2 = 4DD'$. Further, that the condition that the plane $lx + my + nz + pt = 0$ should touch the first sphere is

$$D(l^2 + m^2 + n^2) - (ul + vm + wn - ap)^2 = 0.$$

Thus, the common tangent planes of the two spheres satisfy the condition

$$D^{-1}(ul + vm + wn - ap)^2 = D'^{-1}(u'l + v'm + w'n - a'p)^2;$$

these common tangent planes are thus the planes drawn to touch either sphere from either of the points whose coordinates are

$$(\lambda u + \lambda' u', \lambda v + \lambda' v', \lambda w + \lambda' w', -\lambda a - \lambda' a'),$$

where λ, λ' are such that $\lambda^2 = 1/D$, $\lambda'^2 = 1/D'$. These two points are called the *centres of similitude* of the two spheres.

Prove further that any sphere, drawn through the vertex of a quadric cone which contains the absolute conic, satisfies the condition $E = 0$, formed for itself and the cone regarded as a degenerate sphere; and may, therefore, be said to cut the cone at right angles.

Shew, too, that, if $l = ua' - u'a$, $l' = vw' - v'w$, etc., the equation of the two common tangent planes of the spheres at the points on the absolute conic at which they touch, is

$$(l't + mz - ny)^2 + (m't + nx - lz)^2 + (n't + ly - mx)^2 = 0.$$

Ex. 5. If two plane sections of a quadric cone be taken, prove that a quadric can be described to contain these, passing through an arbitrary point not lying on either of the planes. Shew also that a sphere can be constructed having a given centre, to pass through a further arbitrary point.

Ex. 6. If O, D be given points, and a variable plane be drawn through D, and a point P taken so that the line OP is at right angles to the plane, and the middle point of O and P lies on the plane, shew that the locus of P is the sphere with centre D which passes through O.

Ex. 7. Four lines in the absolute plane meet in six points, the opposite intersections being conjugate in regard to the absolute conic; any four planes, one through each of these lines, meet, in threes, in the points A, B, C, D. These four points are then such that any two opposite joins of them are two lines at right angles. Prove that, if the line be drawn through each of these points which is at right angles to the plane containing the other three points, these four lines meet in a point, say P. Prove, further, that the six middle points of the joins of the pairs of A, B, C, D lie on a sphere; let its centre be G. Prove that G lies on the line joining P to the centre of the sphere which contains A, B, C, D. A line can be drawn to be at right angles to both of any two opposite joins of

A, B, C, D; taking the intersections of this line with these joins, and the four other points similarly arising for the other two pairs of opposite joins, prove that these six points lie on the sphere containing the middle points of the six joins.

Relations of a quadric in general with the absolute conic. The circular sections. Suppose that the quadric considered does not touch the absolute plane, but meets it in a conic which has four distinct intersections with the absolute conic. These two conics have then a common self-polar triad of points, which we may take for points of reference for coordinates, A, B, C (Vol. II, p. 23). Incidentally also we may remark that if the given quadric be expressed, in regard to any reference points, by an equation wherein the coefficients are real, and the absolute conic, referred to these, be imaginary, then the points A, B, C are real (Vol. II, p. 165). If D be the pole of the absolute plane in regard to the quadric, the four points A, B, C, D will form a self-polar tetrad in regard to the quadric. Referred to A, B, C, D the equation of the quadric will then be of the form

$$\frac{x^2}{a}+\frac{y^2}{b}+\frac{z^2}{c}=t^2,$$

unless the quadric be a cone, consisting of points lying on lines all passing through the point D; in this latter case the equation will be of the form $x^2/a+y^2/b+z^2/c=0$. We may, if we please, include both these equations in the single form $x^2/a+y^2/b+z^2/c=mt^2$.

The point D, the pole of the absolute plane, is called the *centre* of the quadric, or, in the case of the cone, its vertex. The lines DA, DB, DC are called the axes of the quadric; every two of them are at right angles, relatively to the absolute conic. The planes DBC, DCA, DAB are called the *principal planes*. It can now be seen, dealing first with the case when the quadric is not a cone, that through each axis there pass two planes which meet the quadric in sections which are circles, and that all sections in planes parallel to one of these circular sections are also circular sections. For, if P, Q, R, S be the four points common to the quadric and the absolute conic, the section of the quadric by any plane through two of these points is a conic meeting the absolute conic in two points, and is therefore a circle, by the definition. The join of two of these points, P, Q, R, S, contains one of the points A, B, C (Vol. II, p. 23), and a definite plane can be drawn through this join to contain, also, the point D. As two of these joins pass through each of A, B, C, what we have said in regard to circular sections is clear. Of any one of the six sets of parallel planes each meeting the quadric in a circle, there will be two which touch the quadric, these being the tangent planes to the quadric from the line, say, for example, PQ, through which the planes of this set all pass. We thus obtain twelve points of contact, of such tangent planes; these are called *umbilici*. Taking either one of the two generating lines of the quadric at the point P, it is met by one of the two generating lines of the quadric at the point Q, say in U, which will be an umbilicus, while the other generating line at P will be met by the other generating line at Q in another umbilicus, say U'. If B be the one of the three points A, B, C through which PQ passes, the line UU', which is the polar line of PQ, lies in the polar plane of B, that is, in the principal plane DAC, and passes through the centre D, this being the pole of the plane ABC. The twelve umbilici thus lie in fours on the three principal planes, and in pairs on six lines through D. Moreover, as we may consider the intersection of a generating line of the quadric at P with a generating line at Q, or R, or S, we see that the twelve umbilici lie in threes upon the eight generators of the quadric at P, Q, R, S, there being two of these generators through each umbilicus.

If the equation of the quadric be taken in the form remarked above, $\Sigma x^2/a = t^2$, the equations of the absolute conic being $t = 0$, $\Sigma x^2 = 0$, and p, q, r be defined by

$$(a-b)(a-c)p = a, \quad (b-c)(b-a)q = b, \quad (c-a)(c-b)r = c,$$

the point whose coordinates are

$$(a+\lambda)p^{\frac{1}{2}}, \quad (b+\lambda)q^{\frac{1}{2}}, \quad (c+\lambda)r^{\frac{1}{2}}, \quad 1,$$

describes a line, as λ varies. The point of this arising for $\lambda = \infty$, namely $(p^{\frac{1}{2}}, q^{\frac{1}{2}}, r^{\frac{1}{2}}, 0)$, satisfies both the equations $\Sigma x^2/a = 0$, $\Sigma x^2 = 0$, and is thus one of the four points P, Q, R, S; it is at once seen that $\Sigma\,(a+\lambda)^2/(a-b)(a-c) = 1$, so that the line lies entirely upon the quadric. By taking all the possibilities of sign for $p^{\frac{1}{2}}$, $q^{\frac{1}{2}}$, $r^{\frac{1}{2}}$, we thus obtain the eight generators of the quadric which contain the twelve umbilici. In particular, the umbilici are obtained by the values $-a$, $-b$, $-c$, of λ.

These eight generators are a set of lines which may be derived from any one of them by a process of harmonic inversion which often occurs, and may be described: if we are given a point O, and a plane ϖ not containing O, we may, from any point P, obtain another point, P', as that point on the line OP which is the harmonic conjugate of P, in regard to O and the point where OP meets the plane ϖ. Then as P describes any line, P' also describes a line, meeting the former on the plane ϖ; and as P describes any plane, P' also describes a plane, meeting the former plane on the plane ϖ. Suppose now we have a tetrad of points, A, B, C, D; we can employ this process of harmonic inversion taking, for O, any one of these four points and, for the associated plane ϖ, the plane containing the other three. Thereby we have four inversions, and we may subject a point to one of these, or to a combination of two or more of them, taken in succession. It is at once seen that thereby only seven new points are obtained; if the original point be of coordinates (x, y, z, t) relative to A, B, C, D, the aggregate of eight points are those of coordinates $(\pm x, \pm y, \pm z, t)$. Similarly from a line, by repeated inversions with this tetrad, eight lines in all are obtained. It is clear from the above expressions that the eight generators containing the umbilici are such a set of eight lines.

Case of a cone. When the quadric reduces to a cone whose vertex is not on the absolute plane, so that its equation is capable of the form $x^2/a + y^2/b + z^2/c = 0$, the equations of the absolute conic being $t = 0$, $x^2 + y^2 + z^2 = 0$, there will still be, in the general case, four intersections P, Q, R, S, of the cone with the absolute conic, and therefore, as before, three principal planes, through the vertex of the cone, the planes $x = 0$, $y = 0$, $z = 0$, intersecting in pairs in the axes of the cone. It is still the case that a plane containing two of the points P, Q, R, S meets the cone in a circle, so that there are six sets of parallel planes each meeting the cone in a circle. The circular sections containing the axes of the cone degenerate however each into two generators of the cone; and the umbilici all coincide with the vertex. A modification of statement is clearly necessary when two or more of the points P, Q, R, S coincide. The case most frequently considered is that in which the cone touches the absolute conic in two distinct points, say, when Q coincides with P and S with R. There are then still triads which are self-polar both in regard to the absolute conic and in regard to the section of the cone by the absolute plane, one point of all of these being the common pole of PR in regard to the two conics, the other two being any pair of points on PR which are harmonic conjugates in regard to P and R. The cone, in this case, has one unique axis, and all sections by planes at right angles to this are circles, so that the cone is said to be a *cone of revolution*, or a *right circular cone*. Any two lines at right angles to one another, through the vertex of the cone, in the plane at right angles to this unique axis, may be regarded as the other two axes. Besides the circular sections spoken of there are no others which are not degenerate. Finally, if the cone has its vertex, C, on the absolute plane, in which case it is called a *cylinder*, there will be two generators of the cone lying in the absolute plane. If these meet the absolute conic in distinct points, respectively, P and R, and Q and S, so that P, C, R are in line, as are Q, C, S, then any plane through either of the four lines PQ, QR, RS, SP, meets the cylinder in a circle. But when P coincides with Q and R coincides with S, or the cylinder touches the absolute plane, no undegenerate circular sections lie in planes through PR. And it is also possible that the vertex of the cone should be on the absolute conic. The necessary modifications may easily be stated. When the cone meets the absolute plane in two distinct lines, its vertex, ***C***, not being on the absolute conic, we may take two points, ***A*** and ***B***, on the polar line of ***C*** in regard to the absolute conic, which shall be conjugate to one another both in regard to the absolute conic, and in regard to the cone, and take for ***D*** a point on the polar line of the absolute plane in regard to the cone; then, with ***A***, ***B***, ***C***, ***D*** as point of reference, the equations of the absolute conic may be supposed to be $t=0$, $x^2+y^2+z^2=0$, and the equation of the cone to be of the form $ax^2+by^2=t^2$. This construction fails if the cone touches the absolute plane, its vertex still not being on the absolute conic. If then ***C*** be the vertex of the cone, and ***CA*** the generator of contact with the absolute plane, the point ***A*** being on the polar line of ***C*** in regard to the absolute conic, and if ***B*** be the pole of ***CA*** in regard to the absolute conic, and ***D*** be any point not on the absolute plane, the triad ***A***, ***B***, ***C*** is self-polar in regard to the absolute conic, whose equations may therefore be supposed to be of the form $t=0$, $x^2+y^2+z^2=0$, while the equation of the cone is of the form $y^2=(Ax+By+Ct)\,t$. This is simplified if we take for ***CD*** the other generator of the cone, beside ***CA***, along which the tangent plane contains ***CB***; the equation then reduces to the form $y^2=mxt$. The case when the vertex of the cone lies on the absolute conic may be similarly dealt with.

Ex. Prove that the equation

$$ax^2+by^2+cz^2+2fyz+2gzx+2hxy=0$$

represents a right circular cone (touching the absolute conic in two points), (1) if $f=g=h=0$ and two of a, b, c be equal, (2) if $g=h=0$ and $(a-b)(a-c)=f^2$, (3) when none of f, g, h is zero, if $a-f^{-1}gh=b-g^{-1}hf=c-h^{-1}fg$. Remark also that in general the equation of the cone is capable of the form

$$(a-f^{-1}gh)\,x^2+(b-g^{-1}hf)\,y^2+(c-h^{-1}fg)\,z^2$$
$$+fgh\,(f^{-1}x+g^{-1}y+h^{-1}z)^2=0.$$

Quadric touching the absolute plane. When the quadric touches the absolute plane at a point, *C*, not lying on the absolute conic, there will be two distinct lines of the surface, passing through *C*, lying in the absolute plane, say these are ***PCR*** and ***QCS***, where ***P***, ***Q***, ***R***, ***S*** are on the absolute conic. It is then possible to take two points, *A* and *B*, on the polar line of *C* in regard to the absolute conic, which shall be conjugate in regard to this conic, and also harmonic conjugates of one another in regard to the two lines ***PCR***, ***QCS***. From the line *AB* it is possible to draw another tangent plane to the quadric beside the absolute plane. Let this touch the quadric in the point D. Then, referred to A, B, C, D, the equation of the quadric assumes the form $ax^2+by^2+2wzt=0$. For, consider the most general form possible

$$ax^2+by^2+cz^2+dt^2+2fyz+2gzx+2hxy+2uxt+2vyt+2wzt=0;$$

then, the intersection with the absolute plane is to reduce to two lines, passing through the point C, harmonic in regard to CA, CB, and two such lines are represented by equations of the form $t=0$, $Ax^2+By^2=0$; we infer, therefore, that $c=f=g=h=0$; further, the intersection with $z=0$ is to reduce to two lines given by equations of the form $z=0$, $lx^2+2mxy+ny^2=0$; we infer, therefore, that $d=u=v=0$. This establishes the form in question. The form of the equations of the absolute conic may still be supposed to be $t=0$, $x^2+y^2+z^2=0$, the triad A, B, C being self-polar in regard to this. Such a quadric may be called a *paraboloid*. There are four sets, each of parallel planes, meeting the surface in circles, namely those containing any one of the lines PQ, QR, RS, SP. The points of contact of tangent planes, other than the absolute plane, drawn to the quadric through these lines, give four umbilici; these lie in pairs on four generators of the surface passing each through one of the points P, Q, R, S. The case when the quadric touches the absolute plane at a point of the absolute conic may be similarly dealt with.

Ex. 1. For the surface $ax^2+by^2+2wzt=0$, if $c=a-b$, the umbilici are given by

$$[0,\ (-ac)^{\frac{1}{2}},\ \tfrac{1}{2}c,\ ab/w] \quad\text{and}\quad [(bc)^{\frac{1}{2}},\ 0,\ \tfrac{1}{2}c,\ ab/w].$$

Ex. 2. Any two circular sections of a quadric, whose planes are not parallel, lie on a sphere. For two plane sections of a quadric meet in two points, and three conics, of which every two have two points in common, lie on a quadric, as has been remarked.

Ex. 3. The condition for a given plane to be a circular section of a given quadric is that the plane should meet the absolute conic in points lying on the quadric. If the absolute conic be $t=0$, $x^2+y^2+z^2=0$, the plane be $lx+my+nz+pt=0$, and the quadric be in general form $ax^2+\ldots+2wzt=0$, prove that the conditions are the two

$$\frac{bn^2+cm^2-2fmn}{m^2+n^2}=\frac{cl^2+an^2-2gnl}{n^2+l^2}=\frac{am^2+bl^2-2hlm}{l^2+m^2}.$$

Ex. 4. Prove that the axes and asymptotes of a plane section of a quadric are parallel to those of the section by any other parallel plane, and that the centres of these sections, by parallel planes, lie in line. Prove that the axes of the section of the quadric $ax^2+by^2+cz^2=t^2$ by the plane $lx+my+nz=0$, being the lines through the centre, in this plane, which are conjugate to one another both in regard to the quadric, and in regard to the absolute conic ($t = 0$, $x^2 + y^2 + z^2 = 0$), are the intersections of the plane with the cone

$$x^{-1}l(b-c) + y^{-1}m(c-a) + z^{-1}n(a-b) = 0.$$

Ex. 5. If the general equation $ax^2 + \ldots + 2wzt = 0$ break up into two linear factors, and so represent two planes, the condition that these planes should be at right angles is that the lines in which they meet the absolute plane should form a conic outpolar to the absolute conic (Vol. II, pp. 36, 144). With the usual form for the equations of the absolute conic, the condition for this is $a + b + c = 0$.

The pair of tangent planes which can be drawn from the line whose coordinates are (l, m, n, l', m', n'), to the quadric

$$x^2/a + y^2/b + z^2/c = t^2,$$

are at right angles if

$$(b+c)l^2 + (c+a)m^2 + (a+b)n^2 = l'^2 + m'^2 + n'^2.$$

Ex. 6. Prove that the tangent planes of a quadric at the points of a generator form an axial pencil which is related to the range formed by their points of contact; and that the normals of the surface at the points of the generator, that is the lines through these points at right angles to the tangent planes, meet this generator, and a certain line in the absolute plane, in two related ranges. These normals are therefore generators of a quadric which touches the absolute plane.

If the equation of the given quadric be taken in the form $xU - yV = 0$, where U, V are linear in x, y, z, t, the equations of the absolute conic being as before, shew that the normals describe the surface $xV_0 + yU_0 = 0$, where U_0, V_0 are obtained from U, V, respectively, by putting $x = 0$ and $y = 0$.

The line of striction for one system of generators of a quadric. If two lines which do not intersect one another meet the absolute plane in P and Q, respectively, and R be the pole of the line PQ in regard to the absolute conic, the transversal drawn from R to the given lines is a line at right angles to both, and the only such, as has been remarked. Now suppose the two lines coincide in one generator of a given quadric; the line PQ will then be replaced by the tangent line, at P, of the section of the quadric by the absolute plane. The transversal from R is then replaced by a line from R meeting the quadric in two coincident points; the point of coincidence will therefore be the intersection of the generator with the polar plane of R in regard to the quadric. This construction determines a single point on the generator; the locus of these points, for all the generators of one system, is called the *line of striction* corresponding to the system.

Ex. 1. If the equation of the quadric be $x^2/a^2+y^2/b^2-z^2/c^2=t^2$, the absolute conic being as before, the coordinates of a point of the quadric can be represented in terms of two parameters, λ, μ, in the forms $x/a=1-\lambda\mu$, $y/b=\lambda+\mu$, $z/c=1+\lambda\mu$, $t=\lambda-\mu$. Then λ is constant for all points of a generator of one system, given by the equations $x/a+z/c=\lambda^{-1}(t+y/b)$, $x/a-z/c=\lambda(t-y/b)$; and μ is constant on the generator of the other system given by

$$x/a+z/c=-\mu^{-1}(t-y/b), \quad x/a-z/c=-\mu(t+y/b).$$

The parameters of the generators of the two systems which meet in a point of the section by $t=0$ are equal, their point of meeting being of coordinates $a(1-\lambda^2)$, $2b\lambda$, $c(1+\lambda^2)$, 0.

Carrying out then the construction above explained it may be shewn that the line of striction, for the generators (λ), meets the generator λ in the point for which μ is given by

$$\mu\lambda(\lambda^2+A)+A\lambda^2+1=0, \quad \text{where } A=(2b^{-2}+c^{-2}-a^{-2})/(a^{-2}+c^{-2}).$$

From this it may be seen that the line of striction is a curve meeting an arbitrary plane in four points, and meeting any generator, μ, of the other system, in three points.

Ex. 2. By the same construction, for the quadric represented by the equation $a^{-2}x^2-b^{-2}y^2=2zt$, the tangent line at the point P being however replaced in this case by a generator lying in the absolute plane, shew that the lines of striction are the sections of the surface by the planes $a^{-3}x \pm b^{-3}y=0$. These sections both touch the absolute plane.

Ex. 3. With the notation above, a generator, λ, of the quadric meeting the absolute plane in P, and R being the pole, in regard to the absolute conic, of the tangent line, at P, of the section of the quadric by the absolute plane, prove that, if RP meet this section again in T, and S be the point of the line of striction which lies on the generator considered, then ST is a generator of the other system.

Ex. 4. Hence shew that if a pair of tangent planes of the quadric, at right angles to one another, be drawn through the given generator, their points of contact being the points H, K of this generator, then the pair H, K belong to an involution of pairs of points on this generator, in which the point S, on the line of striction, is the point conjugate to P.

Ex. 5. Shew that the quartic curve in Ex. 1 lies on a cubic cone whose vertex is $(0, b, 0, 1)$, which intersects the quadric surface also, doubly, in the μ-generator for which $\mu=0$, namely the line given by $x/a=z/c$, $t=y/b$, this being a double line of the cone.

Shew further that a cubic surface can be drawn through the curve and any two μ-generators of the quadric surface; and that no other quadric surface than the original contains the curve.

In the construction given, as the point P varies, the point R describes a conic in the absolute plane, the polar reciprocal, in regard to the absolute conic, of the conic described by P. The polar planes of the points R envelope a quadric cone, whose vertex is the centre of the quadric. The tangent planes of this cone are thus related, in the sense employed in Vol. I, to the generators of the quadric, through the points P; and the curve is the locus of the intersection of a plane of the cone with the corresponding generator. More generally, if $P=0$, $Q=0$, $R=0$, $S=0$, $U=0$, $V=0$, $W=0$ be arbitrary planes, we may consider the locus of the intersection of the plane $U\theta^2+2V\theta+W=0$, which envelopes the cone $UW=V^2$, with the line $P=\theta R$, $Q=\theta^{-1}S$, which is a corresponding line of the quadric $PQ=RS$. The locus is a curve of this quadric lying on the cubic surface $UP^2+2VPR+WR^2=0$, which also intersects the quadric in the generator $P=0$, $R=0$ counted twice. The curve lies also on the cubic surface

$$U(P-\phi S)(P-\psi S)+V[(P-\phi S)(R-\psi Q)+(P-\psi S)(R-\phi Q)] \\ +W(R-\phi Q)(R-\psi Q)=0$$

which contains two arbitrary generators, ϕ, ψ, of the other system, given by $P=\phi S$, $R=\phi Q$, etc.

The construction for the line of striction is evidently not limited to the case when the generators lie on a quadric surface.

Ex. 6. Notice that the two generators of the surface

$$a^{-2}x^2+b^{-2}y^2-c^{-2}z^2=t^2,$$

at the point (x_0, y_0, z_0, t_0), are the intersections of the tangent plane with the two planes $(xy_0-x_0y)/ab=\pm(zt_0-z_0t)/c$.

The director sphere of a quadric. If three tangent planes of a quadric, which does not touch the absolute plane, be such that every two are at right angles, it can be shewn that the point of intersection of the three planes lies on a definite sphere, whose centre is the centre of the quadric.

We can suppose the equation of any plane put into the form $lx+my+nz=pt$, with l, m, n so chosen that $l^2+m^2+n^2=1$. Further the condition that two planes,

$$l_1x+m_1y+n_1z=p_1t, \quad l_2x+m_2y+n_2z=p_2t,$$

should be at right angles, when the equations of the absolute conic are $t=0$, $x^2+y^2+z^2=0$, is that $l_1l_2+m_1m_2+n_1n_2=0$. If then we have three planes of which every two are at right angles, with equations $l_rx+m_ry+n_rz=p_rt$, we may suppose the six equations $l_r^2+m_r^2+n_r^2=1$, $l_rl_s+m_rm_s+n_rn_s=0$ to be satisfied. Therefore, as remarked above (Ex. 3, p. 71), the six equations such as $l_1^2+l_2^2+l_3^2=1$, $l_1m_1+l_2m_2+l_3m_3=0$, are also satisfied. Wherefore, if (x, y, z, t) be the point of intersection of the planes, from $\Sigma (l_r x + m_r y + n_r z)^2 = t^2 \Sigma p_r^2$, we infer $x^2 + y^2 + z^2 = t^2 \Sigma p_r^2$.

Now suppose the planes all touch the quadric whose equation is $x^2/a + y^2/b + z^2/c = t^2$; the conditions for this are the three of the form $al_r^2 + bm_r^2 + cn_r^2 = p_r^2$; these however lead to $\Sigma p_r^2 = a + b + c$. Thus the point of intersection of the planes lies on the sphere whose equation is $x^2 + y^2 + z^2 = t^2 (a + b + c)$.

And it is clear that if the planes touch, not all the same quadric, but, respectively, the three quadrics whose equations are

$$x^2 (a + \lambda_1)^{-1} + y^2 (b + \lambda_1)^{-1} + z^2 (c + \lambda_1)^{-1} = t^2, \text{ etc.},$$

so that we have $(a + \lambda_r) l_r^2 + (b + \lambda_r) m_r^2 + (c + \lambda_r) n_r^2 = p_r^2$, or $al_r^2 + bm_r^2 + cn_r^2 = p_r^2 - \lambda_r$, then $\Sigma p_r^2 = \Sigma \lambda_r + a + b + c$. In this case the point of intersection of the planes lies on the sphere whose equation is $x^2 + y^2 + z^2 = a + b + c + \Sigma \lambda_r$.

When the quadric touches the absolute plane, and has an equation $ax^2 + by^2 + 2wzt = 0$, the condition that a plane

$$lx + my + nz + pt = 0,$$

should touch the quadric is $a^{-1} l^2 + b^{-1} m^2 + 2w^{-1} np = 0$. If then three planes touch this quadric and intersect in the point (x, y, z, t), we have three equations such as

$$t (a^{-1} l_r^2 + b^{-1} m_r^2) - 2w^{-1} n_r (l_r x + m_r y + n_r z) = 0.$$

If every two of the planes be at right angles, we can thus infer, as above, by adding these equations, that $t (a^{-1} + b^{-1}) - 2zw^{-1} = 0$. The locus of the point of intersection of the three tangent planes thus degenerates into a plane, the absolute plane being, in a certain sense, also part of this. The plane in question passes through the polar line, on the absolute plane, in regard to the absolute conic, of the point of contact of the quadric with the absolute plane.

If we take the general tangential equation of a quadric, for a plane, $lx + my + nz + pt = 0$, touching this, which contains a point (x, y, z, t), the equation

$$t^2 (Al^2 + Bm^2 + Cn^2) + D (lx + my + nz)^2 + 2Ft^2 mn + \dots$$
$$- 2Utl (lx + my + nz) - \dots = 0$$

holds. If we have three such planes, mutually at right angles, satisfying this equation, we infer, as above, by addition of the three equations, the equations of the absolute conic being as before, that

$$t^2 (A + B + C) + D (x^2 + y^2 + z^2) - 2Utx - 2Vty - 2Wtz = 0.$$

This is then the equation of the locus of the point of intersection of the planes; it represents a sphere whose centre is (U, V, W, D), which is the centre of the quadric, the pole of the plane $t = 0$. The locus degenerates into the absolute plane $t = 0$, together with another plane, when $D=0$; this is the condition that the quadric should touch the plane $t=0$. In general, the sphere is called the *director sphere* of the quadric.

We may consider the matter from a less algebraical point of view, if we recall what was said in Chap. I (p. 52) in regard to the condition that one quadric be outpolar to another. The condition that a quadric S', given by a point equation $a'x^2+\ldots+2h'xy=0$, should be outpolar to another quadric Σ given by a tangential equation $Al^2+\ldots+2Hlm=0$, is $a'A+\ldots+2h'H=0$. This condition may be proved, as was the corresponding condition for conics (Vol. II, p. 142), to be independent of the choice of the points of reference for coordinates. Evidently if $S_1'=0, S_2'=0$ be two quadrics both outpolar to Σ, so is any quadric whose equation is $S_1'+\lambda S_2'=0$; or, if $\Sigma_1=0$, $\Sigma_2=0$ be two quadrics both inpolar to S', so is any quadric whose equation is $\Sigma_1+\mu\Sigma_2$. The condition does not apply directly to the case when the inpolar quadric Σ is a cone; there is no unique tangential equation to a cone, just as there is no unique point equation to a conic, regarded as existing in three dimensions. We may however speak of a cone S as being outpolar to a cone Σ of the same vertex as S, when the conic sections of these cones by any plane are in the corresponding relation to one another. The condition for this is easily expressed when the common vertex of the cones is taken as one of the points of reference for coordinates. This being understood, a cone, of vertex P, which is outpolar to the enveloping cone drawn from P to a quadric Σ, is outpolar to Σ; in particular a pair of planes which are conjugate to one another in regard to a quadric Σ, form, together, a degenerate quadric outpolar to Σ. Assuming these results, which may easily be verified, consider again a point, P, from which pass three tangent planes of a quadric, Σ, which are mutually at right angles in regard to the absolute conic, ω. These planes touch the enveloping cone from P to Σ; this cone thus meets the absolute plane in a conic, ϵ, which is inpolar to ω, being touched by three lines in the absolute plane which form a self-polar triad in regard to ω. Thus the conic ω is outpolar to ϵ (Vol. II, p. 33), and the cone $P\omega$, joining P to ω, is outpolar to the enveloping cone $P\epsilon$, and, therefore, by what has been said, is outpolar to the quadric Σ. The director sphere thus appears as the locus of a point P such that the conic $P\omega$, joining P to the absolute conic ω, is outpolar to the quadric. This result is analogous to the fact that the director circle of a conic is the locus of a point which is such that the lines joining it to the two absolute points of the plane of the conic form together a degenerate conic outpolar to the conic, in regard to which they are conjugate lines. If we adopt this definition we may prove that the locus in question is a sphere by remarking that if P and P' be two points, there is a system of coaxial spheres of which P and P' are the limiting points, the cones $P\omega$, $P'\omega$ intersecting in two conics, one, ω, lying on the absolute plane, the other lying in a plane which is at right angles to PP' and passes through the middle point of P, P'. This second plane contains the centre of the quadric; for this statement is the same as that the two planes containing the complete intersection of the two cones, $P\omega$, $P\omega'$, are conjugate to one another in regard to the quadric Σ; now it has been shewn above (p. 75) that if the equations of the two cones be, respectively, $\Gamma = 0$, $\Gamma' = 0$, the equation of the two planes is of the form $\Gamma - \lambda\Gamma' = 0$; as Γ and Γ' are both outpolar to Σ, so then is the aggregate of the two planes. This involves that they are conjugate to one another in regard to the quadric Σ. It follows now easily (cf. Ex. 6, p. 78, above) that P' lies on the sphere constructed to pass through P which has its centre at the centre of the quadric. More generally, if we consider any two spheres which are outpolar to the quadric Σ, these define a system of coaxial spheres. If P and P' be the limiting points of this system, the cones $P\omega$, $P'\omega$, whose equations, as has been seen (p. 75, above) are obtained linearly from the equations of these spheres, are equally outpolar to Σ. Thus P and P' lie on the director sphere. Therefore this sphere cuts both the given spheres at right angles, as we have proved. Thus, all spheres outpolar to Σ cut the director sphere at right angles. This is the analogue in three dimensions of Gaskin's theorem for conics (Vol. II, p. 48).

When a conic ϵ is inpolar to a conic ω, lying in the same plane, if any tangent line of ϵ be taken, and the pole of this in regard to ω, the two tangents of ϵ drawn from this pole are conjugate to one another, as well as to the chosen tangent, in regard to ω. Wherefore, if any tangent plane be drawn to the quadric Σ from a point, P, of the director sphere, and the line at right angles to this be drawn through P, the two tangent planes of the quadric drawn through this line are at right angles to one another. In particular, if we consider a point P common to the director sphere and the quadric Σ, and take for the tangent plane drawn through P that which touches the quadric at P, since a tangent plane of the quadric can be drawn through either generating line of the quadric at P to contain also any other line through P, we infer that the two generating lines of the quadric at P are at right angles to one another. Conversely, it can be shewn that the points of the quadric at which the generators are at right angles lie upon a sphere; this would furnish another definition of the director sphere.

Ex. 1. Let the plane of a conic, ω, meet a quadric, Σ, in the conic σ; let a generator, l, of Σ meet σ in P; let the polar of P in regard to ω meet σ in Q and R. Through each of Q and R there is a generator of Σ which intersects l; let these be m_1 and m_2. The two tangent planes of Σ drawn through QR are those containing, respectively, m_1 and m_2; for, for instance, m_1 is met by the generator through R which is of the same system as l. Any pair of planes through QR which are conjugate to one another in regard to Σ are then harmonic conjugates in regard to the planes (QR, m_1) and (QR, m_2). We can infer that there are two generators m_1, m_2, of the quadric Σ, which intersect a given generator l, and are at right angles to this, and, if these meet l in P_1 and P_2, that the plane at right angles to l which contains the middle point of P_1, P_2, passes through the centre of the quadric. From this it follows that the sphere, whose centre is the centre of the quadric, which contains the point P_1, also contains the point P_2. The generator m_2 is, similarly, met at right angles by another generator beside l, in a point similarly lying on the same sphere; and so on continually.

Ex. 2. When the quadric is that representable, as above (p. 85), in terms of parameters λ, μ, by the equations

$$x/a = 1 - \lambda\mu, \quad y/b = \lambda + \mu, \quad z/c = 1 + \lambda\mu, \quad t = \lambda - \mu,$$

prove that the condition that two generators, (λ), (μ), of different systems, should be at right angles, is

$$a^2(1 - \lambda^2)(1 - \mu^2) + 4b^2\lambda\mu + c^2(1 + \lambda^2)(1 + \mu^2) = 0,$$

shewing also that this arises from

$$x^2 + y^2 + z^2 = (a^2 + b^2 - c^2)t^2.$$

Ex. 3. Supposing the equation of the quadric to be

$$x^2/a + y^2/b + z^2/c = t^2,$$

we have shewn above (p. 80) that a generator of the quadric at one of its intersections with the absolute conic is given, varying λ, by the points expressed by

$$\frac{x}{t} = (a + \lambda)p^{\frac{1}{2}}, \quad \frac{y}{t} = (b + \lambda)q^{\frac{1}{2}}, \quad \frac{z}{t} = (c + \lambda)r^{\frac{1}{2}},$$

where $p = a/(a - b)(a - c)$, etc. The point of this line on the absolute plane, $(p^{\frac{1}{2}}, q^{\frac{1}{2}}, r^{\frac{1}{2}}, 1)$, arises by $\lambda = \infty$. This line, meeting the director sphere once at this point, will meet this sphere in one other point. Shew that this is given by $\lambda = 0$, being $(ap^{\frac{1}{2}}, bq^{\frac{1}{2}}, cr^{\frac{1}{2}}, 1)$. Shew further that the cubic equation in θ expressed by

$$a^2p\,(a + \theta)^{-1} + b^2q\,(b + \theta)^{-1} + c^2r\,(c + \theta)^{-1} = 1$$

possesses only the root $\theta = 0$.

Ex. 4. The director sphere of a quadric is the locus of a point such that the cone joining this to the absolute conic is outpolar to the enveloping cone from this to the quadric. More generally, prove that the locus of a point such that the enveloping cone drawn from this to the quadric $x^2+y^2+z^2=mt^2$ is outpolar to the enveloping cone of the quadric $x^2/a+y^2/b+z^2/c=t^2$, is represented by

$$x^2(b+c)+y^2(c+a)+z^2(a+b)+m\left[x^2+y^2+z^2-(a+b+c)\,t^2\right]=0.$$

Dually, prove that a plane whose section with the quadric expressed by $ax^2+by^2+cz^2=t^2$ is outpolar to the section with

$$a_1^{-1}x^2+b_1^{-1}y^2+c_1^{-1}z^2=t^2,$$

touches the quadric expressed by $A^{-1}x^2+B^{-1}y^2+C^{-1}z^2=t^2$, where $\quad A=a_1(bb_1+cc_1+1)\,(aa_1+bb_1+cc_1)^{-1}$, etc.

Ex. 5. If from a point, T, three lines, TP, TQ, TR, can be drawn, to touch a quadric surface E, of which every two are at right angles, the enveloping cone from T to the surface E is outpolar to the cone $T\omega$, joining T to the absolute conic. If the equation of E be $a^{-1}x^2+b^{-1}y^2+c^{-1}z^2=t^2$, the equations of the absolute conic being as before, prove that the plane PQR is a tangent plane of the surface $(a+\lambda)^{-1}x^2+\text{etc.}=t^2$, where $\lambda^{-1}+a^{-1}+b^{-1}+c^{-1}=0$, say, of the surface F. The locus of T is then that of the pole, in regard to E, of the tangent plane of F, namely is the polar reciprocal of F in regard to E, whose equation is $a^{-2}(a+\lambda)\,x^2+\text{etc.}=t^2$; this locus intersects E on the curve where the common tangent planes of E and F touch E. (Cf. Vol. II, p. 133, and Ex. 2, p. 93, below.)

Confocal quadrics, defined algebraically. The quadrics represented, with different values of λ, by the equation

$$(a+\lambda)^{-1}x^2+(b+\lambda)^{-1}y^2+(c+\lambda)^{-1}z^2=t^2,$$

are said to be confocal. It is perhaps easier to deal with the theory of such surfaces, in the first instance, with the help of the algebraic symbols; a more synthetic treatment is suggested below.

If we replace (x, y, z, t) by the coordinates of a particular point, (x_1, y_1, z_1, t_1), we obtain a cubic equation for the parameter λ; there are thus, in general, three confocals passing through a given point. It is easy to prove that, if a, b, c be real, and (x_1, y_1, z_1, t_1) be real, the three values of λ are real; for definiteness suppose $a>b>c$; it can then be shewn that the three roots λ_1, λ_2, λ_3 are such that

$$-a<\lambda_3<-b<\lambda_2<-c<\lambda_1;$$

it is only necessary to assume that, if the cubic polynomial

$$(\lambda+a)(\lambda+b)(\lambda+c)\,t_1^2-(\lambda+b)(\lambda+c)\,x_1^2-\ldots-\ldots$$

assumes values of different sign upon the substitution of two real values of λ, then it vanishes for one (or three) intermediate values of λ. Of the three confocal surfaces thus obtained to pass through the point (x_1, y_1, z_1, t_1), every two cut at right angles. For the condition that the tangent planes,

$$(a+\lambda)^{-1}xx_1+(b+\lambda)^{-1}yy_1+(c+\lambda)^{-1}zz_1=tt_1,$$

and

$$(a+\mu)^{-1}xx_1+(b+\mu)^{-1}yy_1+(c+\mu)^{-1}zz_1=tt_1,$$

should cut at right angles, namely $(a+\lambda)^{-1}(a+\mu)^{-1}x_1^2 + \text{etc.} = 0$, is obtained at once by subtraction of the two equations

$$(a+\lambda)^{-1}x_1^2 + \text{etc.} = t_1^2, \quad (a+\mu)^{-1}x_1^2 + \text{etc.} = t_1^2.$$

Thus any two different confocals cut at right angles at every common point.

For every one of the confocal surfaces the tetrad of points, $(1, 0, 0, 0)$, etc., is self-polar. In each of the four planes of this tetrad there is a conic associated with the confocal system; for instance, in the plane $x=0$, the conic $(b-a)^{-1}y^2 + (c-a)^{-1}z^2 = t^2$, obtainable from the general equation of the confocals by putting $x=0$ and $\lambda = -a$; and so on; the conic in the plane $t=0$ is $x^2+y^2+z^2=0$, obtainable by putting $t=0$ and $\lambda = \infty$. These four conics are called the *focal conics* of the system; each may be regarded as lying on two degenerate surfaces of the confocal system.

When (x_1, y_1, z_1, t_1) are not all real, the three confocals through this point need not be distinct. We have, in particular, remarked above (p. 90) that, when this point is $(ap^{\frac{1}{2}}, bq^{\frac{1}{2}}, cr^{\frac{1}{2}}, 1)$, in which $p = a/(a-b)(a-c)$, etc., the three roots λ of the cubic equation are all $\lambda = 0$, the only confocal of the system through this point being $a^{-1}x^2 + b^{-1}y^2 + c^{-1}z^2 = t^2$. More generally, the confocals through any point, P, of coordinates $[(a+\theta)p^{\frac{1}{2}}, (b+\theta)q^{\frac{1}{2}}, (c+\theta)r^{\frac{1}{2}}, 1]$, are given by $\lambda = 0$, and $\lambda = \theta$, of which the root θ is a double root, as may easily be verified; for every value of θ this point P lies on a generator, of the surface $a^{-1}x^2 + b^{-1}y^2 + c^{-1}z^2 = t^2$, passing through one of the intersections of this quadric with the conic $t=0$, $x^2+y^2+z^2=0$; this generator, it may easily be seen, touches the surface

$$(a+\theta)^{-1}x^2 + \text{etc.} = t^2$$

at the point P. Thus, this generator touches all the confocals (other than that on which it lies); through any point of it there pass only two distinct confocals, the one on which it lies, and that which it touches there; through one point of it, lying on the director sphere of the surface on which it lies, when this director sphere is defined with the focal conic of the plane $t=0$ as absolute conic (cf. p. 90, above), there passes the surface only, of the confocal system. Further, it may easily be verified that through any point, (x_1, y_1, z_1, t_1), where the quadric $a^{-1}x^2 + \text{etc.} = t^2$ is met by the cone $a^{-2}x^2 + \text{etc.} = 0$, there pass, of the confocal system, only this quadric, counting twice, and the surface of parameter $\lambda = (x_1^2 + y_1^2 + z_1^2)\,t_1^{-2} - (a+b+c)$; at these points the tangent plane of the surface $a^{-1}x^2 + \text{etc.} = t^2$ is such as also to touch the conic $t=0$, $x^2+y^2+z^2=0$.

Ex. 1. Prove that the eight generators of the surface

$$a^{-1}x^2 + \text{etc.} = t^2$$

at the points where this meets the conic $t = 0$, $x^2 + y^2 + z^2 = 0$, lie on the surface expressed by the equation

$$[x^2 + y^2 + z^2 - t^2 (a + b + c)]^2 - 4abc\,(a^{-2}x^2 + b^{-2}y^2 + c^{-2}z^2)\,t^2 = 0.$$

Ex. 2. Prove that the polar reciprocal of the quadric

$$(a + \lambda)^{-1}x^2 + \text{etc.} = t^2,$$

in regard to the quadric $a^{-1}x^2 + \text{etc.} = t^2$, that is, the locus of the poles, in regard to the second quadric, of the tangent planes of the first, is the quadric given by

$$a^{-1}x^2 + b^{-1}y^2 + c^{-1}z^2 - t^2 + \lambda\,(a^{-2}x^2 + b^{-2}y^2 + c^{-2}z^2) = 0.$$

Consider now the locus of the poles of an arbitrary plane, say of equation $lx + my + nz = pt$, in regard to all the surfaces of the confocal system. It is evidently the line of which the general point has the coordinates $[(a + \theta)\,l,\ (b + \theta)\,m,\ (c + \theta)\,n,\ p]$, for varying values of θ. This line meets the plane $t = 0$ in the point $(l, m, n, 0)$, and is at right angles to the given plane, when the absolute conic is the focal conic of the plane $t = 0$. The line meets the plane itself in the point for which θ is given by $(a + \theta)\,l^2 + \text{etc.} = p^2$; thus there is one surface of the confocal system touching the plane, that namely for which the parameter λ has this particular value of θ. The line may be called the *axis* of the plane.

It may happen that the axis of a plane lies in the plane itself, namely this is so when the condition $(a + \theta)\,l^2 + \text{etc.} = p^2$ is satisfied for all values of θ. Then the plane, satisfying

$$l^2 + \text{etc.} = 0, \quad al^2 + \text{etc.} = p^2,$$

touches the focal conic in the plane $t = 0$, and touches the surface $a^{-1}x^2 + \text{etc.} = t^2$. In this case, however, we also have, for any value of λ, the equation $(a + \lambda)\,l^2 + \text{etc.} = p^2$, and the plane touches every surface of the confocal system; it touches, then, also the other three focal conics. The points of contact all lie on the line which is the axis of the plane; this line meets all the focal conics. When the plane has the equation $xp^{\frac{1}{2}} + yq^{\frac{1}{2}} + zr^{\frac{1}{2}} = t$, where, now,

$$p = a/(a - b)\,(a - c), \text{ etc.},$$

being then the tangent plane of the quadric $a^{-1}x^2 + \text{etc.} = t^2$ at the point $(ap^{\frac{1}{2}}, bq^{\frac{1}{2}}, cr^{\frac{1}{2}}, 1)$, considered above, the axis is a generator of this quadric, as we have seen. We can thus make the statements: (*a*) Confocal surfaces have the property that a plane which touches two of them, touches all, the points of contact being in line. Such a plane touches all the focal conics, in points lying on this line. Conversely, a plane touching two of these conics, or touching one of these and one of the surfaces, touches all; (*b*) Through any point four planes of this character can be drawn, these being the common tangent planes of the enveloping cones drawn from this point to two of the surfaces. Exception arises when the point is on one of the focal conics; then two such planes can be drawn through this point, both passing through the tangent line of this conic at this point.

Alternative ways of initiating the system of confocal quadrics. If we take any two quadrics which have a common self-polar tetrad of points, that is, as will be seen, any two quadrics which are not in particular relation, their equations may be supposed to be $X^2+Y^2+Z^2=T^2$ and $A^{-1}X^2+B^{-1}Y^2+C^{-1}Z^2=T^2$. Then, a plane, of equation $lX+mY+nZ=pT$, which touches both these surfaces satisfies the two equations $l^2+m^2+n^2=p^2$, $Al^2+Bm^2+Cn^2=p^2$, and, therefore, satisfies, also, the equation

$$(A+\sigma)\,l^2+(B+\sigma)\,m^2+(C+\sigma)\,n^2=(1+\sigma)p^2,$$

whatever σ may be. This plane thus touches the surface

$$P^{-1}X^2+Q^{-1}Y^2+R^{-1}Z^2=T^2, \text{ where } P=(A+\sigma)/(1+\sigma).$$

If we put $x=(A-1)^{-\frac{1}{2}}X$, etc., $t=T$, with $a=(A-1)^{-1}$, etc., and $\lambda=(1+\sigma)^{-1}$, this last equation becomes

$$(a+\lambda)^{-1}x^2+(b+\lambda)^{-1}y^2+(c+\lambda)^{-1}z^2=t^2,$$

which is of the form we have taken to define the system of confocal quadrics.

Or again, suppose we take, in different planes, any two conics, which have no common point; on the line of intersection of the planes of the conics, let A, B be the points which are conjugate to one another in regard to both the conics; let C and D be the poles of this line in regard to the two conics, respectively. Then, referred to A, B, C, D, the equations of the two conics may be supposed to be, respectively,

$$x^2+y^2+z^2=0,\ t=0, \quad \text{and} \quad Ax^2+By^2=t^2,\ z=0;$$

taking c arbitrary we can then take a and b so that $A=(a-c)^{-1}$, $B=(b-c)^{-1}$. Now consider a plane, $lx+my+nz=pt$, which touches both these conics. We then have

$$l^2+m^2+n^2=0, \quad \text{and} \quad (a-c)\,l^2+(b-c)\,m^2=p^2.$$

From these, whatever λ may be, there follows

$$(a+\lambda)\,l^2+(b+\lambda)\,m^2+(c+\lambda)\,n^2=p^2.$$

The plane thus touches any surface whose equation is of the form $(a+\lambda)^{-1}x^2+\text{etc.}=t^2$. Equally, it touches a definite conic in the plane $x=0$, and a definite conic in the plane $y=0$.

Ex. Our original definition of confocal surfaces was for surfaces not touching the absolute plane. If however, as here, we regard as confocal to a given quadric any quadric touching all the tangent planes of this which also touch the absolute conic, we may define quadrics confocal with the surface of equation $a^{-1}x^2 + b^{-1}y^2 = 2zt$, which touches the absolute plane. For the condition that the plane $lx + my + nz = p$ should touch this is $al^2 + bm^2 + 2pn = 0$. The general confocal is then that given tangentially by

$$(a + \kappa)\, l^2 + (b + \kappa)\, m^2 + \kappa n^2 + 2pn = 0\,;$$

it is easily seen that the point equation of this is

$$(a + \kappa)^{-1}x^2 + (b + \kappa)^{-1}y^2 = 2zt + \kappa t^2.$$

The relations of the four focal conics. Begin, as just explained, with two arbitrary conics, having no point in common, lying in different planes; define thereby two other planes, and in each of these a further conic, touched by the common tangent planes of the two given conics; take the four planes as $t = 0, z = 0, x = 0, y = 0$, and denote the conics lying therein by δ, γ, α, β, respectively. It appears then, from what has been said, and is immediately verifiable, that the poles of an arbitrary plane in regard to these conics, that is, the poles, in regard to these conics, of the lines in which the plane intersects the planes of the four conics, respectively, lie in line. Now take the tangent line, say p, at any point, P, of one of the conics α, β, γ, say β; let this line meet the plane of the conic δ in the point T; from T let the tangent lines, TH, TK, be drawn to the conic δ, touching this in H and K. The points P and H are the poles of the plane PTH, respectively, in regard to β and δ; this plane, therefore, touches α and γ at points lying on the line PH. Consider, now, the conics, α', γ', in the plane of the conic δ, which are obtained by projecting the conics α, γ from the point P. Since the plane PHT touches α on PH, the conic α' touches δ at H, as does the conic γ', for the same reason. Similarly, α' and γ' touch δ at K. If we regard δ as the absolute conic, the plane PHK is at right angles to the line PT, that is, to the tangent of the conic β at the point P. The cones joining P to the conics α, γ have thus, both, contact along two generators with the cone joining P to the absolute conic, δ. They are, therefore, what we have above described as right circular cones, or cones of revolution. But, further, as the plane PHT touches all the confocal surfaces derivable from the focal conics, at points lying on the line PH, it similarly follows that the enveloping cone drawn from P to any one of these surfaces is a right circular cone, likewise touching the cone $P\delta$ along the generators PH and PK. Therefore, if we consider the conic in which the plane PHK cuts one of these confocal surfaces, this is touched by the lines PH, PK. If, then, we take, as the two absolute points of any plane, the points in which this plane meets the absolute conic, we have the result that a plane drawn through a point P of one of the focal conics α, β, γ, at right angles to the tangent line of this conic at this point, meets any of the confocal surfaces in a conic of which this point is one focus. When P is at one of the points where the conic, say β, meets the plane of α, (or of γ), the plane PHK, at right angles to the tangent line p, is the plane of this new conic, α. We thus infer that the four points where the plane of one conic, α, of the three α, β, γ, is met by the other two conics, β and γ, are the foci of this conic α.

Ex. 1. Prove that the equation of the enveloping cone drawn from the point, $(\xi, 0, \zeta, 1)$, of the conic β, whose equations are $y = 0$, $(a-b)^{-1}x^2 + (c-b)^{-1}z^2 = t^2$, to the confocal surface of equation $(a+\lambda)^{-1}x^2 + \text{etc.} = t^2$, may be put in the form

$$H\,[(x-t\xi)^2+y^2+(z-t\zeta)^2] - [(a-b)\,x\xi^{-1} + (b-c)\,z\zeta^{-1} - (a-c)\,t]^2 = 0,$$

where $$H = (a+\lambda)(a-b)\,\xi^{-2} - (c+\lambda)(b-c)\,\zeta^{-2}.$$

Ex. 2. Let the line joining the point $(\xi, 0, \zeta, 1)$, or P, of the conic β, to the point $(x, y, 0, 1)$, or Q, of the conic γ, meet the surface $a^{-1}x^2 + b^{-1}y^2 + c^{-1}z^2 = t^2$ in the points L, M. We consider the symbol $(P, Q; L, M)$, explained Vol. II, p. 166. This is the value of λ_1/λ_2, where λ_1, λ_2 are the roots of the quadratic equation obtained by substituting $(x+\lambda\xi, y, \lambda\zeta, 1+\lambda)$ for the coordinates in the equation of the quadric. It is found that this symbol has a value $F(P)/\Phi(Q)$, where $F(P)$ depends only on P, and $\Phi(Q)$ depends only on Q. In fact, with $m^2 = (a-c)(a-b)^{-1}$,

$$F(P) = (a^{-\frac{1}{2}}\xi + m^{-1})/(a^{-\frac{1}{2}}\xi - m^{-1}), \quad \Phi(Q) = (a^{-\frac{1}{2}}x + m)/(a^{-\frac{1}{2}}x - m).$$

If, then, we take two points Q, say Q_1, Q_2, on the conic γ, the ratio of $(P, Q_1; L_1, M_1)$ to $(P, Q_2; L_2, M_2)$ does not vary with the position of P upon the conic β. This result includes that given in Ex. 4, p. 209, of Vol. II.

Verify that if P_1, P_2 be two points of the conic β, and Q_1, Q_2 two points of the conic γ, there are two enveloping cones, of any surface of the confocal system associated with the conics, which touch the four lines P_1Q_1, Q_1P_2, P_2Q_2, Q_2P_1.

Ex. 3. If the absolute points of any plane of space be the intersections of the plane with a single conic, taken as Absolute, prove that through any point there can be drawn six planes whose sections with a given quadric shall have that point as a focus.

If two quadrics touch one another at all the points of a plane section, prove that the tangent plane at an umbilicus of one of these meets the other in a conic of which the umbilicus is one focus.

Ex. 4. The plane at right angles to a focal conic at a point P meets the polar plane of P, in regard to any chosen surface of the confocal system, in a line l. Prove that if any plane through l meet this surface in the conic ζ, the cone joining P to the points of ζ is a right circular cone.

The axes of a confocal system of quadrics. We have seen that the poles of a plane in regard to all the confocal surfaces lie on a line. The lines so determined are of great importance; the necessity, for dynamical purposes, of considering the properties of these lines, is in fact responsible for much of the theory of confocal quadrics. The fundamental property, just stated, depends on the circumstance that the tangential equation of the general confocal surface is of the form $U+\lambda V=0$, where λ is variable; the dual theorem, that the polar planes of a point, in regard to all quadrics whose point equation is of the form $S+\lambda T=0$, pass through a line, will arise below.

By the pole of a plane in regard to one of the focal conics is meant the pole, in regard to this conic, of the line in which the plane meets the plane of the conic. Thus, by what we have seen, the poles of a plane in regard to the surfaces of the confocal system lie on the line joining the poles of this plane in regard to two of the focal conics. This line is then such as to meet the planes of these conics in points, say H and Q, whose polar lines in regard to these conics are two lines which intersect one another (on the line of intersection of the planes of the conics), say in T; and this is a sufficient condition for such a line. The polar lines of T in regard to the conics contain then, respectively, the points H and Q; but, as T is on the line of intersection of the planes of the conics, these polar lines also contain, respectively, the poles, in regard to the conics, of the line of intersection of their planes; let these two poles, which are fixed points, be called B and D. The general construction for a line which is the locus of the poles of a plane in regard to the confocal surfaces is then as follows: Take the pencil of lines through B, in the plane of one of the conics, obtained as the polars, in regard to this conic, of the points, T, of the line of intersection of the planes of the conics; take the pencil of lines through D similarly obtained with the other conic; to any line of the former pencil corresponds a line of the latter, both having T for pole; take any point H of the former line and any point Q of the latter line. The line HQ is such a line as is desired. Such a line depends then on three parameters, one determining the position of T, two others determining the positions of H and Q on definite lines; we say then that there are ∞^3 such lines, the totality of all possible lines being ∞^4, as we have seen in Chap. I. There is in fact one such line arising from any plane.

Ex. A line being given, as in Chap. I, by the equations

$$l'x+m'y+n'z=0,\quad l't+mz-ny=0,$$

etc., the polar lines of the points, $(l, m, n, 0)$, $(0, -n', m', l)$, where the line meets the planes $t=0$, $x=0$, respectively, in regard to the conics $t=0$, $x^2+y^2+z^2=0$ and $x=0$, $(b-a)^{-1}y^2+(c-a)^{-1}z^2=t^2$, intersect on the line $t=0$, $x=0$, provided $all'+bmm'+cnn'=0$. This is then the condition for such lines.

Let such a line be called an *axis of the confocal system*; the plane, of which the line is the locus of poles for the surfaces of the confocal system, if it is not one of the planes touching all the surfaces of the confocal system, touches one of the confocals, and the line passes through the point of contact, and is at right angles to the plane, with respect to any one of the focal conics regarded as absolute conic. The point of contact may be called the *focus* of the plane. If the plane is tangent to all the quadrics of the confocal system, the axis contains all the points of contact, and, in particular, meets each of the focal conics, being a generator of the surface of the confocal system which passes through the point of meeting, as we have seen above. Thus, eight of these axes lie on any quadric of the system, and there are ∞^1 such lines.

The axes of the confocal system which lie in any general plane, ϖ, touch a conic, which touches each of the principal planes $x=0$, $y=0$, $z=0$, $t=0$. This is clear from the construction for such an axis given above. For, let the lines in which the plane ϖ meets the two principal planes there considered, respectively, be the lines m and n; to any point, U, of m there corresponds a line joining it to the point B of the first plane; to this there corresponds a line through D of the related pencil in the second plane, and this meets the line n in a point, V. The ranges (U), (V), respectively on the intersecting lines m and n, being thus related, the line UV, which is one of the axes of the plane ϖ, envelopes a conic touching the lines m and n. On the line of intersection of the two principal planes considered, there are two points, say A and C, such that BA and DA are the polars of C in regard to the conics, respectively, and BAD is a principal plane. If the plane ϖ meet BA and DA respectively in H and Q, the line HQ is tangent to the conic. Similarly the conic touches the principal plane BCD. In fact any line in one of the four principal planes, or through one of the four principal points, is an axis of the confocal system.

The range of four points, in which an axis of the confocal system, lying in the plane ϖ, meets the four principal planes, is thus related to the range in which any other axis in this plane meets these four planes. This range is, however, related to that in which an axis lying in another plane, ϖ', meets the principal planes. For, to any tangent line, t, of the conic in the plane ϖ can be found two tangents of the conic in the plane ϖ' which intersect the former, say t_1' and t_2'; then the lines t and t_1', being axes of the confocal system in the plane (t, t_1'), meet the four principal planes in related ranges. Thus we reach the conclusion that the axes of the confocal system are the lines upon which the intersections with the principal planes are all related ranges, each of four points. The planes joining an axis to the four principal points, A, B, C, D, are then, also, all related axial pencils, of four planes (Vol. I, p. 30); from this it follows that the axes of the confocal system which pass through an arbitrary point lie on a quadric cone containing the points A, B, C, D.

Ex. If the points $(0, -n', m', l)$, $(n', 0, -l', m)$, $(-m', l', 0, n)$, $(l, m, n, 0)$, in which a line whose coordinates are (l, m, n, l', m', n') meets the principal planes, be denoted, respectively, by the symbols P, Q, R, S, we have $lQ = n'S + mP$, $lR = -m'S + nP$. Two such lines are therefore met by the principal planes in related ranges if mm'/nn' be the same for both (Vol. I, p. 154, Vol. II, p. 166). We saw above that the condition for an axis is $all' + bmm' + cnn' = 0$; this, however, in virtue of $ll' + mm' + nn' = 0$, gives $mm'/nn' = (c-a)/(a-b)$.

The lines in space of which the coordinates satisfy a single relation, as here, are said to form a *complex*. We have already briefly considered the linear complex (above, Chap. I). The particular quadratic complex here arising is called the *tetrahedral* complex. It is a general property of quadratic complexes, that the lines of the complex lying in an arbitrary general plane touch a conic, and the lines of the complex passing through an arbitrary general point form a quadric cone. The latter statement appears, if the point be (x_0, y_0, z_0, t_0), by substituting in the quadratic relation connecting l, m, n, l', m', n' which defines the complex, for l, l', etc., respectively, $tx_0 - t_0x$, $yz_0 - y_0z$, etc.; the result, in virtue of $l't_0 = -mz_0 + ny_0$, $m't_0 = -nx_0 + lz_0$, $n't_0 = -ly_0 + mx_0$, is a quadratic relation connecting $tx_0 - t_0x$, $ty_0 - t_0y$, $tz_0 - t_0z$, which is the equation of the cone. The former statement follows in the same way if the line coordinates be defined by the coordinates of two planes, of which, in the proposition considered, the given plane may be taken as one.

For the tetrahedral complex, the cone is given by

$$(b-c)\,x_0l^{-1} + (c-a)\,y_0m^{-1} + (a-b)\,z_0n^{-1} = 0,$$

where $l = tx_0 - t_0x$, etc. The conic, touched by the lines of the complex which lie in the plane $Ax + By + Cz + Dt = 0$, lies on the cone whose equation is

$$[A\,(b-c)\,x]^{\frac{1}{2}} + [B\,(c-a)\,y]^{\frac{1}{2}} + [C\,(a-b)\,z]^{\frac{1}{2}} = 0.$$

It lies also on the cone

$$[(b-c)\,Dt]^{\frac{1}{2}} + [C\,(c-a)\,z]^{\frac{1}{2}} + [B\,(a-b)\,y]^{\frac{1}{2}} = 0.$$

A line is an axis of the system of confocals only if it contains the poles of some plane, taken in regard to two of the surfaces; in this case it contains the poles of this plane in regard to all the confocals. But, if the pole of a plane, in regard to a particular quadric, lie on a line, the polar line of this line, in regard to this quadric, lies in the plane. Thus a line is an axis of the confocals if its polar lines in regard to two of the confocals lie in one plane, in which case its polar lines in regard to all the confocals lie in this plane. This is the same as saying that a line which is an axis of the confocal system is the intersection of the polar planes, in regard to any two of the confocals, of a suitably chosen point. By taking the particular case when one of the two selected confocals is replaced by a focal conic, we reach the conclusion that a line is an axis of the system of confocals if it is at right angles, in regard to one of the focal conics, taken as absolute conic, to its polar line in regard to one of the confocals.

Ex. 1. The polar line of (l, m, n, l', m', n') in regard to the surface $a^{-1}x^2 + \text{etc.} = t^2$ is the line whose coordinates are

$$(al', \ldots, -bcl, \ldots).$$

The condition that these should be at right angles in regard to the absolute conic $t = 0$, $x^2 + y^2 + z^2 = 0$, is $all' + bmm' + cnn' = 0$; and this is also the condition that they should be at right angles in regard to $x = 0$, $(b-a)^{-1}y^2 + (c-a)^{-1}z^2 = t^2$. The condition that the second line should intersect the line

$$[(a+\theta)\,l', \ldots, -(b+\theta)(c+\theta)\,l, \ldots]$$

is also the same.

Ex. 2. If p be the line containing the poles of a plane, ϖ, in regard to the confocals, say the axis of ϖ, meeting ϖ in P, prove that the axes of planes ϵ, drawn through p, lie in the plane ϖ, and meet any two of the principal planes in related ranges, so that they touch a conic touching these planes; further that two of these axes meet in P, and are at right angles to one another in regard to any one of the focal conics, taken as absolute conic; also that any one of these axes is the polar line of p in regard to a properly chosen one of the confocals.

We may consider the locus of the point, in the plane ϖ, which is the intersection of any plane ϵ, drawn through p, with the axis of this plane. If we speak of the conic, in the plane ϖ, which is the envelope of the axes of the confocals lying in this plane, as a parabola, the absolute points of this plane being the intersections of this plane with the focal conic $t = 0$, $x^2 + y^2 + z^2 = 0$, then the point, P, being the intersection of two tangents of the parabola which are at right angles in regard to these absolute points, is on the directrix; and the locus is that of the intersection of a tangent of the parabola with the line drawn at right angles to this tangent from a particular point, P, of the directrix. It may be shewn that this is a curve meeting an arbitrary line of the plane in three points, which passes twice through P.

Ex. 3. If four planes meet in threes in four points, A, B, C, D, which form a self-polar tetrad in regard to a quadric, the lines in which a plane, ϖ, meets these planes intersect in six points, lying on the joins of A, B, C, D, and these six points, it is easily seen, consist of three pairs of points conjugate to one another in regard to the conic section of the quadric by the plane ϖ. This conic is therefore outpolar to any conic in the plane ϖ which touches the four lines spoken of (Vol. II, p. 33).

Thus, in particular, the conic in the plane ϖ, touched by the axes of the confocal quadrics which lie in this plane, is inpolar to the section of any one of the confocals by this plane. Dually, the quadric cone of axes of the confocals which pass through an arbitrary point is outpolar to the enveloping cone drawn from this point to any one of the confocals.

Ex. 4. Shew that if two points, P, Q, of one of the confocals, be such that the lines through these points at right angles respectively to the tangent planes of the quadric at these points, with respect to any one of the focal conics, (called the *normals* of the quadric at these points), meet one another, then PQ is an axis of the confocal system, and conversely.

Ex. 5. For a conic in space, the centre is the pole, in regard to the conic, of the line in which the plane of the conic meets the absolute plane; and the axes of the conic are the lines through its centre at right angles to one another in regard to the absolute conic and also conjugate to one another in regard to the conic itself. Consider now a conic which is the section of one of the confocals by a plane; take, for instance, the principal plane $t=0$ for absolute plane, and the focal conic of this plane for absolute conic; let D be the centre of the quadric, so determined, O the centre of the conic, and OU, OV its axes, the points U, V being on the line, l, in which the plane meets $t=0$. The line DO is then the polar line of l, in regard to the quadric. We desire to see that the axis OU is at right angles to its polar line in regard to the quadric, and, in fact, that the polar line of OU passes through V. For this, as the polar plane of O contains the line UV, or l, it is only necessary to see that the polar plane of U contains V; this is clear because U and V are conjugate in regard to the quadric. Thus a line, which is an axis of the conic section of a quadric of the confocal system by some plane through the line, is an axis of the confocal system. This condition is necessary that a plane may be possible through the line giving a conic section of which the line is an axis.

If we draw through l one of the tangent planes of the quadric, touching it in P, on the line DO, then the polar line of PU is the line PV. These lines are the normals at P of the two confocals, to the given quadric, which pass through P; and are parallel to the axes of any conic section of the given quadric by a plane parallel to the tangent plane at P (that is, intersecting this tangent plane on the absolute plane).

Ex. 6. Taking one of the confocals, an arbitrary plane, and the axis of this plane, the polar line of this axis, in regard to this confocal, lies in the plane, and meets the section of the surface by the plane in two points. Prove that the tangent planes of the surface at these points are at right angles to the plane, and pass through its axis.

Ex. 7. If (l, m, n, l', m', n') satisfy the equation

$$all' + bmm' + cnn' = 0,$$

it is the axis, in regard to the confocal system, of the plane

$$lx + my + nz = pt,$$

where p has the value $mn(b-c)/l'$, or the equal values, $nl(c-a)/m'$, $lm(a-b)/n'$. The normals of the surface $a^{-1}x^2 + \text{etc.} = t^2$, at the points, (x_1), (x_2), where the line meets it, intersect in $(\xi, \eta, \zeta, 1)$, where $a\xi l = px_1x_2$, etc. The plane through the line whose conic section with this surface has the line for an axis has the equation

$$al'(l't + mz - ny) + bm'(m't + nx - lz) + cn'(n't + ly - mx) = 0.$$

Find the equation of the locus of the centres of the conic sections of all the confocals by an arbitrary plane.

Ex. 8. If the normal of a surface, S, of the confocal system, at P, meet the surface S again in P', and meet another confocal, Σ, of the system, in Q and Q', prove that the normals of Σ at Q and Q' intersect in a point lying on the tangent plane of S at P'. Further, that, if Σ vary, the locus of the point of intersection is a conic, in the tangent plane at P'.

Ex. 9. We have seen that the axes of the confocals which lie in a plane touch a conic, and those which pass through a point are generators of a cone. Prove that the points of the conics lying in planes passing through a line (l, m, n, l', m', n') lie on a surface, which is touched by the tangent planes of the cones whose vertices are on this line. Shew that the points of this surface are expressible by two parameters, θ, ϕ, in the forms

$$\beta\gamma x/t = (\theta + a)^2 (l'\phi - p)^{-1}, \quad \gamma\alpha y/t = (\theta + b)^2 (m'\phi - q)^{-1}, \text{ etc.},$$

where $\alpha = b - c$, $\beta = c - a$, etc., and $p = (mn' - m'n)(l'^2 + m'^2 + n'^2)^{-1}$, etc. See Plücker's *Neue Geometrie des Raumes*, zw. Abth.; Leipzig, 1868, pp. 193 ff.

The normals of a quadric, and of confocal quadrics, which pass through a point. In the case of confocal conics, we considered, starting from an arbitrary point, the aggregate of lines formed by the polars of this point in regard to all the confocals. The lines were tangents of a parabola, touching the two axes of the confocals (Vol. II, p. 120). For the system of confocal surfaces we may similarly consider the aggregate of the polar planes of an arbitrarily taken fixed point, (x_0, y_0, z_0, t_0), in regard to all the surfaces of the system. The equation of the general plane of this aggregate is $(a+\lambda)^{-1}xx_0+(b+\lambda)^{-1}yy_0+(c+\lambda)^{-1}zz_0=tt_0$; particular planes of the aggregate are the principal planes $x=0$, $y=0$, $z=0$, $t=0$, arising respectively for $\lambda=-a$, $\lambda=-b$, $\lambda=-c$, $\lambda=\infty$. Through an arbitrary point there pass three of these planes, which, when the point is (x_0, y_0, z_0, t_0), are mutually conjugate in regard to all the focal conics. Such an aggregate of planes, each determined by a chosen value of a parameter, λ, is called a developable; and, in this case, as three planes of the aggregate pass through an arbitrary point, it is called a cubic developable. If we take a particular quadric of the confocal system, say $a^{-1}x^2+\text{etc.}=t^2$, and then consider the poles, in regard to this confocal, of all the planes of the developable, the points obtained lie upon a curve, of which three points lie in an arbitrary plane, so that the curve is said to be of the third order. It may properly be regarded as the polar reciprocal of the developable in regard to the quadric chosen. The coordinates of the points of this curve are given by

$$[ax_0(a+\lambda)^{-1},\ by_0(b+\lambda)^{-1},\ cz_0(c+\lambda)^{-1},\ t_0],$$

for varying values of λ; it contains the principal points forming the common self-polar tetrad for the confocal surfaces (respectively for $\lambda=-a, -b, -c, \infty$), and also the point (x_0, y_0, z_0, t_0), for $\lambda=0$. The theory of cubic curves in space will be considered below; such a curve can, in an infinite number of ways, be regarded as consisting of all the points common to two quadric surfaces which have also a generator in common, other than the points of this generator, of which only two lie on the curve. The line which joins two points of the curve being called a chord of the curve, the chords which pass through an arbitrary point of the cubic curve in space are the generators of a quadric cone, and the curve may be defined as consisting of the intersection of two of these cones, other than the generator joining their vertices, which is common to both. For the particular cubic curve now under consideration, every chord, being the polar line, in regard to the surface $a^{-1}x^2+\text{etc.}=t^2$, of the intersection of the polar planes of (x_0, y_0, z_0, t_0) in regard to two confocals of the system, is, like this line, an axis of the confocal system. The chords of the curve passing through an arbitrary point of the curve, (x_1, y_1, z_1, t_1), are then the axes of the confocal system through this point, lying on the cone whose equation is

$$(b-c)\,x_1(xt_1-x_1t)^{-1}+(c-a)\,y_1(yt_1-y_1t)^{-1}+\text{etc.}=0.$$

Consider now a point common to the surface, $a^{-1}x^2 + \text{etc.} = t^2$, and the cubic curve. The tangent plane of the surface at this point will be the polar plane of (x_0, y_0, z_0, t_0) in regard to one of the confocals; thus (x_0, y_0, z_0, t_0) will lie on the axis of this plane. This axis is at right angles to the plane, with respect to every one of the focal conics taken as absolute conic, and is the normal of the surface $a^{-1}x^2 + \text{etc.} = t^2$ at the point of contact of the plane. The normals of this surface which can be drawn through the point (x_0, y_0, z_0, t_0) are then the lines joining this point to the intersections of this surface with the cubic curve. The number of such intersections, of a cubic curve with a quadric surface, is in fact six. In the present case they may be determined from the roots of the sextic equation

$$\frac{ax_0^2}{(a+\lambda)^2} + \frac{by_0^2}{(b+\lambda)^2} + \frac{cz_0^2}{(c+\lambda)^2} = t_0^2.$$

Ex. 1. If a line be drawn from the point (x_0, y_0, z_0, t_0), at right angles, in regard to the focal conic $t = 0$, $x^2 + y^2 + z^2 = 0$, to any plane, ϖ, drawn through the centre of the surface $a^{-1}x^2 + \text{etc.} = t^2$, such that this line meets the diameter of this plane (namely the polar line of the line in which the plane ϖ meets the plane $t = 0$), prove that the locus of the point of meeting is the cubic curve just described.

Ex. 2. Shew that the two lines of Ex. 1, that through (x_0, y_0, z_0, t_0), and the diameter, are such as to meet any plane in two related plane systems (in the sense of Vol. I, p. 148). In general, if two corresponding points, P_1 and P_2, of two related plane systems, which may be in different planes, be joined, respectively, to two fixed points O_1, O_2, of arbitrary position, shew that, for positions of P_1 for which O_1P_1 and O_2P_2 meet, the locus of the point of meeting is a cubic curve.

Ex. 3. Shew that the plane containing the three points (λ_1), (λ_2), (λ_3), of the cubic curve just described, has the equation

$$\frac{x}{ax_0}\frac{(a+\lambda_1)(a+\lambda_2)(a+\lambda_3)}{(a-b)(a-c)} + \frac{y}{by_0}\frac{(b+\lambda_1)(b+\lambda_2)(b+\lambda_3)}{(b-c)(b-a)} + \frac{z}{cz_0}\frac{(c+\lambda_1)(c+\lambda_2)(c+\lambda_3)}{(c-a)(c-b)} = \frac{t}{t_0}.$$

Ex. 4. Shew that the six roots of the sextic equation which gives the six points of the quadric $a^{-1}x^2 + \text{etc.} = t^2$ at which the normals pass through (x_0, y_0, z_0, t_0), are such that

$$\prod_{r=1}^{6} (a + \lambda_r) = -a(a-b)^2(a-c)^2 x_0^2 t_0^{-2},$$

with similar values for the products of the quantities $b + \lambda_r$, and of the quantities $c + \lambda_r$; hence, denoting these six points by

$N_1, N_2, \ldots, N_6$, prove that, if the equation of the plane $N_1N_2N_3$ be written in the form $a^{-\frac{1}{2}}lx + \text{etc.} = t$, the equation of the plane $N_4N_5N_6$ will be of the form $a^{-\frac{1}{2}}l^{-1}x + \text{etc.} = -t$.

Ex. 5. Through every point of the cubic curve there is a line, called the tangent of the curve, such that any plane through this line meets the curve in two points coincident at this point, and in only one other point. Shew that the tangent at the point (x_0, y_0, z_0, t_0) is the line drawn through this point at right angles to the polar plane of this point in regard to the surface $a^{-1}x^2 + \text{etc.} = t^2$. In general only one cubic curve can be drawn to contain six given points. The present cubic curve is thus determined by the facts that it passes through the principal points, the common self-polar tetrad for the confocals, passes through (x_0, y_0, z_0, t_0), and has the line described, as the tangent line at (x_0, y_0, z_0, t_0).

Ex. 6. The chords $N_1N_2, N_1N_3, \ldots, N_1N_6$ of the cubic curve, being axes of the confocal system, lie upon the quadric cone, of vertex N_1, containing the axes of the confocals which pass through N_1. This cone is independent of the point, O, of the normal at N_1, from which the other normals ON_2, etc., are drawn. Thus, as O varies on the normal at N_1, the points N_2, etc., vary on the curve of intersection of the surface $a^{-1}x^2 + \text{etc.} = t^2$ with the cone in question.

Ex. 7. Taking an arbitrary plane section of the surface

$$a^{-1}x^2 + \text{etc.} = t^2,$$

and a fixed point N_1 of this section, there are two other points of this section which are such that the normals of the surface at these points meet the normal of the surface at N_1. For, if the normal at N_2 meet the normal at N_1, the line N_1N_2 is an axis of the confocals; and the axes which lie in this plane touch a conic lying in this plane; two of them, therefore, pass through N_1, say N_1N_2 and N_1N_3; the normals of the surface at the points N_2 and N_3 of the section intersect the normal at N_1, generally in points which do not coincide. If, however, these points coincide, the normals at N_2N_3 intersect one another, and the line N_2N_3 is an axis of the confocals. When this is so, the conic, Σ, of the plane, enveloped by all the axes of the confocals which lie in this plane, is triangularly inscribed in the conic section of the quadric by the plane. This conic, Σ, we have seen, is always inpolar to the other. When both facts are true, the two conics are in the particular relation discussed in Vol. II, p. 149, each being both inpolar and outpolar to the other. It may be proved that, if the equation of the plane be $Ax + By + Cz = Dt$, the condition for this particular relation is

$$\Sigma\,(b-c)^2\,(bcB^2C^2 - aA^2D^2) = 0\,;$$

and that, then, the locus of the intersection of the existing triads of concurrent normals is a line.

The normals of the confocals which are at right angles to a given line, and the polars of this line in regard to the confocals. Consider a line l, which we suppose not to be an axis of the confocal system; in particular, it does not lie in one of the four principal planes nor pass through one of the four principal points. These possibilities are considered below. Every plane, ϖ, drawn through l determines a further line, λ, the axis of the plane ϖ; every confocal, S', also determines a further line, l', the polar line of l in regard to S'. The pole, in regard to S', of any plane through l, in particular of the plane ϖ, lies on l'; the poles of the plane ϖ, in regard to all the surfaces of the confocal system, in particular in regard to the surface S', lie on the axis λ. Thus the lines l' and λ have a point in common. If we take different surfaces S', the corresponding lines l' do not intersect, or l would be one of the axes of the confocals. By considering in the first instance three surfaces S', and the corresponding lines l', we see that the axes, λ, of all the planes, ϖ, drawn through l, are the generators, of one system, of a quadric surface; and, then, that the polar lines l', for all the confocal surfaces, are the generators of the other system of this surface. The system of polar lines l' will have a line in each of the principal planes, the polars, namely, in regard to the focal conics, respectively, of the point in which the line l meets these planes. The quadric surface in question thus touches each of the principal planes.

Considering any particular two of the polar lines l', the ranges in which these are met by all the lines λ will be related to one another, and these both related to the axial pencil of planes ϖ from which the lines λ are determined. For, let X, T be the intersections of the line l with two of the principal planes, respectively; and x, t the polar lines of these points, respectively, with regard to the focal conics in these planes. Any plane, ϖ, through l, will meet these planes, respectively, in two lines, say p and s, passing through X and T, and the poles, say P and S, of these lines, in regard to the appropriate conics, will be points of the lines x and t, respectively. As ϖ varies, the lines p, s will describe related pencils in their respective planes, and the points P, S will, therefore, describe related ranges. The line λ, corresponding to a plane ϖ, is the join PS; this line, therefore, meets x and t in ranges related to the axial pencil of planes ϖ; and it is a general property of quadric surfaces that the line λ meets all the generators l', of which x and t are two particular ones, in related ranges. The line λ, or PS, may evidently be regarded as the intersection of corresponding planes of two related axial pencils of planes, one having x, the other having t, for axis. The point where the line λ meets ϖ, which is the point of contact with one surface of the confocal system of a tangent plane drawn thereto from the line l, may, therefore, be regarded as the intersection of corresponding planes from three related axial pencils of planes, having, respectively, the lines x, t and l for axes. The line of intersection of corresponding planes of two of these axial pencils, as follows from what was said in Chapter I, describes a quadric surface of which both the axes are generators. We thus have, here, three quadric surfaces, say (x, t), (x, l), (t, l), of which any two have a generator in common. It follows that the point where the plane ϖ, through l, meets its corresponding axis, λ, describes a curve which is that common to two quadric surfaces having a common generator. Such a curve evidently meets an arbitrary plane in three points; it is in fact identical with such a cubic curve as that considered above. The theory shews that the curve has two points on each of the lines l, x, t; by similar reasoning it has two points on every polar line, l', of the line l, in regard to the confocal surfaces. And, by definition, it has a simple point on every axis, λ, of a plane ϖ passing through l.

Ex. 1. Putting $b-c=\alpha$, $c-a=\beta$, $a-b=\gamma$, prove that the polar lines of the line whose coordinates are $(l, m, n, \alpha u, \beta v, \gamma w)$, in regard to surfaces confocal with $a^{-1}x^2+\text{etc.}=t^2$, lie on the quadric surface whose equation is

$$uvw\,(u^{-1}x+v^{-1}y+w^{-1}z)\,(lx+my+nz)-plxt-qmyt-rnzt+lmnt^2=0,$$

where $$p=mv+nw, \quad q=nw+lu, \quad r=lu+mv.$$

Ex. 2. The cubic curve which is the locus of points of contact of tangent planes from this line to the confocals has, for the coordinates of any point,

$$L\,(M^2\gamma-N^2\beta+1), \qquad M\,(N^2\alpha-L^2\gamma+1),$$
$$N(L^2\beta-M^2\alpha+1), \qquad L^2+M^2+N^2,$$

where L, M, N are linear functions of a variable parameter, θ, of which L is given by

$$L=\alpha u\theta+(\gamma mw-\beta nv)\,(\alpha^2u^2+\beta^2v^2+\gamma^2w^2)^{-1},$$

and M, N have similar forms.

When the line l is one of the axes of the confocal system the preceding argument fails. We have already (above, Ex. 2, p. 100) considered the case when the line is an axis in general position. The polars of the line then lie in a plane, and the points of contact of tangent planes to the confocals, drawn through the line, lie on a plane curve having the property of meeting any line of its plane in three points.

When the line l lies in one of the principal planes, its polar lines also lie in a plane, through the corresponding principal point; and the points of contact of the tangent planes, through the line l, lie on a conic in this plane, which meets the principal plane considered in two points conjugate to one another in regard to the focal conic of this plane, the tangents of the locus at these two points meeting in the corresponding principal point. In this case the polar lines of l, in regard to the confocals, all pass through a principal point, that corresponding to the plane in which l lies; by an argument already given, they all meet the axis, λ, in regard to the confocals, of any particular plane, ϖ, drawn through l. Thus these polar lines lie in a plane, σ. The line in which this plane σ meets the principal plane considered is, in fact, the locus of the poles of l in regard to the sections of the confocals by this principal plane. If the plane σ meet l in Q, and O be the pole of l in regard to the focal conic of the principal plane, and P the point of contact of a tangent plane from l to one of the confocals, it is at once seen that the pencils $Q\,(P)$ and $O\,(P)$ are related. This proves the statement made.

Lastly, when the line l passes through one of the principal points, the polar lines of l, in regard to the confocals, lie in the corresponding principal plane, as do the axes of the planes drawn through l, all these lines touching a conic, lying in this plane. The circumstances are then sufficiently dealt with by the remarks made above for the case when l is any axis of the confocals.

Ex. When the line l is the line given by $t = 0$, $l'x + m'y + n'z = 0$, the polar lines of this line in regard to the confocals lie in the plane $\alpha x/l' + \beta y/m' + \gamma z/n' = 0$, where $\alpha = b - c$, etc. The points of contact of tangent planes to the confocals drawn from this line lie on the conic expressed by $x = l'(\theta^2 + \gamma m'^2 - \beta n'^2)$, etc., $t = \theta\,(l'^2 + m'^2 + n'^2)$, where θ is a variable parameter.

The enveloping cones drawn from a point to the surfaces of the confocal system, and the tangent planes drawn from a line. We have seen that any plane which touches two surfaces of the confocal system touches every one of these surfaces. Thus, if the two enveloping cones be drawn from an arbitrary point O to two of the surfaces, the four common tangent planes of these two cones, which touch both these surfaces, are equally tangent planes of the cone drawn from O enveloping any other of the surfaces. The enveloping cones from O are thus a system with four common tangent planes. They will meet any one of the principal planes in a system of conics having four common tangent lines, which, in particular, will be tangents of the focal conic of that plane. We may denote the point-pairs in this plane through which these four tangents pass respectively by S_1, H_1; S_2, H_2; S_3, H_3; the three lines S_1H_1, S_2H_2, S_3H_3 will then be a self-conjugate triad in regard to every one of the conics, in particular in regard to the focal conic of the plane. There are thus, through O, three planes forming a self-polar triad for every one of the enveloping cones; and, in regard to any one of the focal conics taken as an absolute conic, these planes are mutually at right angles. The line of intersection of any two of these planes thus contains the pole of the third plane in regard to every one of the focal conics, and, therefore, contains the pole of this plane in regard to all the surfaces of the confocal system. From this it is clear that the three planes are the tangent planes at O of the three confocals of the system which pass through O. Further, a point-pair such as S_1, H_1 is a degenerate form of a conic of the system touching the four lines in the principal plane considered, the tangents of this conic being all lines passing through S_1 or H_1. A degenerate enveloping cone from O consists therefore of all planes passing through one of the lines OS_1, OH_1. Thus these lines are the generating lines at O of one of the confocals which pass through O. The generating lines of the other confocals are, respectively, OS_2, OH_2 and OS_3, OH_3.

The three planes are common *principal* planes of the cones; the six lines OS_1, OH_1, etc., are common *focal* lines of the cones, with reference to the focal conic, taken as absolute conic, in the principal plane considered. As is easy to see, any one of these lines has the property that a plane drawn at right angles to it, in regard to the absolute conic, meets the cone in a conic of which one focus is the intersection of the line with the plane.

Consider now the pairs of tangent planes which can be drawn to the surfaces of the confocal system from an arbitrary line. Taking any point, O, of this line, the pairs of tangent planes from the line to the surfaces are the pairs of tangent planes, from the line, drawn to the enveloping cones of the surfaces which have O for vertex. These cones, however, we have seen, have four common tangent planes; thus, as in the theory of conics in one plane which have four common tangent lines, the pairs of tangent planes to the confocals (two to each surface) are an axial pencil of pairs of planes in involution. There are thus two planes through the line, the double elements of the involution, each of which consists of two coincident tangent planes drawn from the line to one of the surfaces; in other words there are two surfaces of the confocal system which touch the line. And the tangent planes, through the line, of these two confocals, are harmonic conjugates in regard to the pair of tangent planes drawn from the line to any other one of the confocal surfaces. In particular, considering one of the focal conics, and taking it as absolute conic, the tangent planes through the line, of the two confocal surfaces which touch the line, are at right angles to one another in regard to this focal conic. When the line is a generator of one of the confocals, either plane through it touching another confocal, touches all the confocals, and the proof, and theorem, fail.

Ex. 1. Let the equations of the three surfaces of the confocal system, which pass through any point $(x_0, y_0, z_0, 1)$, be

$$(a+\lambda_r)^{-1}x^2 + (b+\lambda_r)^{-1}y^2 + (c+\lambda_r)^{-1}z^2 = t^2,$$

for $r = 1, 2, 3$. Also, denote $a+\lambda_r$, $b+\lambda_r$, $c+\lambda_r$, respectively, by a_r, b_r, c_r, and put $p_1^2 = a_1b_1c_1(a_1-a_2)^{-1}(a_1-a_3)^{-1}$, etc. It may easily be verified that $x_0^2(a-b)(a-c) = a_1a_2a_3$, $y_0^2(b-c)(b-a) = b_1b_2b_3$, $z_0^2(c-a)(c-b) = c_1c_2c_3$, and that $p_1^{-2} = a_1^{-2}x_0^2 + b_1^{-2}y_0^2 + c_1^{-2}z_0^2$, etc. Take for points of reference for coordinates the point $(x_0, y_0, z_0, 1)$, and the points on the plane $t = 0$ which lie on the normals, at $(x_0, y_0, z_0, 1)$, of the three confocals through this point; let such coordinates be denoted by $(\xi, \eta, \zeta, 1)$. Prove, then, that the enveloping cone drawn from $(x_0, y_0, z_0, 1)$ to the confocal surface $(a+\lambda)^{-1}x^2 + \text{etc.} = t^2$ has for equation

$$(\lambda_1-\lambda)^{-1}\xi^2 + (\lambda_2-\lambda)^{-1}\eta^2 + (\lambda_3-\lambda)^{-1}\zeta^2 = 0.$$

Also, that the generators, at $(x_0, y_0, z_0, 1)$, of the three confocals which pass through this point, lie in threes upon four planes, touching all the confocal surfaces, whose equations are

$$(\lambda_2-\lambda_3)^{\frac{1}{2}}\xi \pm (\lambda_3-\lambda_1)^{\frac{1}{2}}\eta \pm (\lambda_1-\lambda_2)^{\frac{1}{2}}\zeta = 0.$$

Also, that the polar plane of $(x_0, y_0, z_0, 1)$ in regard to the surface $(a+\lambda)^{-1}x^2 + \text{etc.} = t^2$ has for equation

$$(\lambda_1-\lambda)^{-1}p_1\xi + (\lambda_2-\lambda)^{-1}p_2\eta + (\lambda_3-\lambda)^{-1}p_3\zeta - 1 = 0.$$

Denoting this by $U = 0$, prove that the equation of the surface $(a+\lambda)^{-1}x^2 + \text{etc.} = t^2$ is

$$(\lambda_1-\lambda)^{-1}\xi^2 + (\lambda_2-\lambda)^{-1}\eta^2 + (\lambda_3-\lambda)^{-1}\zeta^2 - MU^2 = 0,$$

where $M = (\lambda_1-\lambda)(\lambda_2-\lambda)(\lambda_3-\lambda)/(a+\lambda)(b+\lambda)(c+\lambda)$. This fails when λ is one of $\lambda_1, \lambda_2, \lambda_3$; prove that the equation of the surface $(a+\lambda_1)^{-1}x^2 + \text{etc.} = t^2$ is capable of either of the two forms

$$(\lambda_1-\lambda_2)^{-1}(p_1\eta - p_2\xi)^2 + (\lambda_1-\lambda_3)^{-1}(p_1\zeta - p_3\xi)^2 + \xi^2 - 2p_1\xi = 0,$$

$$p_1\left[N_1\xi^2 + (\lambda_1-\lambda_2)^{-1}\eta^2 + (\lambda_1-\lambda_3)^{-1}\zeta^2\right]$$
$$- 2\xi\left[(\lambda_1-\lambda_2)^{-1}\eta p_2 + (\lambda_1-\lambda_3)^{-1}\zeta p_3 + 1\right] = 0,$$

where $N_1 = a_1^{-1} + b_1^{-1} + c_1^{-1} - (a_1-a_2)^{-1} - (a_1-a_3)^{-1}, = p_1^2\Sigma a_1^{-3}x_0^2$.

Ex. 2. If we take for points of reference for coordinates the common centre of the confocals and the three points where the normals of the confocals through $(x_0, y_0, z_0, 1)$ meet the plane $t = 0$, denoting the coordinates by $(X, Y, Z, 1)$, prove that the sections of the three confocals through $(x_0, y_0, z_0, 1)$ by the planes $X = 0$, $Y = 0$, $Z = 0$ (the planes through the centre parallel, in regard to $t=0$, to the tangent planes at $(x_0, y_0, z_0, 1)$), have the respective equations

$$X=0,\quad (a_1-a_2)^{-1}Y^2+(a_1-a_3)^{-1}Z^2=1\,;$$
$$Y=0,\quad (a_2-a_1)^{-1}X^2+(a_2-a_3)^{-1}Z^2=1,\ \text{etc.}$$

These three conics are therefore such that any plane touching two of them touches the third, and touches the focal conic of the confocals which lies in $t=0$.

Shew that three confocal surfaces can be constructed to have their common centre at $(x_0, y_0, z_0, 1)$, their axes being the normals at this point of the original confocals, to pass through the common centre of the original confocals, and have for normals at this point the axes of the original confocals (cf. Chasles, *Aperçu historique*, 1837, Note xxv, p. 359). Prove, also, that if $(x_0, y_0, z_0, 1)$ lie on a plane drawn through the original centre touching all the original confocals, then this plane equally touches all the new confocals.

Ex. 3. Considering four points P, Q, P', Q' of a line, of which the symbols of P', Q' are expressible by those of P, Q by $P'=P+mQ$, $Q'=P+nQ$, we have previously considered the symbol denoted by $(P', Q'\,;\ P, Q)$, which is equal to $m^{-1}n$ (Vol. II, p. 166). We may call this the cross-ratio of P', Q' in regard to P, Q, or of P, Q in regard to P', Q'. Now consider the involution of pairs of points, on the line, of which P, Q are one pair and P', Q' are another pair. Any pair of this involution is given by an equation $\phi+\lambda\psi=0$, where $\phi=0, \psi=0$ are quadratic equations giving two arbitrarily chosen pairs of the involution (Vol. II, p. 111). Any pair of points of the involution is thus given by one parameter, λ. Let λ, λ' be the respective values of this parameter for the two pairs P, Q and P', Q'. Also let w, w' be the respective values of this parameter for the two double pairs of the involution. We may consider the quantity E defined by $E=(\lambda'-w)(\lambda'-w')^{-1}/(\lambda-w)(\lambda-w')^{-1}$, which we may here speak of as the cross-ratio of the parameters λ, λ' in regard to the parameters w, w'. There is a definite relation connecting the cross-ratio $(P', Q'\,;\ P, Q)$ with the cross-ratio E. This may be expressed, putting the former equal to $e^{2i\alpha}$, and the latter equal to $e^{2i\beta}$, by $\sin\alpha\sin\beta=\pm 1$. This result can be immediately proved by interpreting the involution on a conic (cf. Vol. II, p. 210). Similar remarks hold of course for involutions of pairs of lines of a plane pencil of lines, or for involutions of pairs of planes of an axial pencil.

We apply this now to the involution of pairs of tangent planes which can be drawn from a line to the surfaces of a confocal system, remarking that the parameter which determines one of these pairs of the involution may be taken identical with that which determines the particular surface to which the planes are tangent. For the pair of tangent planes, drawn from the line of coordinates (l, m, n, l', m', n') to the surface $(a+\lambda)^{-1}x^2 + \text{etc.} = t^2$, is given by $\phi + \lambda\psi = 0$, where $\phi = a\xi^2 + b\eta^2 + c\zeta^2 - \tau^2$, $\psi = \xi^2 + \eta^2 + \zeta^2$, in which $\xi = l't + mz - ny$, etc., $\tau = -(l'x + m'y + n'z)$.

We thus have the result that if, from a line which touches the two confocals of parameters respectively $\lambda = p$, $\lambda = q$, there be drawn the pair of tangent planes to the surface of parameter μ, and also the pair of tangent planes to the surface of parameter ν, then the cross-ratio of the former pair of tangent planes in regard to the latter pair, say $e^{2i\alpha}$, depends upon the cross-ratio of the parameters μ, ν in regard to the parameters p, q, say $e^{2i\beta}$, these being connected by a relation $\sin\alpha \sin\beta = \pm 1$. The former cross-ratio is thus the same as for any other line also touching the two surfaces p, q, proper regard being paid to the order in which the pair of tangent planes to a confocal are taken.

Through any point of the surface of parameter p there can be drawn two lines, lying in the tangent plane of this surface at this point, which also touch the surface of parameter q, these being generators of the enveloping cone from this point to the surface (q). From what has been shewn above in regard to the enveloping cones drawn to the confocals from any point, it is clear that these two lines are a pair of an involution of lines through the point, in the tangent plane, obtained by varying q, of which the double rays are the normals of this point of the other two confocals which pass through the point. It can be shewn that there exist curves on the surface (p) with the property that, the tangent line of the curve, at any point, is a tangent line also of the surface (q); all these curves, which are called *geodesics*, touch the curve in which the surface (p) is met by the surface (q), any tangent line of this latter curve being a common tangent line of the surfaces (p) and (q).

Ex. 4. The two geodesics which can be drawn, as in Ex. 3, from any point of the confocal (p), to touch the curve of intersection, say (p, q), of the surfaces (p) and (q), may suggest the two tangent lines which can be drawn in a plane, to a conic, from an arbitrary point. It can in fact be shewn that, if the various curves, (p, q), of the surface (p), obtained by its intersection with various confocal surfaces (q), be projected from one of the principal points, say $(0, 0, 1, 0)$, each giving rise thereby to a quadric cone, then these cones have four common tangent planes. If we consider on the principal plane $t = 0$, the focal conic on the plane, and the section of the surface (p), there will be two common chords of these conics which intersect in the centre of projection $(0, 0, 1, 0)$; each of these two chords is the intersection of two of the four common tangent planes spoken of. Taking then the focal conic of $t = 0$ as absolute conic, and the two intersections of any plane with this conic as the absolute points of this plane, we reach the conclusion that the curves (p, q'), for various confocals (q'), project from $(0, 0, 1, 0)$, upon any plane of circular section of the surface (p) which does not contain this point, into a system of confocal conics, $[p, q']$. For definiteness consider one of the planes of circular section which contains the common centre of all the confocals, and also the point $(0, 1, 0, 0)$. Two foci of the confocal conics are then projections of umbilici in the plane $y = 0$.

Now consider a particular point of the surface (p), say P, and the two tangent lines through P which also touch the surface (q). These are the intersections with the tangent plane at P of the two tangent planes drawn to the surface (q) from the normal, at P, of the surface (p). The cross-ratio of these planes in regard to the two tangent planes drawn from this normal to the focal conic of the plane $t = 0$ (which touch this conic at points lying on the tangent plane at P) depends, we have seen, upon the cross-ratio of the two parameters, q and ∞, giving these confocals, in regard to the two parameters, q_1 and q_2, of the two confocals, other than (p), which pass through P, namely depends on $(q - q_1)/(q - q_2)$. Again, the point $(0, 0, 1, 0)$ being C, as the pairs of tangent planes from CP, to the cones projecting from C the curves (p, q'), are in involution, the cross-ratio of the two tangent lines from $[P]$, the projection of P, to the conic $[p, q]$, in regard to the two lines joining $[P]$ to the absolute points of the plane of projection, depends in the same way upon the same quantity $(q - q_1)/(q - q_2)$. Thus, defining the measure of angle as in Vol. II, pp. 167, 192, we may say that the two tangents from P to the surface (q) intersect at the same angle as the two tangents from $[P]$ to the conic $[p, q]$. The two former lines however do not project into the two latter.

Ex. 5. Consider the curve of intersection of two confocals $(a + \mu)^{-1}x^2 + \text{etc.} = t^2$, $(a + \nu)^{-1}x^2 + \text{etc.} = t^2$, say the surfaces (μ), (ν). Through any point, P, of this curve there pass two generators of the third confocal, say (λ), which can be drawn through P. Consider one of these two generators, say p. Through any other point P', of this generator, there pass, beside the surface (λ), two other confocals, (μ') and (ν'), and the curve of intersection of these, say the curve (μ', ν'). Consider all these curves (μ', ν'), for varying positions of P' on this chosen generator p. They are all intersected by one of the two generators of the third confocal which can be drawn through any other point, Q, of the first curve (μ, ν), say the generator q. The generators, q, so obtained meet any one of the principal planes in the points of a conic. Also, if the generator q meet the curve (μ', ν') in the point Q', the range of points Q' on q, as the curve (μ', ν') varies, but so as always to meet the generator p, in P', is related to the range of points P' on the generator p. A particular case is that the two points, say Q_1 and Q_2, in which any particular confocal (M), other than (λ), is met by the generator q, each describes, on this confocal (M), as Q varies on the curve (μ, ν), a curve, (M, N), which is the intersection of the surface (M) with another confocal (N). Thus, if the surface (M) be met by p in P_1 and P_2, and Q', Q'' be two positions of Q corresponding to the positions P', P'', of P, the cross-ratio $(Q', Q''; Q_1, Q_2)$ is equal to $(P', P''; P_1, P_2)$. As in the case of a plane, where we may measure the interval between two points with reference to an absolute conic, we may thence speak of the interval (Q', Q''), with reference to the surface (M), as being equal to the interval (P', P''). But, also as in the case of a plane, we may replace (M) by one of the focal conics, and so obtain a Euclidean measure of distance (cf. Vol. II, p. 184). In this sense we may speak of the two generators p, q as being divided into segments of equal length by the curves (μ', ν'). The measurement of distance, and the theory of movements, will be considered in a later volume.

The analytical proof of what has been stated is very easy. It is easy to verify that one of the eight points of intersection of the surfaces (λ), (μ), (ν), say, the point P, has coordinates

$$\left[\frac{(a+\lambda)(a+\mu)(a+\nu)}{(a-b)(a-c)}\right]^{\frac{1}{2}}, \quad \left[\frac{(b+\lambda)(b+\mu)(b+\nu)}{(b-c)(b-a)}\right]^{\frac{1}{2}},$$

$$\left[\frac{(c+\lambda)(c+\mu)(c+\nu)}{(c-a)(c-b)}\right]^{\frac{1}{2}}, \qquad 1,$$

or say $[(a+\lambda)^{\frac{1}{2}}U, \ (b+\lambda)^{\frac{1}{2}}V, \ (c+\lambda)^{\frac{1}{2}}W, \ 1]$. Consider now the point in the plane $t=0$ whose coordinates are

$$[(a+\lambda)^{\frac{1}{2}}u, \quad (b+\lambda)^{\frac{1}{2}}v, \quad (c+\lambda)^{\frac{1}{2}}w, \quad 0],$$

where

$$u=[(a+\lambda')/(a-b)(a-c)]^{\frac{1}{2}}, \quad v=[(b+\lambda')/(b-c)(b-a)]^{\frac{1}{2}}, \quad \text{etc.},$$

say the point T. Here λ' is to be so taken that

$$(b-c)[(a+\mu)(a+\nu)(a+\lambda')]^{\frac{1}{2}}+(c-a)[(b+\mu)(b+\nu)(b+\lambda')]^{\frac{1}{2}} \\ +(a-b)[(c+\mu)(c+\nu)(c+\lambda')]^{\frac{1}{2}}=0,$$

a condition which, for given values of μ and ν, is satisfied by two values of λ'. Thence, in addition to the identity, $u^2+v^2+w^2=0$, we have the relation $Uu+Vv+Ww=0$. We also have the identity $U^2+V^2+W^2=1$. Now consider, for any value of h, the point of coordinates

$$(a+\lambda)^{\frac{1}{2}}[U+hu], \quad (b+\lambda)^{\frac{1}{2}}[V+hv], \quad (c+\lambda)^{\frac{1}{2}}[W+hw], \quad 1;$$

for all values of h this point lies on the surface $(a+\lambda)^{-1}x^2+\text{etc.}=t^2$; for fixed values of λ, μ, ν, and one of the two corresponding fixed values of λ', this point describes a line as h varies. The point is, therefore, the general point of one of the two generators above explained, at P, of the surface (λ). It meets the plane $t=0$ in the point T, which, as λ varies, μ, ν and therefore λ' remaining fixed, describes the conic $(a+\lambda')^{-1}x^2+\text{etc.}=0$, $t=0$. The line similarly meets the plane $x=0$ in the point of coordinates $(0, -w, v, iu)$, for we easily see that $vW-wV=iu$, $wU-uW=iv$, etc. As λ varies this point describes the conic $(b+\sigma)^{-1}y^2+(c+\sigma)^{-1}z^2=t^2$, $x=0$, where $\sigma=(bv^2+cw^2)u^{-2}$.

To find the curve (μ', ν') which passes through any point of the generator p, we have to solve for μ', ν' the three equations such as

$$(a+\lambda)^{\frac{1}{2}}(U+hu)=(a+\lambda)^{\frac{1}{2}}U',$$

wherein U' denotes $[(a+\mu')(a+\nu')/(a-b)(a-c)]^{\frac{1}{2}}$. Herein λ, μ, ν, h are given, and λ' is that, of the two possible values, which belongs to the generator p, through P, the other value of λ' belonging to the other generator of the surface (λ) through this point. The three equations are equivalent to two, as we see from $U'^2+V'^2+W'^2=1$, and lead to definite values of μ', ν'. These values are however independent of λ; thus as λ, and the surface (λ), vary, the curves (μ', ν') are all met by generators, q, meeting the curve (μ, ν), each lying on one of the surfaces (λ). That the ranges on the generators q, by the various curves (μ', ν'), are related, is clear from the fact that the value of h which belongs to a point P' on p is the same as that belonging to the point Q' of q which lies on the same curve (μ', ν'). Incidentally this argument shews that the lines q meet any one of the confocals, say (M), upon two curves (μ', ν'), say (M, N_1) and (M, N_2). In particular, to find the locus of the other intersection, beside the curve (μ, ν), of the lines q with the surface (μ), we shall be required to solve, for ν_1, the equations

$$(a+\lambda)^{\frac{1}{2}}(U+hu)=(a+\lambda)^{\frac{1}{2}}U_1,$$

where

$$U_1=[(a+\mu)(a+\nu_1)/(a-b)(a-c)]^{\frac{1}{2}}, \text{ etc.}$$

Beside $\Sigma U_1^2=1$, these equations require $\Sigma(a+\mu)^{-1}U_1^2=0$, which determines h; then ν_1 is to be found from

$$\Sigma U_1 u=0, \quad \text{or} \quad \Sigma(b-c)[(a+\mu)(a+\lambda')(a+\nu_1)]^{\frac{1}{2}}=0;$$

of the two roots of this equation for ν_1, one is ν itself. The remainder of the statement made is now clear.

The equation above, by which λ' is determined from μ and ν, is capable of interpretation by elliptic functions, and will be considered in a later section. Geometrically, it expresses that one of the intersections of the three confocals (μ), (ν), (λ') lies on one of the four planes drawn from the common centre of the confocals to touch all these surfaces, the equation of such a plane being $\Sigma x(b-c)^{\frac{1}{2}}=0$.

Thus, if λ_1', λ_2' denote the two values of λ' when μ and ν are given, we infer that each of these four planes contains two of the intersections of (μ), (ν), (λ_1'); and two of the intersections of (μ), (ν), (λ_2').

If the equation connecting μ, ν and λ' be rationalised it will be found to be symmetrical in regard to the two sets μ, ν, λ' and a, b, c. Another irrational form of the equation is therefore

$$(\mu - \nu) L' + (\nu - \lambda') M + (\lambda' - \mu) N = 0,$$

where

$$L' = (a + \lambda')^{\frac{1}{2}} (b + \lambda')^{\frac{1}{2}} (c + \lambda')^{\frac{1}{2}}, \text{ etc.}$$

Further, denoting the equation by $(\mu, \nu, \lambda') = 0$, it can be shewn that λ, μ, ν can be eliminated from the three equations $(\mu, \nu, \lambda') = 0$, $(\nu, \lambda, \mu') = 0$, $(\lambda, \mu, \nu') = 0$, the result being $(\lambda', \mu', \nu') = 0$.

Ex. 6. From the preceding results we have an immediate proof of the porism of Poncelet[1] in regard to conics (Vol. II, p. 55), so far as it relates to triangles. Here it may be stated in the form: If the join of a point, M, lying on the conic $(a + \mu)^{-1} x^2 + \text{etc.} = 0$, to a point, N, lying on the conic $(a + \nu)^{-1} x^2 + \text{etc.} = 0$, be a tangent of the conic $x^2 + y^2 + z^2 = 0$, the locus of the point of intersection, T, of the other tangents drawn to this latter conic from the points M, N is a third conic, $(a + \lambda')^{-1} x^2 + \text{etc.} = 0$. The four conics involved all have four common tangents. To prove this, consider, in the first instance, any three confocals of the system of confocal quadrics, (λ), (μ), (ν), intersecting in a point O. Let the generators at O, of the surface (λ), meet the plane $t = 0$ in the points T, T_1, lying on the conic $(a + \lambda)^{-1} x^2 + \text{etc.} = 0$, $t = 0$; the generators at O, of the surface (μ), meet the plane $t = 0$ in the points M, M_1, lying on the conic $(a + \mu)^{-1} x^2 + \text{etc.} = 0$; and the generators at O, of the surface (ν), meet the plane $t = 0$ in the points N, N_1, lying on the conic $(a + \nu)^{-1} x^2 + \text{etc.} = 0$. By what we have seen (p. 110), the six points T, T_1, M, M_1, N, N_1 lie in threes on four lines, in which the plane $t = 0$ is met by the four planes drawn from O to touch all the confocals; we suppose the notation so chosen that these lines are MNT_1, TMN_1, TNM_1, $T_1M_1N_1$; these lines all touch the conic $x^2 + y^2 + z^2 = 0$, $t = 0$. If the line joining O to the common centre, D, of the confocals, meet the plane $t = 0$ in H, the polar line of DH, in regard to any of the surfaces (λ), (μ), (ν), lies in the plane $t = 0$, and, therefore, contains the points of contact of the tangents drawn from H to the section of that confocal by $t = 0$; thus these points of contact lie on the tangent plane at O of the corresponding confocal. In other words, the six tangents of the conics at T, T_1, M, M_1, N, N_1 meet in H. Now, retaining the surfaces (μ), (ν) the same, allow the surface (λ) to vary, the point O varying on the curve (μ, ν). Then the points M, N will vary on the conics (μ), (ν), the line MN continuing to touch the focal conic, and, by what is proved above, the point T, the intersection with $t=0$ of one of the generators at O of the surface (λ), will describe a conic (λ'), where λ' is connected with μ, ν by the relation $(\mu, \nu, \lambda')=0$. The other value of λ' which satisfies this equation gives the conic (λ_1'), described by the point T_1, where the other generator at O of the surface (λ) meets $t=0$.

---

[1] See frontispiece of this Volume.

Conversely, if, as above, M, N be two points of the plane $t=0$, lying respectively on the conics (μ), (ν), the line MN touching the focal conic, and the other tangents to this conic from M and N intersecting in T, we can construct the figure above used, and the locus of T, as follows: By hypothesis the conics (μ), (ν) on which M and N lie, and the focal conic touched by MN, have four common tangents. We can therefore refer them to a common self-polar triad, and suppose their equations to be as we have taken them above, and then, further, taking an arbitrary point D, not in the plane $t=0$, suppose these conics to arise from a confocal system of quadrics, as above, with D as centre. Then, through each of the lines TM, MN, NT there pass two planes which touch all the surfaces of this confocal system, a pair of such planes having equations of the form

$$lx+my+nz\pm pt=0, \quad \text{where} \quad p^2=al^2+bm^2+cn^2.$$

The three pairs of planes give rise to eight points through each of which passes a plane of each pair, these eight points lying in couples on four lines through D. Taking one of these eight points for the point O, such a figure as that above described can be constructed; but, the conics (μ), (ν) being given, and, therefore, the point, H, of intersection of the tangents of these conics at M and N, it is necessary to take for O one of the two points such that DO passes through H. These two points O give rise to the same surface (λ), and the same conic (λ'), the point T being the intersection of two generators of the surface (λ).

When M, N vary, respectively on the conics (μ), (ν), the conic (λ) varies, and T remains on (λ'), while H describes a conic, the projection from D of the curve (μ, ν). The conic (λ'), and the conic (λ), have, at T, tangents which are conjugate in regard to the focal conic of the plane $t=0$. We may similarly consider the conics, (μ'), through M, and (ν'), through N, whose tangents at these points are conjugate, respectively, to those of (μ) and (ν). Then, when M and N vary on (μ'), (ν'), respectively, T also varies on (λ'). Calling for brevity the line conjugate, in regard to the focal conic, to a tangent of one of the conics, the *normal*, we may thus say that when a triad of points, one on each of the conics, is such that their joins touch the focal conic, not only the tangents of two of these conics and the normal of the other, meet in a point, but also the normals of these conics meet in a point, and these points of concurrence describe conics.

Ex. 7. If the line joining two points P_0, P, of respective coordinates $(x_0, y_0, z_0, 1)$, $(x, y, z, 1)$, meet the confocal surface $(a+\theta)^{-1}x^2 + \text{etc.} = t^2$ in the points M, N, and the cross-ratio $(P_0, P; M, N)$ be written e^{2iw}, prove that

$$\cosh w = \frac{(\theta+a)(\theta+b)(\theta+c) - \Sigma x x_0 (\theta+b)(\theta+c)}{[\Pi(\theta-\lambda)(\theta-\lambda_0)]^{\frac{1}{2}}},$$

where λ_0, μ_0, ν_0 are the parameters of the confocals through P_0, and λ, μ, ν the parameters of the confocals through P, so that we may replace x_0 by $[(a+\lambda_0)(a+\mu_0)(a+\nu_0)/(a-b)(a-c)]^{\frac{1}{2}}$, and x by the same function of λ, μ, ν. This expression is unaffected by the interchange of λ and λ_0, whereby P_0 is replaced by a point P_0' on the same curve (μ_0, ν_0), and P is replaced by a point P' on the same curve (μ, ν), provided the signs of xx_0, yy_0, zz_0 are unaltered.

The value of $\cosh^2 w$ is unity, not only for $\theta = -a, -b, -c, \infty$, but also for two other values of θ; these give the two confocals touched by the line P_0P. Thus the line $P_0'P'$ also touches these two confocals. And the cross-ratio $(P_0, P; M, N)$ is equal to that obtained, for the same surface θ, for the line $P_0'P'$.

By supposing θ to become infinitely great, and regarding the focal conic of the plane $t=0$ as the absolute conic, it can hence be inferred, as will be seen later, that the *distances* P_0P and $P_0'P'$, which arise as the limits of $\theta^{\frac{1}{2}}w$, are equal. This result is known as Ivory's theorem, and is of importance in the theory of the Newtonian attraction of a material ellipsoid. The geometrical theory is capable of great development. See a paper by A. L. Dixon, *Messenger of Mathematics*, XXXII, 1903, p. 177, and a note by the author, *Proc. Camb. Phil. Soc.* XX, 1920, p. 129.

Ex. 8. The planes touching all the confocals of the system are those represented by the equation $Px + Qy + Rz = t$, where

$$P = (a+\lambda)^{\frac{1}{2}}(a-b)^{-\frac{1}{2}}(a-c)^{-\frac{1}{2}}, \text{ etc.}$$

These planes, depending on a single parameter, determine a developable. They meet an arbitrary plane in the tangent lines of a curve. Upon each plane, of the developable, there is a line, of which the points are given by $x = t(a+\phi)P$, etc., for varying values of ϕ; the intersections of these lines with the arbitrary plane are the points of the curve spoken of. The planes of the developable meet, each in three coincident points, a curve of which the general point is given by $x = t(a+\lambda)^{\frac{3}{2}}(a-b)^{-\frac{1}{2}}(a-c)^{-\frac{1}{2}}$, etc. The lines in question are called the generating lines of the developable; each of them touches all the confocals, other than one of these, of which it is a generator; through this line there is one plane of the developable touching all the confocals at points of this line. More generally, the line of intersection of any two planes of the developable is a generator of one of the confocal surfaces; for the surface drawn to touch an arbitrary plane through this line of intersection will be touched by three planes through the line; it will thus contain the line entirely. If we call the line of intersection of two planes of the developable an *axis* of the developable, (it corresponds dually to a chord of a curve), we thus see that the aggregate of all the generators of the confocals is the same as the aggregate of the axes and generating lines of the developable.

The line given by $x = t(a + \phi)P$, etc., is a generator of the surface $(a + \lambda)^{-1}x^2 + \text{etc.} = t^2$, touching the surface $(a + \theta)^{-1}x^2 + \text{etc.} = t^2$ at the point given by $\phi = \theta$; this point is one of the eight intersections of the surfaces (λ), (θ) with the quadric which is the polar reciprocal of the surface (λ), on which the line is a generator, with respect to the surface (θ). (Cf. pp. 80, 92.)

Dual method of developing the theory of confocal surfaces. If any two quadric surfaces be given, the curve in which they intersect is such as to have four points upon an arbitrary plane, these being the intersections of the conics in which the plane severally meets the quadrics. Through this curve, and an arbitrary point, can be drawn another quadric; for if $S = 0$, $S' = 0$ be the equations of the given quadrics, the equation $S + \lambda S' = 0$ represents a quadric passing through the common points of the two given quadrics; and the value of λ can be taken so that this passes through the arbitrary point. No other quadric can be drawn through this curve and this point, since, of such a quadric, five points are determined lying on an arbitrary plane drawn through this point. Thus the equation $S + \lambda S' = 0$ is that of the general quadric through the curve $S = 0$, $S' = 0$. We have seen that the tangential equation of the general quadric of the confocal system is of the form $\Sigma + \lambda\Sigma' = 0$; we may, then, clearly develop, in dual form, the theory of a confocal system, as that of the quadrics $S + \lambda S' = 0$. Without entering into a detailed account, it is interesting to consider what corresponds to some of the leading theorems already obtained for confocals. We suppose that the surfaces $S = 0$, $S' = 0$ have a common self-polar tetrad, so that their equations can be supposed to be, respectively,

$$Ax^2 + By^2 + Cz^2 + Dt^2 = 0, \quad A'x^2 + \text{etc.} = 0;$$

their curve of intersection will then not contain a line, or a conic, as part, as is possible for two quadrics in general. Through the curve of intersection there pass four quadric cones; in fact $S + \lambda S' = 0$ represents a cone for $\lambda = -A/A'$, etc. These cones, each enveloped by an aggregate of planes passing through one of the four principal points, of which two planes can be drawn to contain an arbitrary line through this point, correspond dually to the four focal conics of the confocal system, each the locus of points in a principal plane, of which two points lie on an arbitrary line of the plane. The coordinates can be chosen so that the equation of the system of quadrics now considered is

$$(a+\mu)x^2+(b+\mu)y^2+(c+\mu)z^2=t^2,$$

where $\mu=\infty$ gives rise to one of the cones, $x^2+y^2+z^2=0$. The other three cones then arise for $\mu=-a$, $\mu=-b$, $\mu=-c$. It is at once clear that the polar planes of an arbitrary point, in regard to the system of quadrics now being considered, all pass through a line. These polar planes have an equation $P+\mu P_0=0$, where P, P_0 are the polar planes of the point in regard to the fixed quadrics $ax^2+\text{etc.}=t^2$, and $x^2+y^2+z^2=0$. The line is the intersection of four planes, arising for $\mu=\infty, -a, -b, -c$, each containing one of the principal points, and the axial pencil formed by these planes is related to that similarly arising for any other such line. These are the lines corresponding to what have been called the axes of the confocal system; as in that case they constitute a tetrahedral complex; every line in a principal plane, or through a principal point, belongs to this complex. Considering, next, an arbitrary line, this is intersected, by the quadrics considered, in pairs of points belonging to an involution, the two points of intersection with any quadric being determined by one of them. There are thus two quadrics of the system touching the line. The proof and theorem fail if the line contains two points of the common curve of intersection of the quadrics, in which case the line is a generator of one of the quadrics; when the line is a tangent of this curve, it is a generator of one of the quadrics, and touches all the other quadrics at this point. In the general case, the tangent planes of the quadrics, at the points where the line meets them, form an aggregate of which three pass through an arbitrary point; also the polar lines of the given line in regard to the quadrics are generators of a quadric, which passes through the four principal points. When the line belongs to the tetrahedral complex, the tangent planes of the quadrics, at the point where the line meets them, all pass through a point. In particular, when the line passes through one of the principal points, these tangent planes touch a quadric cone, whose vertex is in the corresponding plane. Lastly, considering an arbitrary plane, there are three quadrics of the system which touch this plane. The quadrics of the system meet this plane in conics having four points in common; the generators, in this plane, of the three quadrics which touch this plane, are the three line-pairs which contain these four points. If we consider the aggregate of planes touching two particular quadrics of the system, and, in any such plane, the generators of the third quadric of the system other than these two, which touches this plane, then these generators are projected from one of the principal points by tangent planes of two particular quadric cones.

Ex. 1. The polar lines of the line (l, m, n, l', m', n'), in regard to the quadrics of equation $(a+\lambda)x^2 + \text{etc.} = t^2$, lie on the quadric expressed by

$$l'\alpha yz + m'\beta zx + n'\gamma xy - lxt - myt - nzt = 0,$$

where $\alpha = b - c$, $\beta = c - a$, $\gamma = a - b$. When the line belongs to the tetrahedral complex expressed by $all' + bmm' + cnn' = 0$, this quadric is a cone of vertex $(l', m', n', -\sigma)$, where σ is $\alpha m'n'/l, = \beta n'l'/m$, etc. When the line passes through one of the principal points the quadric breaks up into two planes; for instance, when $l' = m' = n' = 0$, it is $t(lx + my + nz) = 0$.

Ex. 2. The tangent planes of the quadrics $(a+\mu)x^2 + \text{etc.} = t^2$, at the points where these are met by the line $x/l = y/m = z/n$, touch the cone

$$(xP + yQ + zR)(xp + yq + zr) = t^2,$$

where $(l^2 + m^2 + n^2)P = l(\gamma m^2 - \beta n^2)$, $(l^2 + m^2 + n^2)p = l$, etc., so that $Pp + Qq + Rr = 0$.

CHAPTER III

CUBIC CURVES IN SPACE. THE INTERSECTION OF TWO OR MORE QUADRICS

The curve of intersection of two quadrics. A conic is a curve of which the points are in unique correspondence with the points of a line; it is defined by the intersection of associated rays of two related flat pencils of lines in a plane. In three dimensions there exists a curve, in many ways simpler than a conic, of which the points are also in unique correspondence with the points of a line. Three points of this curve lie on an arbitrary plane, so that the curve is called a cubic. The curve may be defined, analogously to a conic in a plane, by the intersection of associated planes of three related axial pencils of planes. The curve may also be defined as the partial intersection of two quadric surfaces. We have, however, in the theory of confocal quadrics, been led to consider a curve which is the intersection of two quadrics, and is not a cubic. It will therefore add to clearness if, before considering the cubic curve in detail, we enumerate all the possibilities in regard to the intersection of two quadrics; the proof that the list is exhaustive will be given in a later Volume. Since an arbitrary plane meets each of the quadrics in a conic, and two conics in the same plane intersect in four points, the complete intersection of two quadrics must meet an arbitrary plane in four points. This intersection may however consist of several irreducible pieces (curves), of which two may coincide.

(1) The curve of intersection of two quadrics may consist of one piece, that is of one curve, which will then be a quartic, as meeting an arbitrary plane in four points. In the most general case the points of this curve are not in unique correspondence with the points of a line. If we take two points of the curve, and the line, or *chord* of the curve, which joins them, and consider the planes through this chord, (which are in correspondence with the points of a line), each of these planes gives rise to two points of the curve. The coordinates of the points of the curve are in fact rational functions of two parameters, ξ, η, themselves connected by a relation $\eta^2 = f(\xi)$, wherein $f(\xi)$ is a polynomial in ξ of the fourth order; conversely, both ξ and η are rational functions of the ratios of the coordinates of a point of the quartic curve.

There is however a particular case of this in which the curve of intersection still consists of a single quartic curve; namely when the curve crosses itself, or has a double point. Then any plane drawn through this point and another fixed point of the curve has but one further intersection with the curve; the points of the curve are in this case in unique correspondence with the points of a line. The cases in which the curve crosses itself twice occur below; the curve does not then consist of one piece.

(2) The curve may consist of a line and a curve consisting of one piece. This last is then the cubic curve above referred to; it meets the line in two points.

(3) The curve may consist of two conics, which then have two points of intersection. We have met with this possibility in the last chapter, in the case of two spheres, one of the common conics being then the absolute conic. The two conics may touch one another.

(4) In particular one of the conics may consist of two straight lines, each of which meets the other conic. When the point of intersection of these lines lies on the other conic, the plane of the lines contains the tangent line of this conic at this point.

(5) Or both conics may consist of two lines. In this case the two quadrics have in common two generators of each of the two systems of either quadric.

(6) Two of the four lines may coincide, in which case the intersection consists of a line at every point of which the two quadrics have the same tangent plane, together with two lines intersecting this.

(7) More particularly still, the four lines may consist of two, each occurring twice; the lines will intersect, and the tangent planes of the quadrics will be the same at every point of both.

(8) Finally, the intersection may consist of a single conic at every point of which the quadrics have the same tangent plane. This conic thus counts doubly in the intersection.

In the cases (6), (7), (8) we say that the common curve is multiple, or contains a multiple portion.

Ex. 1. The quadrics whose equations are $x^2+y^2-z^2-t^2=0$, $ax^2+by^2+cz^2+dt^2=0$, intersect in a curve of which the points are expressed by $x=\theta+\phi$, $y=1-\theta\phi$, $z=1+\theta\phi$, $t=\theta-\phi$, provided θ, ϕ are connected by the equation

$$A(1+\theta^2\phi^2)+B(\theta^2+\phi^2)+2C\theta\phi=0,$$

where $A=b+c$, $B=a+d$, $C=a-b+c-d$.

The quadrics whose equations are

$$2xy+z^2-t^2=0,\quad 2xy+y^2+(1-m^2)z^2-(1-n^2)t^2=0$$

intersect in a curve expressed by

$$x=PQ,\quad y=2m^2n^2,\quad z=mn^2(\theta+\theta^{-1}),\quad t=m^2n(\theta-\theta^{-1}),$$

where

$$2P = (\theta - \theta^{-1})\,m + (\theta + \theta^{-1})\,n, \quad 2Q = (\theta - \theta^{-1})\,m - (\theta + \theta^{-1})\,n,$$

θ being variable. This curve crosses itself at (0, 1, 0, 0), either of the two planes, $mz + nt - \theta y = 0$, $mz - nt - \theta^{-1}y = 0$, meeting the curve in only one further point.

The quadrics whose equations are

$$2xy + z^2 + t^2 = 0, \quad 2xy + 2yz + z^2 + (1 - n^2)\,t^2 = 0$$

intersect in a curve expressed by

$$x = -(\theta^2 + n^4), \quad y = \tfrac{1}{2}\theta^4, \quad z = n^2\theta^2, \quad t = \theta^3,$$

where θ varies. This curve has a cusp at (0, 1, 0, 0), any plane $2y = \theta t$ meeting the curve in only one further point.

Ex. 2. The quadrics whose equations are

$$xy + zt = 0, \quad 2xy + 2czt + y^2 + t^2 = 0$$

intersect in a curve expressed by

$$x = -(1 + \theta^2), \quad y = 2(1 - c)\,\theta^2, \quad z = \theta(1 + \theta^2), \quad t = 2(1 - c)\,\theta,$$

as well as in the line $y = 0$, $t = 0$. The curve meets an arbitrary plane in three points, and meets the line in (1, 0, 0, 0) and (0, 0, 1, 0).

The quadrics whose equations are

$$xy + zt = 0, \quad 2xy + 2zt + 2yt + z^2 = 0$$

intersect in a curve expressed by $x = 1$, $y = -2\theta^3$, $z = 2\theta^2$, $t = \theta$, as well as in the line $y = 0$, $z = 0$. This line meets the curve in two coincident points, any plane $y + \theta z = 0$ meeting the curve in only one further point.

Ex. 3. The quadrics $x^2 + y^2 + z^2 + t^2 = 0$, $x^2 + y^2 + cz^2 + dt^2 = 0$ meet in two conics having two points in common. The quadrics $2xy + z^2 + t^2 = 0$, $2xy + y^2 + z^2 + dt^2 = 0$ meet in two conics touching one another on the line $y = 0$, $t = 0$.

Ex. 4. The quadrics $2xy + z^2 - t^2 = 0$, $2xy + y^2 + c(z^2 - t^2) = 0$ intersect in two lines $y = 0$, $z = \pm t$, and in a conic, lying in the plane $y + 2x(1 - c) = 0$, meeting both these lines. The quadrics $2xy + z^2 - t^2 = 0$, $2xy + 2yz + z^2 - t^2 = 0$ intersect in two lines $y = 0$, $z = \pm t$, and in a conic, lying in the plane $z = 0$, which contains the intersection of the two lines and is touched, at this point, by the plane of these.

Ex. 5. The quadrics $x^2 + y^2 + z^2 + t^2 = 0$, $x^2 + y^2 + c(z^2 + t^2) = 0$ have four lines in common.

Ex. 6. The quadrics $xy + zt = 0$, $xy + zt + yt = 0$ have in common the lines $x = 0 = t$, $y = 0 = z$, and $y = 0 = t$, of which the last counts doubly, the tangent planes of the quadrics at any point of this being the same.

Ex. 7. The quadrics $xy+zt=0$, $2xy+2zt+y^2=0$ have in common the lines $y=0=t$ and $y=0=z$, each doubly, the tangent planes of the quadrics at any point of either being the same.

Ex. 8. The quadrics $x^2+y^2+z^2+t^2=0$, $x^2+y^2+z^2+dt^2=0$ touch one another at every point of the conic $t=0$, $x^2+y^2+z^2=0$, and have no other common point.

Ex. 9. We have seen that the theory dual to that of the theory of confocal surfaces is that of the quadrics passing through the common curve of two quadrics of sufficient generality. In particular, the dual of a focal conic, of which every tangent line lies in (two of the) planes touching all the confocal surfaces, is a quadric cone of which every generating line passes through a point of the common curve of the two quadrics. It is thus of interest to determine, in each of the thirteen cases just enumerated, the quadric cones containing the complete curve of intersection of the two quadrics. Moreover, the tangent planes touching the confocal surfaces are the common tangent planes of any two of the focal conics. It is thus of interest to consider the aggregate of tangent planes common to two conics which are not in so general relation to one another as are two of the focal conics; in particular, of two conics in different planes which both touch the line of intersection of their planes. It is this problem, essentially, which we now proceed to consider, in its dual form.

The cubic curve in three dimensions. Consider first two quadric cones, of vertices O and Q, so related that the line OQ is a generator of both, the tangent planes of the cones along this generator being different. These cones meet an arbitrary plane in two conics, among the four intersections of which will be the point in which the line OQ meets the plane. There are then three points of the plane, not on this line, which belong to both cones. The curve of points common to the two cones, other than their common generator, thus meets an arbitrary plane in three points, and is, for this reason, called a *cubic* curve. Any plane through OQ meets each cone in a further generator; the point of intersection of these two lines is a point of the curve; the other two points of the curve lying in this plane are the points O and Q. If R be any point of the curve, any plane drawn through R meets the curve in two other points; if then we consider the aggregate of lines joining R to all other points of the curve, there are two of these in any plane through R. We infer, therefore, that these lines are the generators of a quadric cone. This may be deduced also by remarking that the axial pencils of planes which join two fixed generators of a quadric cone to a variable generator are related pencils, and conversely. For let P be a variable point of the curve; as OP is a variable generator of the quadric cone of vertex O, of which OQ and OR

are two fixed generators, the axial pencils $OQ(P)$ and $OR(P)$ are related; also, as QP is a variable generator of the quadric cone of vertex Q, of which QO and QR are two fixed generators, the axial pencils $QO(P)$ and $QR(P)$ are related. As then the axial pencils $RO(P)$ and $RQ(P)$ are related, it follows that RP is the variable generator of a quadric cone of vertex R, of which RO and RQ are two fixed generators. The cubic curve may then be defined as the locus of the common points of the two quadric cones with vertices at O and R, other than their common generator OR. It follows too that the axial pencil of planes, joining the chord OQ to the points P of the curve, is related to the axial pencil joining the chord QR to the same points P, and, therefore, to the axial pencil joining any other chord, RS, to the same points P of the curve. In view of what has been said previously in regard to related ranges, this is sufficiently clear also from the fact that an arbitrary plane through OQ, by determining a definite further point, P, of the curve, determines a definite plane RSP, and conversely. The curve is thus like a conic in being the seat of related ranges, of points lying upon it, any four points, P_1, P_2, P_3, P_4, of the curve, being related to four other points, P_1', P_2', P_3', P_4', if the planes joining the first four points, to an arbitrary chord of the curve, be related to the planes joining the second four points to another, also arbitrary, chord. In other words, the curve, like a conic, may be regarded as having its points in (1, 1) correspondence with the points of a line. The curve is, in fact, as appears from what has been said, the locus of the intersection of three corresponding planes; one from each of three related axial pencils of planes, of which the axes are any three chords of the curve.

Consider any two points D, A, of the curve, and the quadric cones which project the curve from these two points, respectively, say (D) and (A). Let the tangent plane of the cone (D) along DA meet the cone (A) also in the line AB, and the tangent plane of the cone (A) along AD meet the cone (D) also in the line DC. Let B be determined as the intersection of the tangent plane of (D), along DC, with AB; and C be determined as the intersection of the tangent plane of (A), along AB, with DC. Then, with A, B, C, D as fundamental points for coordinates, the cones (D), (A) may be supposed to have the respective equations $xz = y^2$ and $yt = z^2$. The former is generated by the intersection of planes of equations $x = y\theta$, $y = z\theta$; the latter by the intersection of planes of equations $y = z\theta$, $z = t\theta$, where θ is variable. The coordinates of any point of the curve are then of the form $(\theta^3, \theta^2, \theta, 1)$. The three points in which any plane, of equation $lx + my + nz + pt = 0$, meets the curve, are then given by the roots of the cubic equation $l\theta^3 + m\theta^2 + n\theta + p = 0$. In particular, the plane $x = 0$, or BCD, meets the curve in three coincident points at the point D, for which $\theta = 0$; and the plane $t = 0$, or BCA, meets the curve in three coincident points at the point A, for which $\theta^{-1} = 0$. The line DC meets the curve in two coincident points at the point D, any plane, $x = y\theta$, through this line, meeting the curve in only one other point; so the line AB meets the curve in two coincident points at the point A, any plane, $z = t\theta$, through this line, meeting the curve in only one other point. It appears thus that there is through any point of the curve a line, called the *tangent*, meeting the curve in two coincident points at this point; and a plane through the tangent, called the *osculating plane*, which meets the curve in three coincident points at this point. The two arbitrary points A, D of the curve being taken, the points B and C are the intersections of the tangents at these points, respectively, with the line in which the osculating planes of the curve, at these points, intersect.

More generally, given any three lines, the equations of three corresponding planes of axial pencils, which are related to one another, having these lines as axes, can be supposed to be of the forms $P - \theta Q = 0$, $P_1 - \theta Q_1 = 0$, $P_2 - \theta Q_2 = 0$, where each of P, Q, etc. is a linear function of coordinates x, y, z, t, with any fundamental points of reference. Supposing that the axes, and the manner of relation of the axial pencils, are so general that these three planes do not meet in a line, the point of intersection of these planes has coordinates, found by solving the three linear equations, each proportional to an expression of the form $a\theta^3 + b\theta^2 + c\theta + d$. We may then suppose x, y, z, t respectively equal to $f_1(\theta), f_2(\theta), f_3(\theta), f_4(\theta)$, where each of these functions is such an expression. There can be no identical relation, $\Sigma A_r f_r(\theta) = 0$, where the four coefficients A_r are independent of θ, or the locus of (x, y, z, t) would lie in a plane, which we suppose not to be the case. Wherefore, by reverting the equations, we can express each of θ^3, θ^2, θ, 1 as a linear function of x, y, z, t, say $X = \theta^3$, $Y = \theta^2$, $Z = \theta$, $T = 1$. We then have the expression of the curve found above, with X, Y, Z, T as coordinates.

Taking any two chords, l, m, of the cubic, a line, p, can be drawn, from any point, P, of the curve to meet both l and m. This line lies in both the planes $l(P)$, $m(P)$. When P varies on the curve, these planes, by what we have seen, describe related axial pencils, so that the line p describes a quadric surface containing both l and m. Thus a quadric surface can be drawn containing the curve and any two of its chords. The generators of this surface which are of the same system as l and m all meet the generator, p, through any particular point of the curve; the plane containing p and any one of these generators, say n, meets the curve in three points; as the curve lies on the quadric surface, and the plane meets this only in the lines p, n, these three points must lie on these lines; by the construction,

p meets the curve in only one point, P. Wherefore the generators, n, of the same system as l and m, which meet p, are all chords of the curve. We have seen that we may consider related ranges of points upon the curve; we may thus consider involutions of pairs of points upon the curve. In fact the chords, n, meeting the line p, intersect the curve in pairs of points of such an involution, that, namely, determined by the two pairs of points of the curve which are on the chords l and m, respectively. This is clear by considering the cone which projects the curve from P; the two generators of this cone which join P to the two points where one of the chords n meets the curve, lie on a plane passing through the fixed line p; as for conics, this is the necessary and sufficient condition for an involution of pairs of generators of the cone. We thus see that, if we consider any involution of pairs of points of the cubic curve, the chords of the curve, each containing a pair of the involution, are the generators, of one system, of a quadric surface containing the curve. Also, if an arbitrary line, p, be drawn through a point, P, of the curve, not meeting the curve again, any variable plane through p meets the curve in two points, each determining the other, which are a pair of an involution upon the curve. Of the chords joining the pairs of this involution there is one through any point, say O, of the line p. Thus, through any point O of space can be drawn a chord of the curve; for take any point, P, of the curve, and consider, in what has just been said, the line p as being the line OP. Two such chords are not possible through O, since the plane containing these would meet the curve in four points. It appears thus that through any line, p, which meets the curve in one point, and the curve, a quadric surface can be drawn; and further that if a series of such lines p be taken, all containing a point O, these quadric surfaces have all a common generator. More generally it appears that a quadric surface can be drawn to contain the curve and two arbitrary points not lying on the curve; for, taking the chords of the curve passing, respectively, through these points, this is the surface containing the curve, and these two chords.

This last result is in accordance with the fact, which we can reach without difficulty, that the equation of the general quadric surface containing the curve is of the form $\lambda U + \mu V + \nu W = 0$, where U, V, W are definite quadric functions, and λ, μ, ν are arbitrary constants. This is the equation of a general quadric conditioned to pass through seven given points of independent position; for the unconditioned equation of a quadric contains ten terms. In fact, a cubic curve which does not lie wholly upon a quadric surface meets this in six points, as we see by substituting in the equation of the quadric respectively θ^3, θ^2, θ, 1 for the coordinates. Wherefore, a quadric surface prescribed to pass through seven general points of a cubic curve contains the curve entirely.

We may remark at this point: (*a*), that a cubic curve can be made to pass through six arbitrary points of space, say A, B, C, D, O, Q; for the five points A, B, C, D, O lie on a definite quadric cone of vertex Q, and the five points A, B, C, D, Q lie on a definite quadric cone of vertex O. The curve is the intersection, other than the common generator OQ, of these two cones; (*b*), that through five general points, say A, B, C, D, E, of a quadric surface, two cubic curves can be drawn which lie entirely upon the surface. For, if l, m be the generators of the surface at E, a definite quadric cone can be constructed, with vertex at E, to contain one of these generators, say l, and also the four points A, B, C, D; the points common to this cone and the quadric, other than the points of the line l, constitute a cubic curve, passing through E. For, let P be any point of the curve of intersection, and p the line drawn from P to meet l and to meet any other fixed generator, k, of the quadric, of the same system as l, so that p is also a generator of the quadric; the quadric is the locus of the points of the lines p, as P varies, and p is the intersection of corresponding planes of two related axial pencils whose axes are l and k, two of these planes being $l(P)$ and $k(P)$. The quadric cone drawn with vertex at E is however the locus of the lines of intersection of corresponding planes of two related axial pencils whose axes are l and (for example) the line EA, two of these planes being $l(P)$ and EAP. By taking k to pass through A, the point P, which is the intersection of the corresponding planes $l(P)$, $k(P)$, EAP, appears as lying on another quadric cone, of vertex A, which is the locus of the intersection of the corresponding planes, $k(P)$, AEP, of two related axial pencils. Another cubic curve lying on the given quadric surface, and passing through the points E, A, B, C, D, is that lying on the cone of vertex E described to contain A, B, C, D and the second generator, m, at the point, E. As we see by considering the intersection of the cone of vertex E, and of the quadric, with an arbitrary plane drawn through l, the former cubic curve has l for a chord; the latter has m for a chord. We see, further: (*c*), that every cubic curve on a quadric surface has all the generators of one system as chords, meeting every generator of the other system each in one point. For the plane of two intersecting generators of the quadric meets the quadric only on these lines, and meets, therefore, a cubic curve lying on the surface only on these lines. The curve cannot meet either of these lines in three points, since else an arbitrary plane through this line would have no further intersection with the curve, which, therefore, would degenerate into the line itself (taken three times). If the curve meets one of these lines in two points it must meet every generator of the surface, which meets this, in one point; if it meets one of these lines in one point, it must meet every generator of the surface, which meets this, in two points. Thus also, a cubic curve, in (*b*), through E, A, B, C, D, must have either l or m for a chord; there is then no other cubic through these points than those two found in (*b*).

We have defined a cubic curve as the locus of the points common to two quadric cones which have a common generator, and have shewn that quadric surfaces can be drawn through the curve; two of these with a chord of the curve as common generator intersect then further in the curve. Conversely, if we take any two quadric surfaces with a common generator, their remaining intersection is a curve meeting an arbitrary plane in three points. That this is not a more general cubic curve than that above found, may be shewn in detail by proving, as in the above argument under (*b*), that it can be regarded as the intersection of two quadric cones with a common generator.

The construct which is dual to a cubic curve will be that of the aggregate of planes touching two quadric surfaces which have a common generator, other than those passing through this line; or, as follows by the dual of the reasoning above given, of the aggregate of planes touching two conics in different planes which both touch the line of intersection of these planes; or, also, of the aggregate of planes meeting three lines in the corresponding points of three related ranges upon these lines, the ranges being such that the three corresponding points do not always lie in line. There is, evidently, an ∞^1 of such planes, that is, the planes are each determined by a value of a single varying parameter; they are therefore said to constitute a *developable*. And, of such planes, three pass through an arbitrary point, as in the dual case. The aggregate is thus called a cubic developable. Consider this developable as defined by the common tangent planes of two conics in different planes, touching the line of intersection of their planes respectively in A and B. Let P, Q be points, of these two conics respectively, which are such that the tangent lines of these conics at P and Q intersect one another, in the point C, of the line AB. From any point, O, of the line PQ, the conics are projected into two quadric cones; these touch one another along the line OPQ. These cones have four common tangent planes, of which OAB is one, and $OPQC$ is another; this last is to be regarded as two coincident planes; and there is another plane tangent to both cones passing through O; let this plane touch the conics, respectively, in P' and Q', and meet the line AB in C', so that $C'P'$ and $C'Q'$ touch the conics respectively at P' and Q'; let $C'P'$, $C'Q'$ meet CP, CQ, respectively, in M and N, so that MN passes through O, as being on the plane $C'P'Q'$ and intersecting PQ. Then, as O varies on the line PQ, the point C' will vary on AB, and M, N will vary on CP, CQ, respectively. But, as $C'P'M$ is a tangent of one conic, of which AB and

CP are fixed tangents, the ranges (C'), (M) will be related; likewise the ranges (C'), (N) are related. Thus MN envelopes a conic in the plane CPQ, of which CP, CQ are tangents, as also is PQ, since when C' is at C, the points P' and Q' are respectively at P and Q. Let T be the point of contact of this conic with PQ. Then, when O is at T, this third plane of the developable drawn from O, which in general is $OC'P'Q'$, coincides with the former one $OCPQ$. Thus, the developable is such that in any plane of it, (CPQ), there is a line, (PQ), such that, of the three planes of the developable drawn from any point of the line, two coincide with this plane; and on this line there is a point, (T), with the property that the three planes of the developable drawn from it all coincide with this plane. The line is called a *generator* of the developable; it is the dual of the tangent line of the cubic curve above explained. The point T is similarly the dual of the osculating plane of the cubic curve.

It can be proved, however, that, like the conic, the cubic curve is a self-dual construct, the osculating planes forming a cubic developable; and, similarly, the cubic developable is self-dual, the points T above obtained describing a cubic curve, the osculating plane of which, at the point T, is the plane of the developable in which T has been constructed. Thus, not only does the osculating plane of the cubic curve, at a point P, have all its three intersections with the curve coincident at P, but the three osculating planes which can be drawn of the cubic curve through a general point, all coincide, when this point is at P, with the osculating plane at P. The tangent lines of the cubic curve are the generators of the cubic developable which is the aggregate of its osculating planes, and, dually, the tangent line of the locus of the points T is the generating line PQ. The locus of the points T, regarded as arising from the developable, is often called the *cuspidal edge* of the developable.

The proof that the cubic curve is a self-dual construct in the sense explained is very easy with the symbols. The curve being regarded as the locus of the point $(\theta^3, \theta^2, \theta, 1)$, the plane whose equation is $x-py+qz-rt=0$, where $p=\alpha+\beta+\gamma$, $q=\beta\gamma+\gamma\alpha+\alpha\beta$, $r=\alpha\beta\gamma$, evidently contains the three points of the curve for which $\theta=\alpha$, $\theta=\beta$, $\theta=\gamma$. Thus the plane whose equation is

$$x-3\theta y+3\theta^2 z-\theta^3 t=0$$

is the osculating plane at the point θ. Evidently three such planes pass through an arbitrary point. Further, these planes meet the plane $t=0$, the osculating plane at $\theta^{-1}=0$, in the lines

$$x-3\theta y+3\theta^2 z=0,$$

which are tangent lines of the conic $t=0$, $3y^2=4xz$, the point of contact of one such line with this conic being $(3\theta^2, 2\theta, 1, 0)$; and these planes meet the plane $x=0$, the osculating plane at $\theta=0$, in the lines $3y - 3\theta z + \theta^2 t = 0$, which are tangent lines of the conic $x = 0$, $3z^2 = 4yt$, the point of contact of one such line with this conic being $(0, \theta^2, 2\theta, 3)$. The generator of the developable formed by these planes, being the line joining the points of contact of the variable plane with these conics, is the line whose general point is expressed by $(3\theta^3, 2\theta^2 + \lambda\theta^2, \theta + 2\lambda\theta, 3\lambda)$; this is immediately proved to be the tangent of the original curve at the point θ. The general point of a tangent line of the cubic, of which, as has been remarked, the coordinates are $3\theta^3, (\lambda + 2)\theta^2, (2\lambda + 1)\theta, 3\lambda$, is easily shewn to describe a surface of which the equation is $V^2 = 4UW$, where $U = xz - y^2$, $V = xt - yz$, $W = yt - z^2$. Thus four tangent lines of the cubic curve meet an arbitrary line; or, through an arbitrary line can be drawn four planes each of which contains a tangent line of the cubic curve. Dually, the generators of the cubic developable meet an arbitrary plane in the points of a curve of which four points lie on an arbitrary line of this plane. This plane meets the cuspidal edge, which is a cubic curve, in three points. Each of these three points is a *cusp* of this plane quartic curve; that is, it is a double point of this curve, or a point such that every line, in the plane of the curve, drawn through this point, meets the curve in two coincident points at this point (and, therefore, meets the quartic curve in two other points); and it is a double point at which the two tangents of the curve coincide. It is for this reason that the name cuspidal edge is given.

As the notion of a developable, and its cuspidal edge, is fundamental for the understanding of the dual of a curve, it may be desirable to refer to a concrete representation. Let two pieces of paper, laid one over the other, be simultaneously cut by a pair of scissors along an open portion of an arbitrary curve, say an arc of a circle, which thus becomes a portion of the boundary of each piece of paper. Let the two pieces of paper be now connected along this arc by means of tissue paper gummed to both pieces of paper, to the upper side of the upper piece of paper and to the lower side of the lower piece. Now let tangent lines be drawn to this arc on the upper side of the upper piece of paper, and on the lower side of the lower piece; let the portion of a tangent line on the upper piece which lies on one side of the point of contact with the arc be coloured red, and the continuation of this tangent which lies on the lower piece be also coloured red; let the other portion of this tangent line on the upper piece be coloured blue, and the continuation of this tangent which lies on the lower piece be also coloured blue; let this be done, in a continuous way, for a succession of tangent lines. If now the two pieces of paper be lifted by a corner of the upper piece, not lying on the arc, the paper being stiff enough for the red tangent lines, which are partly on one sheet and partly on the other, to remain straight, the blue lines being allowed to curve, and the arc not remaining in a plane, these red lines will represent generators of a developable surface of which the arc is a portion of the cuspidal edge; at each point of this edge there will be a red tangent line. (Thomson and Tait, *Natural Philosophy*, Part I (1879), p. 114, § 149.)

We may usefully consider the properties of a cubic developable in more detail, taking the steps dual to those followed for the cubic curve. As a line joining two points of the curve is called a chord, let the line of intersection of two planes of the developable be called an *axis*. As for the cubic curve we took two quadric cones with a common generator, so now we take two conics, say Σ and Σ', in different planes, say ϖ and ϖ', both conics touching the line of intersection of their planes. A plane of the developable will be any plane touching both these conics; it will meet the two planes in tangents of the two conics, of which each will determine the other by the fact that they intersect on the line of intersection of the two planes. In particular each of the two given planes will be a plane of the developable. In the case of the cubic curve two chords determine a quadric surface containing the curve, and from any point of the cubic there passes a line, intersecting these two chords and all the other chords which are generators of this quadric, of the same system; these chords determine an involution of pairs of points of the cubic curve, and project from any point of the curve into chords of a conic meeting in a point. Conversely, if an arbitrary line be drawn from any point of the cubic curve, and the chord be drawn to the cubic from any point of this line, these chords are generators of a quadric surface. In the dual figure, if any point, P, be taken in the plane ϖ, two tangents can be drawn from P to the conic Σ, meeting the line of intersection of the planes ϖ, ϖ' in two points; from each of these can be drawn, beside this line of intersection, a tangent line to the conic Σ', and these meet in a point, P', of the plane ϖ'. The line PP' is an axis of the developable, and the construction establishes a $(1, 1)$ correspondence between the points of the planes ϖ, ϖ', which is in fact of the kind considered (Vol. I, p. 148). In the original figure there is similarly a correspondence between the planes drawn through the vertex of one of the two cones with the planes drawn through the vertex of the other cone. Consider now various points P lying on an arbitrary line of the plane ϖ. These will be the dual of various planes passing through the vertex of one of the two cones of the original figure, all having in common a line through this vertex. The axes PP' will then be all generators of a quadric surface, touching all the planes of the developable; the pairs of these planes through the various axes PP' will be pairs of an involution of planes of the developable; the locus of the points P' will be a line, which, like the line on which P is taken, is a generator of the quadric surface generated by the lines PP'. So long as this quadric surface does not degenerate, these two corresponding lines of the planes ϖ, ϖ' do not intersect. This happens, however, when the line on which P varies is a tangent line of the conic Σ; then the locus of P' is a tangent of the conic Σ', and the plane of these intersecting lines is a plane of the developable. In the original figure the corresponding statement is: if from two arbitrary points as centres lines be drawn generating two related central systems, so that the points in which these lines meet a plane, not passing through the centres, are two related plane systems, then corresponding lines, one from each centre, do not in general intersect; when, however, they do, their point of intersection lies on a cubic curve, and the intersecting lines are generators of two quadric cones which intersect in this curve. This gives a new definition of the curve. The theorem relates to the most general way of relating two central systems of lines. What particular cases can arise will be seen from the detailed consideration of two related plane systems given later.

Examples in regard to the cubic curve in space. *Ex.* 1. The tangent line of the curve at any point is a generating line of the quadric cone projecting the curve from this point; the osculating plane of the curve at this point is the tangent plane of this cone along this generator.

Ex. 2. The osculating planes at any three points of the curve meet in a point lying in the plane containing these points. If the point of meeting be (x_0, y_0, z_0, t_0), the plane has the equation $xt_0 - 3yz_0 + 3zy_0 - tx_0 = 0$. This is the focal plane of the point (x_0, y_0, z_0, t_0) in regard to the linear complex expressed by $l + 3l' = 0$; in particular when (x_0, y_0, z_0, t_0) is on the curve, it is the osculating plane of the curve at this point, all the tangent lines of the curve belonging to this linear complex. Further, if any line be taken, and the four tangents of the cubic curve which meet this line, the second of the two transversals of these four tangents is the polar line of the first in regard to this linear complex.

Ex. 3. Since the four planes which join a chord of the cubic curve to four arbitrarily chosen fixed points, A, B, C, D, of the curve form a pencil related to that of the planes joining these points to any other chord, it follows that all the chords of the curve belong to a quadratic tetrahedral complex depending upon A, B, C, D (see Chap. II, p. 99 above). If the values of the parameter θ which belong to the points A, B, C, D be, respectively, a, b, c, d, the coordinates, relative to A, B, C, D, of any point of the cubic, can be taken to be $(\theta - a)^{-1}$, $(\theta - b)^{-1}$, $(\theta - c)^{-1}$, $(\theta - d)^{-1}$, and the line coordinates l, l', etc., of any chord are then such that

$$ll'/(b-c)(a-d) = mm'/(c-a)(b-d) = \text{etc.}$$

Ex. 4. Shew that the general equation of a quadric surface containing the cubic curve, of which the general point is $(\theta^3, \theta^2, \theta, 1)$, is $A\xi + B\eta + C\zeta = 0$, where $\xi = xz - y^2$, $\eta = xt - yz$, $\zeta = yt - z^2$, one system of generators of this meeting the curve in the pairs of points (θ), (ϕ), of the involution given by $A\theta\phi + B(\theta + \phi) + C = 0$. Further, that the line coordinates of the chord of the curve passing through any point (x, y, z, t) are, respectively, $\eta^2-\xi\zeta$, $\eta\zeta$, ζ^2, $-\xi\zeta$, $\xi\eta$, $-\xi^2$.

Ex. 5. We have seen that a cubic curve lying on a quadric surface meets every generator of the surface of one system in one point, and every generator of the other system in two points. Thus, taking the intersections, with a fixed arbitrary plane section of the quadric, of the generators through the points of the curve, there is determined on this section a (1, 2) correspondence (see Vol. II, p. 134). Conversely, such a correspondence upon any plane section of the quadric determines two cubic curves lying on the surface.

Ex. 6. If A, B, C, A', B', C' be any six points of the cubic curve, the three quadric surfaces containing the curve, of which the first contains the two chords BC', $B'C$, the second contains the two chords CA', $C'A$, and the third the two chords AB', $A'B$, have all in common, as generator, another chord of the curve (cf. Vol. II, p. 16). Further, any chord of the curve is met in pairs of points of an involution by the quadrics through the six points.

Ex. 7. A cubic developable is formed, we have seen, by the planes joining corresponding points of three related ranges of points, on three lines, of which no three corresponding points are in line. If we have five lines l, m, l', m', p, in space, of which no two intersect, these lines not having a common transversal, and, from a variable point of p, the transversal be drawn to l and m, and also the transversal to l' and m', the plane of these two transversals describes a cubic developable, of which the five given lines are axes (cf. Ex. 22, below). If P, Q describe related ranges upon a conic, and R describe a range related to both, on a line not in the plane of the conic, prove that, in general, the planes PQR form a cubic developable. Also, if P, Q, R describe three related ranges of points on a cubic curve, the planes PQR form a cubic developable. Further, if the points P, Q of a cubic curve are in (2, 2) correspondence, so that to any position of P corresponds two positions, Q and Q', of Q (and conversely), then the planes PQQ' form a cubic developable, and the point of this plane which is the intersection of the osculating planes at P, Q, Q', of the original cubic, describes another cubic curve.

Ex. 8. From the variable point P, of a fixed straight line, the chord PQR is drawn to a cubic curve, and thereon is taken the point, T, which is the harmonic conjugate of P in regard to R and Q. Thus T is conjugate to P in regard to all quadrics containing the curve. Prove that the locus of T is a cubic curve, meeting the given cubic in four points. Further, if $P_0Q_0R_0T_0$ be a particular position of the line $PQRT$, and O be a fixed point of the cubic, and the transversal from O to $PQRT$ and $P_0Q_0R_0T_0$ meet the latter in

P', prove that the ranges (P), (P') are related, the planes joining O to the chords $PQRT$ being tangents of a quadric cone. This cone also touches the fixed line, on which P is taken. Also, for a fixed position of P, the polar planes of P in regard to the cones which project the cubic from the points of the curve, envelope a quadric cone whose vertex is T.

Ex. 9. If six lines, of which no two intersect, be all met by another line, shew that a variable plane, whose points of intersection with the seven lines lie on a conic, describes a cubic developable, of which the first six lines are axes. (Cf. Ex. 7, p. 195, below.)

Ex. 10. It is a familiar fact that if $f, = ax^2 + 2hxy + by^2$, and $f_1, = a_1x^2 +$ etc., be two quadratic forms in x, y, and we take the two values of x/y for which, for proper values of λ/λ_1, the form $\lambda f + \lambda_1 f_1$ is a perfect square, the quadratic $F, = Ax^2 +$ etc., which vanishes for these values of x/y, is such that both the expressions $Ab - 2Hh + Ba$, $Ab_1 - 2Hh_1 + Ba_1$ vanish (Vol. II, p. 8). More generally, if $f_r, = a_{r0}x^n + na_{r1}x^{n-1}y + \ldots + a_{rn}y^n$, for $r = 1, 2, \ldots, n$, be n forms each homogeneous of the nth order in x, y, there are n sets of values of the ratios of $\lambda_1, \lambda_2, \ldots, \lambda_n$ such that the form $\lambda_1 f_1 + \ldots + \lambda_n f_n$ is the nth power of a linear form, $px + qy$. The form F, of the nth order, which vanishes for the n values of x/y for which these linear forms vanish, is expressed by a determinant of $(n+1)$ rows and columns of which the $(s+1)$th row consists of the elements $a_{1s}, a_{2s}, \ldots, a_{ns}, y^{n-s}(-x)^s$. Denoting this form by $A_0x^n + nA_1x^{n-1}y +$ etc., each of the n expressions

$$A_0\, a_{r,n} - nA_1 a_{r,n-1} + \binom{n}{2} A_2\, a_{r,n-2} - \text{etc.}$$

is zero, and F is the form which is *apolar* to all the forms $f_1, \ldots, f_n$ (cf. Vol. II, p. 114, etc.).

Ex. 11. Any plane drawn through an arbitrary point, O, has an equation of the form $\lambda_1 U_1 + \lambda_2 U_2 + \lambda_3 U_3 = 0$, where

$$U_r = a_r x + 3b_r y + 3c_r z + d_r t \quad (r = 1, 2, 3),$$

and $U_r = 0$ are three planes of general position through this point. If f_r denote what U_r becomes by putting θ^3, θ^2, θ, 1, respectively, for x, y, z, t, it is in accordance with Ex. 10 that three osculating planes of the cubic curve can be drawn through the point O. By that example, the three points of the cubic curve, say A, B, C, where these osculate the curve, correspond to a cubic form which is apolar to that corresponding to the three intersections of the curve with any plane drawn through O. We call O the pole of the plane ABC. Thus, in particular, any plane drawn through the chord of the cubic which passes through O, meets the curve in three points giving rise to a cubic which is apolar with the cubic associated with the points

A, *B*, *C*. Thus we infer that the Hessian of this last cubic (*A*, *B*, *C*), corresponds to the ends of the chord of the curve drawn through *O* (cf. Vol. II, p. 124). Further, it follows, as on p. 136 of Vol. II, that an involution of sets of three points upon the cubic curve is given by the intersections of the curve with planes through an arbitrary fixed line; and, then, as here, that if one of these sets of points, *A*, *B*, *C*, be such that the pole, *O*, of the plane *ABC*, lies upon this line, then this is the case for every one of the sets, every two of which are then apolar. In general, the poles of planes passing through a line (l, m, n, l', m', n') lie on the line $(-3l', m, n, -\frac{1}{3}l, m', n')$.

Ex. 12. We have seen in Vol. II (p. 124) that the Hessian points of three points, *A*, *B*, *C*, of a conic, may be obtained by taking the three points such as the intersection of the line *BC* with the tangent of the conic at *A*, and then the points where the line containing these three points meets the conic. When the cubic curve is projected to a conic, on an arbitrary plane, from any point, *D*, of itself, any point of this conic may evidently be represented by the parameter, θ, appropriate to the point of the cubic of which it is the projection. From this we have a construction for the Hessian pair of the three points *A*, *B*, *C* of the cubic, and for the chord of this curve drawn through the pole, *O*, of the plane *ABC*: namely, if we take the line in which the plane *DBC* is met by the plane joining *D* to the tangent line of the curve at *A*, the three such lines lie on a plane through *D*, whose intersections, other than *D*, with the curve, are the Hessian points of *A*, *B*, *C*. The chord joining these points meets the plane *ABC* in its pole, *O*. Or, if the tangent lines of the curve at *A*, *B*, *C*, respectively, meet the planes *DBC*, *DCA*, *DAB* in *A′*, *B′*, *C′*, the plane *A′B′C′* contains *D*, and contains the Hessian chord of *A*, *B*, *C*.

Ex. 13. Now let, again, *A*, *B*, *C*, *D* be any four points of the cubic curve. As the osculating planes of the curve at *A*, *B*, *C* meet in a point, *O*, of the plane *ABC*, and similarly for the osculating planes of any three of these four points, the four points such as *O* form a Moebius tetrad both in- and circumscribed to *A*, *B*, *C*, *D* (Vol. I, p. 61). But, also, if *A′*, *B′*, *C′*, *D′* be the points where the tangent lines of the curve at the points *A*, *B*, *C*, *D*, respectively, meet the planes *DBC*, etc., it follows from the preceding example: (i), that the points *A′*, *B′*, *C′*, *D′* form a tetrad in- and circumscribed to *A*, *B*, *C*, *D*, the plane *A′B′C′* containing *D*, etc., and, (ii), that the points *A′*, *B′*, *C′*, *D′* are a tetrad which is also in- and circumscribed to the tetrad of the four poles such as *O*, the plane *A′B′C′* containing *O*, while *D′* lies in the osculating plane at *D*. Thus, if *L* be the pole of the plane *DBC*, namely the intersection of the osculating planes at *D*, *B*, *C* and, similarly, *M*, *N* be the poles of the planes *DCA*, *DAB*, respectively, the three tetrads *A*, *B*, *C*, *D*; *L*, *M*, *N*, *O*;

A', B', C', D' are such that every two are a pair of Moebius tetrads. It can be shewn to follow from this that the four planes $AA'L$, $BB'M$, $CC'N$, $DD'O$ meet, in threes, in a tetrad in- and circumscribed to each of the three tetrads referred to. For this it is sufficient to shew that the three planes $AA'L$, $BB'M$, $CC'N$ meet in a point lying on the planes ABC, $A'B'C'$ and in the osculating plane at D. The theorem, however, is a case of that enunciated in the succeeding example.

Ex. 14. The general tetrad of points, A_1, B_1, C_1, D_1, forming a Moebius tetrad with four points A, B, C, D, are a set whose coordinates, relative to A, B, C, D, are capable of the forms

$$(0, -n_1, m_1, -l_1), (n_1, 0, -l_1, -m_1), (-m_1, l_1, 0, -n_1), (l_1, m_1, n_1, 0),$$

depending on the ratios of the arbitrary quantities l_1, m_1, n_1. Another such tetrad, depending on l_2, m_2, n_2, form a Moebius tetrad with A_1, B_1, C_1, D_1 if $l_1l_2 + m_1m_2 + n_1n_2 = 0$. Thus a set of four tetrads of which every two are Moebius tetrads arises if $(l_1, m_1, n_1, 0)$, $(l_2, m_2, n_2, 0)$, $(l_3, m_3, n_3, 0)$ are a self-polar triad of points in regard to the conic $t = 0$, $x^2 + y^2 + z^2 = 0$.

Two tetrads, A_1, B_1, C_1, D_1 and A_2, B_2, C_2, D_2, each both inscribed and circumscribed to A, B, C, D, can also be obtained by taking AA_1, BB_1, CC_1, DD_1 as the transversals to two arbitrary generators, of the same system, of an arbitrary quadric, in regard to which A, B, C, D are self-polar, and AA_2, BB_2, CC_2, DD_2, as the transversals to two other generators of the same system. When the two latter generators are harmonic conjugates in regard to the two former, then the two tetrads, A_1, B_1, C_1, D_1 and A_2, B_2, C_2, D_2, are also mutually inscribed. In this case the four planes such as DD_1D_2, AA_1A_2 give rise, by their intersections, to a fourth tetrad inscribed and circumscribed to the previous three tetrads. (See pp. 67, 68, above.)

Ex. 15. Four such tetrads are also representable, for any values of a, b, c, d, by the rows (or by the columns) of the scheme

$$\begin{array}{cccc}
iPi & iPj & iPk & iP \\
jPi & jPj & jPk & jP \\
kPi & kPj & kPk & kP \\
Pi & Pj & Pk & P
\end{array}$$

where $P = ai + bj + ck + d$, the symbols i, j, k are such that

$$i^2 = j^2 = k^2 = -1, \quad jk = -kj = i, \quad ki = -ik = j, \quad ij = -ji = k,$$

and $xi + yj + zk + t$ represents the point (x, y, z, t).

Ex. 16. We may consider a general involution of sets of four points upon the cubic curve, given (Vol. II, p. 136) by the condition $U + \lambda V = 0$, for varying values of λ, where U, V are each polynomials of the fourth order in the parameter θ which gives a point of the curve. It can be shewn: (a), that the tetrads of points of the cubic so obtained are all self-polar in regard to a certain quadric; (*b*), that the planes joining three points of the tetrad are those of a cubic developable. In fact, if θ_1, θ_2 be two roots of the quartic equation, so that $U_1+\lambda V_1=0$, $U_2+\lambda V_2=0$, the identity $(U_1V_2-U_2V_1)/(\theta_1-\theta_2)=0$, which does not depend on λ, is linear in regard to both the two sets (x_1, y_1, z_1, t_1), (x_2, y_2, z_2, t_2), where $x_1=\theta_1^3$, $y_1=\theta_1^2$, $z_1=\theta_1$, $t_1=1$, $x_2=\theta_2^3$, etc., and is symmetrical in regard to the two points with these coordinates. Thus it expresses that these points are conjugate in regard to a definite quadric. Further, denoting this relation by $(\theta_1, \theta_2)=0$, we also have $(\theta_1, \theta_3)=0$, $(\theta_1, \theta_4)=0$. Thus the coordinates of the plane joining the points $(\theta_2, \theta_3, \theta_4)$, which are 1, $-(\theta_2+\theta_3+\theta_4)$, $\theta_2\theta_3+$ etc., $-\theta_2\theta_3\theta_4$, appear as proportional to four cubic polynomials in θ_1. Therefore, as θ_1 varies, the plane $(\theta_2, \theta_3, \theta_4)$ describes a cubic developable. This may be spoken of as the polar reciprocal of the given cubic curve in regard to the quadric surface obtained. The theorems, however, arise incidentally below (Ex. 28).

Ex. 17. If a cubic curve in space, and a conic, have three points in common, a quadric surface exists containing both curves. Also, if two cubic curves in space have five points in common, a quadric surface exists containing both curves; this is not necessarily the case for two cubic curves with only four common points. Prove, further, that two cubic curves lying on a quadric surface have four common points, or five common points; the former is the case when the curves are such as to have the lines of the same system of generators of the quadric as chords, the latter when this is not so. Shew that in the latter case the cubic curves have no common chord other than a join of two of the five common points.

Ex. 18. It has been shewn that a cubic curve can be described to contain six arbitrary points. Shew that a cubic curve can be constructed to pass through five arbitrary points and have a given line as chord. In fact, two independent quadrics can be constructed to pass through the five points and have the line as a generator. Or, if coordinates be taken with four of the five given points as points of reference, a transformation of the form

$$x'=Ax^{-1},\ y'=By^{-1},\ z'=Cz^{-1},\ t'=Dt^{-1},$$

changes the given line into a cubic curve through the four points of reference; from the point which arises, by this transformation, from the fifth given point, a single chord can be drawn to this curve. The curve which is sought is that obtained from this chord by applying the inverse of the transformation referred to.

Ex. 19. Now consider the problem of describing a cubic curve through four given points to have two given lines as chords. Through such a curve would pass a quadric surface containing the lines as generators; in general, however, a quadric surface cannot be drawn through four given points to contain also two given lines. The construction of the cubic curve is, therefore, impossible in general. Suppose however the given lines are two generators, of the same system, of a quadric surface containing the four given points. Then we have seen that a cubic curve can be drawn to satisfy the given conditions, lying on the quadric surface and passing through a fifth arbitrary point of this surface (p. 129, above). Consider the case when the given lines intersect.

Ex. 20. Next suppose we are given three points and three lines of general position. We can clearly describe a cubic curve to have these lines as chords, containing the three points. We have only to consider related axial pencils of planes having these lines as axes, these pencils being related by the fact that three corresponding planes meet in each of the three given points.

Ex. 21. If we are given two points and four lines, of which no two intersect, a cubic curve can be constructed passing through the two given points to have each of the four given lines as a chord. For, let A, B be the given points and l, m, l', m' the given lines. Consider the transversal, a, drawn from A to meet l and m, and the transversal, a', drawn also from A, to meet l' and m', and the plane of these two transversals. Consider also the transversal, b, drawn from B to meet l and m, and the transversal, b', also drawn from B, to meet l' and m', and the plane of these two transversals. These two planes meet in a line, n, which is the only line other than AB which meets the four lines a, a', b, b'. If a cubic curve exists through A, B with l, m, l', m' as chords, it lies on a quadric containing l and m, of which therefore a, b are also generators; for each of a, b contains, beside, the point A or B, two other points of the quadric, lying, respectively, on l and m. The curve equally lies on a quadric containing l' and m', of which therefore a', b' are also generators. These two quadrics, having this cubic in common, must further intersect in a line, which then is a chord of the curve, and of the same system of generators of the first quadric as are l, m; it will therefore meet a and b. Similarly it will meet a', b'. The common generator is, therefore, the line n. Conversely, let a quadric, which is unique, be constructed to contain the lines l, m, n; this quadric then contains a, b and, therefore, A and B. Similarly, the quadric containing the lines l', m', n contains a', b' and, therefore, A and B. These two quadrics, having n in common, determine the cubic curve required, as their remaining intersection.

Ex. 22. If we are given one point, and five lines of which no two intersect, these lines not having a common transversal, a cubic curve exists passing through the given point of which the five given lines are chords. Denote the point by A, and the lines by l, m, l', m', p. Remark first that, by means of the two given pairs of lines, l, m and l', m', a definite plane is determined through any point, P, of space, namely the plane of the transversals drawn from P to l, m and from P to l', m'. Denote this plane by (P). As P varies on the line, p, this plane, describing related ranges on l, m, l', m', p, describes a cubic developable, of which these lines are axes. Of this developable there is then one definite axis on the plane (A), say the line n; this is the intersection of two planes of the developable, passing through positions of P, say B and C, upon the line p; the three planes of the developable which pass through B consist of the plane (B), and the two planes intersecting in the axis p. Evidently, now, A is the intersection of a line meeting l, m, n and a line meeting l', m', n; as, similarly, are B and C. The two quadric surfaces, with n as common generator, determined, respectively, by l, m, n and l', m', n, thus meet in a cubic curve having l, m, l', m' as chords, passing through A, B, C; this curve, therefore, has also p as a chord, and is the curve desired.

It may be remarked, in anticipation, that when the five given lines have a common transversal (in which case there is a position of P on p for which the plane (P) is indeterminate) there are cubic curves in infinite number having these lines as chords; but these all lie on a surface (a cubic surface; *v.* p. 175); one such cubic curve can be drawn passing through two points of this surface.

Ex. 23. If we have two cubic curves in space, of general position, there are ten lines each of which is a chord of both curves. To prove this, first notice that through any point, O, of one cubic, ρ, can be drawn six chords of this curve each of which meets the other curve, σ. For the points of the curve, into which the curve σ is projected from O on to an arbitrary plane, have coordinates proportional to cubic polynomials of the parameter which gives the position of a point of the curve σ; if these be substituted in the equation of the conic into which the curve ρ is projected from O, the result is an equation of order six. Now take any variable point, P, of the curve ρ, and draw from it the chord to the curve σ, meeting it in Q and Q'. From Q draw the chord to the curve ρ, and so from Q'. The point P of the curve ρ thus gives rise to four other points of this curve; let P' be one of these. To pass back from P' to P, we must first draw from P' a chord of ρ which meets σ, say in Q, which is possible in six ways; and then from Q we must draw a chord of σ which meets ρ, in the point P, also possible in six ways. The point P' thus arises from thirty-six different possible positions of P. Thus, if θ, θ' be the parameters giving the positions of P, P', respectively, upon the curve ρ, there is a relation $(\theta, \theta')=0$, an integral polynomial in both θ and θ', of order 36 in

θ and of order 4 in θ'. Or, as it is usual to say, there is a correspondence (36, 4) between P and P' (cf. Vol. II, p. 134). The values of θ and θ' are therefore the same for $36+4$ or 40 values of θ. When this is the case the chord PQQ', drawn from the point P, of ρ, to meet σ in Q and Q', meets ρ again, say in the point H. This common chord however arises in four ways in the construction given: not only when P coincides with a corresponding position P' arising with Q as intermediary, but also when P coincides with a corresponding position arising with Q' as intermediary; and not only when P coincides with P', but also when H coincides with a corresponding position, arising through Q or Q'. The number of common chords of the two curves is therefore one quarter of 40, namely is ten.

Ex. 24. We can hence shew that, if we be given six lines, of general position, there are six cubic curves all having these six lines as chords. Let these lines be l, m, l', m', p, q. We have shewn in Ex. 22 that a cubic curve having the five lines l, m, l', m', p as chords has, as another chord, an axis of the cubic developable described by the planes (P), there explained, as P moves on p. Similarly this cubic, if it have q also as a chord, has as another chord an axis of the cubic developable described by the planes (Q), as Q moves on q. This other chord is the same in both cases, being that meeting the curve in the common pair of the two involutions determined thereon by l, m and by l', m'. These two cubic developables have, however, by the dual of Ex. 23, ten common axes. Of these, four are the lines l, m, l', m'. There remain then six others. Taking any one of these, say n, the cubic required is the locus other than n, of the common points of the quadrics (l, m, n), (l', m', n).

The theorem that there are six cubic curves having six given chords is subject to modification when these chords are not lines of general position. For instance, when the six lines have a common transversal, it may be shewn that there is only one proper, or undegenerate, cubic curve having these as chords. Or again, when every five of the six given lines have a common transversal, there is an infinite number of such curves. Or, as another case, when the six lines, say a, b, c, l, m, n, are such that each of the three sets of five, b, c, l, m, n; c, a, l, m, n; a, b, l, m, n, have a common transversal, there is no proper cubic curve with the six lines as chords; in this case six degenerate curves, each consisting of three lines of which one meets the other two, can be found.

Ex. 25. The theory of the last preceding examples is essentially due to Cremona (*Crelle's J.*, Vol. LX, 1862, p. 191. See also Cayley, *Papers*, Vol. VII, p. 170, 1870). Another method of proof employs a method of transformation which it is desirable to explain. We have already above employed a reversible cubic transformation $x' = Ayzt$, $y' = Bzxt$, $z' = Cxyt$, $t' = Dxyz$, which changes a line into a cubic curve having four fixed points. A reversible cubic transformation of much generality is obtained by taking three fixed quadric surfaces, and making correspond to any point, (x, y, z, t), the point of intersection, (x', y', z', t'), of the polar planes of (x, y, z, t) in regard to these surfaces. Then, as (x, y, z, t) describes any line, the three polar planes describe axial pencils of planes, all related to the range of points (x, y, z, t), whose axes are the polar lines of the line in regard to the three quadric surfaces. Thus (x', y', z', t') describes a cubic curve, having these lines as chords. We can however choose the three quadric surfaces so that the cubic curve so obtained has four fixed lines as chords, which are independent of the line of which the cubic curve is the transformation, and may be taken quite arbitrarily; conversely, in this case, any cubic curve having these four lines as chords is transformed into a line. By the transformation so obtained, the theorem, for example, that a cubic curve can be described to pass through two given points and have four given lines as chords, becomes the theorem that a line can be drawn through two points. Again, the theorem that a cubic curve can be drawn through a given point to have five given lines as chords, when these lines have no common transversal, becomes the theorem that a line can be drawn through an arbitrary point to be a chord of a given cubic curve. Lastly, the cubics having six given lines, of general position, as chords become, by the transformation, the common chords, other than four given ones, of two given cubics.

We may obtain the particular cubic transformation in question, in dual form, in a simple manner, by proceeding as follows: Taking the Moebius tetrads, A, B, C, D and A', B', C', D', the latter points being of equations relative to the former, respectively $U=0$, $V=0$, $W=0$, $P=0$, where $U = c'v - b'w - ap$, $V = -c'u + a'w - bp$, $W = b'u - a'v - cp$, $P = ua + vb + wc$, the point-pairs (A, A'), (B, B'), (C, C'), (D, D') are not independent, their equations being connected by the identity $uU + vV + wW + pP = 0$. Thus the poles of an arbitrary plane in regard to these four point-pairs lie in one plane, as do the poles of an arbitrary plane in regard to three independent quadrics. The pole of a plane in regard to a point-pair, such as A, A', is the point of the line AA' which is the harmonic conjugate, in regard to A and A', of the point where the plane meets the line AA'. The new plane may be taken to correspond to the original plane, which, conversely, corresponds to the new plane by the same rule. It is this correspondence which is effected by the transformation in question. Consider, now, all the planes which correspond, by this rule, to the planes, say α, which can be drawn through an arbitrary fixed line, say l. If a plane α meet the lines AA', BB', CC', respectively, in U, V, W, the ranges (U), (V), (W), being sections of an axial pencil of planes, are related; therefore, the ranges (U'), (V'), (W'), where U', V', W' are the points lying respectively on AA', BB', CC' for which the ranges A, U, A', U'; B, V, B', V'; C, W, C', W' are harmonic, are also related. Whence, the plane $U'V'W'$ describes a cubic developable. Of this developable each of the lines AA', BB', CC', DD' is an axis. For instance, there are two planes α, passing through l, of which the corresponding planes both pass through DD', those, namely, containing l and the two common transversals of the four lines l, AA', BB', CC'; it is, in fact, a property of two Moebius tetrads that, when U, V, W are in line, the plane $U'V'W'$ contains DD' (Chap. I, p. 67, Ex. 20). The two planes α may also be defined as the two tangent planes through l of the quadric described to have the lines AA', BB', CC' as generators.

It is now to be shewn, conversely, that given any four lines, of which no two intersect, it is possible to find two Moebius tetrads, A, B, C, D and A', B', C', D', of which A, A' are on the first line, B and B' on the second, and so on. This is always possible; formulae applicable for this purpose are given in Ex. 22, p. 68; it is only necessary to express that the four pairs of points A, A'; B, B', etc., each harmonic conjugates in regard to the points in which their join is met by the two common transversals of the four joins, are not independent.

Dually, the polar planes of a point, P, in regard to the plane pairs, $x\xi = 0$, $y\eta = 0$, $z\zeta = 0$, $t\tau = 0$, where

$$\xi = a't + bz - cy,\ \ldots,\quad \tau = -(a'x + b'y + c'z),$$

meet in a point P', which, as P describes a line, l, of general position, describes a cubic curve having as chords the four lines, k, such as $x = 0 = \xi$. The points of intersection of the cubic with one of these lines, k, correspond to the points where the original line, l, meets the quadric containing the other three of the lines k.

An incidental consequence of the last remark may be referred to in passing: In order that it may be possible to describe a cubic curve touching each of the four given lines, it is necessary and sufficient that the four quadrics each containing three of these lines should all be touched by a line. It can be shewn that they are then touched by an infinite number of lines, all generators of a quadric, of the same system. There is then an infinite number of cubic curves touching the four lines. This is also clear by considering that if we take four tangents of a cubic curve there is an infinite number of linear complexes to which these four tangents belong; the poles, in regard to any one of these complexes, of the osculating planes of the given cubic curve, describe another cubic curve also touching the four given tangents. The problem of finding a common tangent line of the four quadrics which each contain three of four non-intersecting lines is the same, in fact, as of finding a plane section of a quadric surface, which contains four points A, B, C, D, which shall touch the sections of this surface by the four planes BCD, CAD, ABD, ABC. For the surface

$$fyz + gzx + hxy + t\,(ux + vy + wz) = 0,$$

the condition that this shall be possible can be shewn to be $l^{\frac{1}{2}} + m^{\frac{1}{2}} + n^{\frac{1}{2}} = 0$, where $l = \sigma\,(fu)^{\frac{1}{2}}$, $m = \epsilon\,(gv)^{\frac{1}{2}}$, $n = \sigma\epsilon\,(hw)^{\frac{1}{2}}$, in which $\sigma^2 = 1$, $\epsilon^2 = 1$. If $(l_1, m_1, n_1, l_1', m_1', n_1')$, etc., be the line coordinates of four tangent lines of a cubic curve, and

$$\varpi_{12} = l_1 l_2' + l_2 l_1' + \text{etc.},$$

it can be proved that $\alpha^{\frac{1}{4}} + \beta^{\frac{1}{4}} + \gamma^{\frac{1}{4}} = 0$, where $\alpha = \varpi_{23}\varpi_{14}$, etc.

Ex. 26. There is another problem of construction for cubic curves which may be referred to: Given four lines of general position, and upon each of them an involution of pairs of points, there are two cubic curves having these four lines as chords whose points of meeting with each of these lines are a pair of the involution lying thereon. This may be deduced from a theorem, given by Chasles (*Liouville's J.*, t. IV, 1839, p. 348), that the lines of space which meet the generators of one system of a quadric surface in points lying on pairs of a given involution, of pairs of these generators, are lines of a linear complex. (Above, Ex. 15, p. 67.)

Ex. 27. Consider a cubic curve, θ, and a quadric surface, Σ. Let l, m be any two chords of the curve. To any plane, α, drawn through l, meeting the curve again in a point P, can be drawn a plane, β, through m, conjugate to the former in regard to Σ. As α varies, describing an axial pencil about l, the plane β will describe a related axial pencil about m, and if β meet the curve again in Q, the ranges (P), (Q) will be related. The pairs of points P, Q will then belong to an involution on the curve if, for one pair, not only Q corresponds to P but P also corresponds to Q (Vol. II, p. 2); that is, if not only the planes lP, mQ be conjugate in regard to Σ, but also the planes lQ, mP be conjugate.

Now suppose that upon the curve θ there are four points, A, B, C, D, forming a self-polar tetrad in regard to Σ. Take any point, T, of the curve, and let its polar plane in regard to Σ meet the curve in X, Y, Z. We can then shew that T, X, Y, Z are a self-polar tetrad in regard to Σ. For consider pairs of planes, conjugate to one another in regard to Σ, drawn respectively through the chords BC and YZ; the plane joining YZ to D, which is the pole of the plane BCA, is conjugate to this plane, joining BC to A; similarly the plane joining YZ to A is conjugate to the plane joining BC to D. Wherefore, these pairs of planes determine an involution on the curve. But the plane joining BC to T is conjugate to the plane joining YZ to X, since T is the pole of the plane XYZ; wherefore the plane BCX contains the pole of the plane YZT. By similar reasoning the pole of the plane YZT lies on each of the six planes joining X to a pair of the points A, B, C, D. This pole is therefore at X. Similarly, Y, Z are the poles of the planes ZXT, XYT, respectively, and X, Y, Z, T are a self-polar tetrad.

A cubic curve which contains four points forming a self-polar tetrad in regard to a quadric Σ will be spoken of as *outpolar* to Σ. It contains not only other self-polar tetrads, as has been proved, but is such that it is met by any quadric, S, which is outpolar to Σ, and does not contain the curve, in six points, say H, forming what has been called a self-conjugate hexad in regard to Σ (Chap. I, p. 47), that is, six points such that the plane containing any three of them is conjugate, in regard to Σ, to the plane containing the other three. A descriptive proof of this may be given. But we may argue as follows: Since there are three independent quadric surfaces containing the curve, all of which contain the points of any self-polar tetrad of points of the curve, we have, through the six points H, four quadrics all of which are outpolar to Σ, namely the three quadrics containing the curve and the quadric S. The equations of these four quadrics are linearly independent, since S does not contain the curve; and, as there are ten terms in the equation of a quadric, the number of quadrics through six points, with equations which are linearly independent, is just four. The number could be more than four only if every quadric described through five, or fewer, of these points, necessarily passed through the others (as a plane described through three of four coplanar points necessarily passes through the other). The six points H have not this character, since, else, a degenerate quadric consisting of a plane through three of the points and a plane through two others would necessarily pass through the sixth. Thus we can infer that every quadric passing through these points H is outpolar to the quadric Σ; in particular a pair of planes containing these six points form together such an outpolar quadric, that is they are conjugate in regard to Σ. Conversely, of such a self-conjugate hexad of points upon the cubic curve, five points may be taken arbitrarily. In particular, if we take five points upon the curve, X, Y, Z, T, U, of which T, U are the extremities of the chord of the curve drawn through the pole of the plane XYZ, in regard to the quadric Σ, then every other point of the curve forms with these five a self-conjugate hexad;

thence it follows that the pole of the plane containing any three of the points X, Y, Z, T, U lies on the line joining the other two. These points constitute then what is called a self-conjugate pentad.

We have defined the cubic as outpolar to Σ when it contains four points forming a self-polar tetrad of Σ. It can, however, be shewn that if the cubic contains the points of a self-conjugate hexad (or of a pentad), it contains also the points of a self-polar tetrad. This is obvious from what was shewn in Chap. I (p. 51); for, thence, the four linearly independent quadrics containing the six points will all be outpolar to Σ; in particular, the three quadrics passing through the curve. Also, it may be remarked, in the notation of p. 47, that if A, B, C, D, E, F be a self-conjugate hexad of points of the curve, the quadric $\Phi(A, B, C, D)$ is that quadric containing the curve which contains the chord EF and is outpolar to Σ.

Ex. 28. A cubic curve, θ, consists of the points common to three quadrics of which every two have a common generator, and is outpolar to a quadric Σ when this last is inpolar to the three former quadrics containing the curve. Similarly a cubic developable, Θ, consists of the planes common to three quadrics regarded as aggregates of their tangent planes, of which every two have a common generator, and the cubic developable may be spoken of as inpolar to a quadric S when this last is outpolar to the three tangential quadrics defining the developable. When Σ consists of the tangent planes of S, we may speak of the curve θ as outpolar to the developable Θ. This case has already arisen in a preceding example (Ex. 16); if an involution of sets of four points be taken on θ, each of these sets forms a self-polar tetrad in regard to a certain quadric, and the planes containing threes of the four points are those of a developable Θ.

Ex. 29. If A, B, C, D and A', B', C', D' be two tetrads of points both self-polar in regard to a quadric, the cubic curve, described to contain A, B, C, D and C', D', has $A'B'$ for a chord, meeting this in two points, P, Q, which are harmonic conjugates in regard to A' and B'. For, by what we have seen, the polar plane of D', in regard to the quadric, which passes through C', meets the curve again in points, P and Q, such that D', C', P, Q are a self-polar tetrad. Thus P, Q lie on the join of A', B' and are harmonic in regard to these.

The equation of the general quadric through A, B, C, D, C', D' is of the form $\lambda U + \mu V + \nu W + \rho\Phi = 0$, where $U=0$, $V=0$, $W=0$ may be taken to be independent quadrics containing the cubic curve through these six points. As these three quadrics contain P and Q, we see that the quadrics through the six points meet the line PQ in pairs of points of an involution, of which P, Q are one pair. One such quadric, therefore, contains both A' and B'. Thus, there are three independent quadrics, containing the eight points A, B, C, D, A', B', C', D', any quadric containing A, B, C, D, B', C', D' necessarily passing also through A'.

Any seven general points may be regarded as being seven points from two tetrads which are both self-polar in regard to a properly chosen quadric. For a quadric can be found having four points as a self-polar tetrad, in regard to which every two of three other arbitrary points are conjugate to one another; the pole of the plane of these three, in regard to this quadric, then forms a second self-polar tetrad.

Thus we infer that if two tetrads, of points of general position, be both self-polar in regard to a quadric, any two tetrads formed from these eight points are also two self-polar tetrads in regard to a properly chosen quadric. Also, that all quadrics passing through seven general points pass also through an eighth point. This eighth point may be found by drawing the cubic curve through any six of the seven given points, and then the chord to this curve from the seventh point, and taking thereon the harmonic conjugate of the seventh point in regard to the two points where the chord meets the curve. Or, if the seven given points be A, B, C, D, B', C', D', the eighth point is A', constructed as above, as the pole of the plane $B'C'D'$ in regard to the quadric for which A, B, C, D is self-polar and every two of B', C', D' are conjugate.

In another phraseology, if we have two self-polar tetrads in regard to a quadric, the cubic curve containing any six of the points is outpolar to the point-pair constituted by the remaining two, regarded as a degenerate tangential quadric. The squares of the left sides of the equations of the eight points are in fact connected by a linear relation (cf. Chap. I, p. 51).

Eight points which are such that all quadrics through seven of them necessarily pass through the remaining one, are said to be eight *associated* points. Some particular properties of such a set are given below (p. 154).

Ex. 30. Prove that the squares of the left sides of the equations of eight points of a cubic curve are connected by a linear relation of the form $\Sigma c_r P_r^2 = 0\ (r = 1 \dots 8)$. See, for instance, *Proc. Lond. Math. Soc.* IX, 1910, p. 174. For the theory of outpolar cubics, see also Wakeford, *ibid.*, XXI, 1922, p. 101, and *ibid.* p. 114. For the descriptive theory, see Telling, *Proc. Camb. Phil. Soc.*, XXI, 1922, p. 249.

Ex. 31. Consider a focal system (p. 60), and a quadric, such that two particular lines which are polars in the focal system are also polars of one another in regard to the quadric. Let P_1, P_2 be any two points of which the focal planes, respectively ϖ_1, ϖ_2, intersect in the line P_1P_2. Denote by δ the interval P_1P_2 measured with respect to the quadric, in the manner employed for a conic in Vol. II, p. 168, and by θ the angular interval between the planes ϖ_1, ϖ_2, similarly measured with respect to the tangent planes drawn from the line P_1P_2 to the quadric. Consider $\sin\theta/\sin\delta$, expressing this when the focal system and quadric are given by

$$n + kn' = 0, \quad Ax^2 + By^2 + Cz^2 + Dt^2 = 0.$$

Shew that the quadric can be so taken that $\sin\theta/\sin\delta$ is independent of P_1 and P_2 (cf. Lie-Scheffers, *Berührungstransformationen*, 1896, p. 233. The corresponding theorem given by Lie for a non-linear complex, *ibid.*, p. 308, is not true).

The rational curve of order n in space of n dimensions. A conic in a plane, and the cubic curve in three dimensions, are evidently both particular cases of a curve in space of n dimensions, of which the coordinates, $x_0, x_1, \ldots, x_n$, of any point of the curve, are respectively proportional to $(n+1)$ integral polynomials in a variable parameter, say θ. We do not enter into the general theory here; but it seems well to remark that any curve in space of r dimensions, in which $r < n$, of which the coordinates of any point are expressible as polynomials of order n in a variable parameter, θ, may be regarded as arising, by projection, from this curve of order n in space of n dimensions; which is thus of fundamental importance. For instance, to illustrate a general proof of this theorem, consider a curve in a plane of which the coordinates, x, y, z, of any point, are expressible as cubic polynomials in θ. Take a point (X, Y, Z, T), in space of three dimensions, of which X, Y, Z are precisely the same functions of θ as are x, y, z, while T is an arbitrary cubic polynomial. This point (X, Y, Z, T) then describes a cubic curve in three dimensions. But to any point of this curve there follows by the equations $x/X = y/Y = z/Z$, that is by projection from the point $(0, 0, 0, 1)$, a corresponding point of the given plane curve. This plane curve has, therefore, a double point, lying on the chord of the space cubic which can be drawn to it from $(0, 0, 0, 1)$; but the space cubic has no double point. For, if it had, a plane, drawn through this double point and two arbitrary points of the curve, would meet the curve in four points, and, therefore, contain it entirely. By a similar argument the curve in space of n dimensions is without double points.

It is supposed in general, in speaking of a curve which is representable rationally by a parameter, that not only is one point of the curve given by each value of the parameter, but, conversely, only one value of the parameter corresponds to a general point of the curve. The parameter can therefore be defined as a rational function of the coordinates of the point of the curve. It can be shewn that if a parameter has been chosen for which this converse expression is not possible, another parameter, a rational function of the former, can be substituted for which this is possible (cf. Vol. II, p. 136. The several values of the unsuitable parameter which correspond all to the same point of the curve are sets of a general involution).

It is clear that the number of points of the general rational curve of the nth order of which the coordinates satisfy a homogeneous equation of the rth order in the $(n+1)$ coordinates, is nr. It is characteristic of the curve that these can be arbitrarily taken. For instance, there are $2r$ points of a conic lying upon a general curve in the plane whose equation is given by a homogeneous equation of order r in the coordinates; but, conversely, such a curve of order r can be drawn through any $2r$ points taken upon the conic, as may be readily verified. Or, again, a surface of equation of order r can be drawn through any $3r$ points taken arbitrarily upon the cubic curve in space of three dimensions, not entirely containing the curve. For instance, a quadric surface can be drawn through any six points of the curve, not entirely containing the curve; or a cubic surface, not entirely containing the curve, through any nine points.

Ex. 1. Find the most general relation, homogeneously of the third order in x, y, z, t, which is identically satisfied by $x=\theta^3$, $y=\theta^2$, $z=\theta$, $t=1$.

Ex. 2. Shew that if a general cubic surface, expressed by the vanishing of a homogeneous relation of the third order in x, y, z, t, be put through two non-intersecting generators of a quadric surface, the remaining intersection is a curve meeting an arbitrary plane in four points, of which the coordinates of a point are expressible rationally by a parameter. Shew, also, how to define, by intersections of manifolds in space of four dimensions, a rational curve of order four which projects into this curve.

Ex. 3. Shew that the equations, for x, y, z, t in terms of a parameter θ,

$$(p\theta+a)x=\theta x_2+ax_1,\ (p\theta+b)y=\theta y_2+by_1,\ \ldots,\ (p\theta+d)t=\theta t_2+dt_1$$

represent a quartic curve containing the points of reference and the two points (x_1, y_1, z_1, t_1), (x_2, y_2, z_2, t_2); and that it can be made to pass through two further arbitrary points by suitable choice of the constants a, b, c, d, p. In how many ways is this possible? Find a quadric surface, and a cubic surface containing this curve.

Ex. 4. Shew that a conic, regarded as a curve in three dimensions, depends upon eight parameters. In particular, given seven lines of which no two intersect, which have a common transversal, prove that there exists a single conic which meets every one of the seven lines and also meets the transversal. Analytically, we may regard the conic as the intersection of two quadric cones whose vertices are on the transversal, which touch along this line; we are thus led to seven linear homogeneous equations in eight unknown coefficients. (See Ex. 7, p. 195, below.)

It may be proved that there are ninety-two conics meeting eight lines of general position. See J. Lüroth, *Crelle*, LXVIII (1868), and C. Hierholzer, *Math. Annal.* II (1870).

The curve of intersection of two general quadric surfaces. If two quadric surfaces have a common self-polar tetrad of points, their curve of intersection is essentially different from the cubic curve which has been considered. The coordinates of its points cannot be expressed rationally in terms of a parameter; they can be expressed rationally in terms of *two* parameters, of which one is the square root of a quartic, or cubic, polynomial in the other, or, what is the same thing, if x, y, z, t be the coordinates of a point of the curve, a cubic curve can be found in a plane, in which the coordinates are ξ, η, ζ, this curve being expressed by the vanishing of a homogeneous cubic polynomial in ξ, η, ζ, such that the ratios of x, y, z, t are rational functions of the ratios of ξ, η, ζ, and the ratios of ξ, η, ζ are rational functions of the ratios of x, y, z, t. Such a cubic curve is obtained by projecting the space curve on to a plane from any point of itself. Further, this space curve has the property that, of its intersections with an arbitrary surface, not all can be arbitrarily taken, one of them being always determined when the others are assigned. For instance, the curve meets an arbitrary plane in four points; but, of these, one is determined by the plane containing the other three. Or again, it can be shewn that the curve meets a general quadric surface in eight points (see below); and that the quadric surfaces through seven of these all pass through the remaining one, which, therefore, cannot be taken arbitrarily upon the curve when these seven are given.

Ex. 1. If two quadric surfaces be expressed by the respective equations

$$x^2 + y^2 - z^2 = t^2, \quad ax^2 + by^2 - cz^2 = t^2,$$

any point upon the former is given in terms of θ and ϕ by the expressions $x = \theta + \phi$, $y = 1 - \theta\phi$, $z = 1 + \theta\phi$, $t = \theta - \phi$; if this point lie also on the latter there is a (2, 2) relation connecting θ and ϕ, by means of which either is expressible rationally in terms of the other, and the square root of a quartic polynomial in this other. The systematic consideration of this relation is best undertaken in close connexion with the theory of elliptic functions, and we do not enter upon this here.

Ex. 2. Prove that the quartic curve in space now being considered meets in two points every generator of any quadric surface which contains the curve. Further, that if a variable plane be drawn through two points of the curve, the join of its two other intersections with the curve describes a quadric surface containing the curve. Further, that such a curve can be drawn through eight general points of space. Also, that two chords of the curve can be drawn through an arbitrary point, not lying thereon; and that no line exists meeting the curve in three points.

Ex. 3. Shew that the algebraic determination of the common self-polar tetrad of two general quadrics can be carried out as for the common self-polar triad of two conics given p. 141 of Vol. II; and that the theorem for the reality of the roots of the determining quartic equation, given for the cubic on p. 165 of Vol. II, remains also true.

The determination of a quadric by given conditions. The equation of a quadric contains ten terms; that the quadric should pass through a point of assigned coordinates imposes one linear condition for the coefficients in its equation. That the quadric should pass through several, say through r, given points, requires r such linear conditions for the ten coefficients. If these conditions are independent there are $10-r$ of the coefficients in terms of which the remaining ones can be linearly expressed; then the equation of the general quadric through the r assigned points is of the form $\Sigma\lambda_s U_s = 0$, with $s = 1, \ldots, 10-r$, wherein the $\lambda_1, \lambda_2, \ldots$ are arbitrary, but $U_1=0$, $U_2=0$, ... represent definite quadrics passing through the assigned points. When this is so the assigned points are called *independent*. It may happen however that, of the r linear conditions for the ten coefficients, one or more is obtainable as a linear aggregate of the others; a very simple example would be that in which four of the assigned points were in line; then a quadric containing any three of these would contain the line, and the condition that it contained the fourth point would be a consequence of the conditions that it contained these three. Algebraically, as the equations are linear, the equation expressing the fourth condition would be a linear function of the equations expressing the three others. These considerations have their application chiefly when the assigned points are already conditioned in some way, as by lying on a curve, or a surface.

For instance, upon the curve of intersection of two quadric surfaces there must be sets of eight points furnishing independent conditions for quadrics required to pass through them; there cannot be nine such independent points; for, by definition, such nine points entirely determine a quadric, whereas, in the present case, if $U=0$, $V=0$ be the given quadrics, the quadric $U+\lambda V=0$ contains all points of their common curve, in particular the nine points, and can yet, by choice of λ, be made to pass through a further arbitrary point. But there must be as many as eight independent points upon the curve; for if, for example, there were but seven, this would mean that every quadric through these seven necessarily contained all points of the common curve; it would then be possible to describe a quadric through this curve and two other arbitrary points. We can, however, prove that only one quadric can be passed through this curve and a further single point, O; namely by considering the section of the quadrics with a general plane drawn through O. In this argument we have spoken of a quadric passing through all the points common to two given quadrics, as if this were a description quite free of ambiguity; when the given quadrics have multiple points of intersection, as for example in the case when they touch at all points of a plane conic, the description needs interpretation. This is furnished by first agreeing as to what is meant by a conic passing through all the points common to two given conics, even when there are coincidences among these; and then speaking of a quadric as passing through all points common to two given quadrics when it meets every plane in a conic which passes through all the points common to the sections, by this plane, of the two given quadrics. It will be seen that this meets all cases.

Ex. 1. The necessary and sufficient condition that two quadrics $U = 0$, $V = 0$ should intersect in two conics, lying in planes $P = 0$, $Q = 0$, is the existence of an identity of the form $\lambda U + \mu V + \nu PQ = 0$, where λ, μ, ν are constants. And this remains true when the two conics coincide, the quadrics touching one another at all points of this.

Ex. 2. Three quadric surfaces, which have no common curve, meet in eight points. Taking for points of reference a self-polar tetrad for one of the quadrics, the common points may be found by substituting, in both the other two quadric equations, the coordinates $x = \theta + \phi$, $y = 1 - \theta\phi$, $z = 1 + \theta\phi$, $t = \theta - \phi$. The result is two equations, $(2, 2) = 0$ and $[2, 2] = 0$, which are both polynomials of the second order in each of θ and ϕ. The elimination of ϕ between these leads to an equation for θ by the solution of which the intersections can be found. Geometrically, regarding $(\theta, \phi, 1)$ as coordinates in a plane, the statement is that two quartic curves in a plane, which have common two double points, have eight other common points. The result may be regarded as always true, by proper interpretation of multiple intersections.

Ex. 3. Every quadric through seven points of space of which no four lie in a plane, and, therefore, no three lie in a line, has an equation of the form $\lambda U + \mu V + \nu W = 0$, wherein U, V, W can be supposed to be of the respective forms

$$yz + (a_1 x + b_1 y + c_1 z)\,t,\ zx + (a_2 x + b_2 y + c_2 z)\,t,\ xy + (a_3 x + b_3 y + c_3 z)\,t.$$

We can now prove that $U = 0$, $V = 0$, $W = 0$ have eight common points, so once more proving that all quadrics through seven given points have an eighth point common. In fact $V=0$, $W=0$ both contain the line $x=0$, $t=0$; thus they also intersect in a cubic curve, meeting this line in two points. This curve will meet $U=0$ in six points; these, with the two points in which $U=0$ is met by the line $x=0$, $t=0$, are the eight points in question, and, of these six, two are on the line $y=0$, $z=0$. If we put $x=\theta t$ in $V=0$, $W=0$, we find $a_2x+b_2y+(c_2+\theta)z=0$, $a_3x+(b_3+\theta)y+c_3z=0$, from which we have the expression of the cubic curve by the parameter θ. Substituting this expression in $U=0$, the determination of the four points of intersection of the three quadrics, beside the given points of reference (1, 0, 0, 0), (0, 1, 0, 0), etc., is reduced to the solution of a quartic equation.

Upon the curve of intersection of two general quadrics, there can be taken such seven independent points as we have supposed. Thus, the curve of intersection of two general quadrics is such that, of its intersections with another quadric, one is determined by the assignment of the other seven.

Ex. 4. Shew that if three quadric surfaces have a line in common, they have four common points not lying on this. And, if three quadric surfaces have a conic in common, they have two common points not lying thereon.

Ex. 5. If all possible quadric cones be constructed which contain six arbitrary fixed points of general position, prove that the vertices of these cones lie upon a surface meeting an arbitrary line in four points (Weddle's surface). Shew that this surface contains the fifteen lines joining the pairs of the six given points, and the ten lines of intersection of the pairs of planes each containing three of the points; and contains also the cubic curve passing through the six given points. Any line drawn through one of the six given points meets the surface in only two other points.

Ex. 6. The vertices of the quadric cones containing seven arbitrary fixed points of general position lie upon a curve which meets an arbitrary plane in six points. This curve has for chords the twenty-one joins of the seven points, and also the seven joins of these points to the further point common to all the quadrics containing these seven given points. (Hesse, *Crelle's J.*, XLIX, 1855, p. 279.)

Theorems for eight associated points. Some results may be given in regard to a set of eight points which are such that every quadric through seven of them also passes through the eighth.

Ex. 1. If A, B, C, M, D', L be six points of a conic it follows, from Pascal's theorem, that the point (CM, LA) is on the line joining the point (AB, MD') to the point $(BC, D'L)$.

Now let A, B, C, D be any points of a quadric surface, of which l and m are two generators of the same system. Let these generators meet the section of the quadric by the plane ABC respectively in

L and M, and let the generator of the quadric, of the opposite system, which passes through D, meet this section in D'. The point (CM, LA) is then on the line of intersection of the planes Cm, lA; the point (AB, MD') is the point where the line AB meets the plane mD, and may be described as the point (AB, mD); so the point $(BC, D'L)$ is the point (BC, Dl). Thus the line (Cm, lA) meets the join of the points (AB, mD), (BC, Dl).

Ex. 2. Let A, B, C, D and A', B', C', D' be any general set of associated points. There are then three linearly independent quadrics passing through these, and a quadric can be put through A, B, C, D to have $A'B'$ and $C'D'$ as generators of the same system. Denoting the points, respectively, by the numbers 3, 4, 5, 8 and 1, 2, 6, 7, and identifying the lines l, m of Ex. 1 respectively with the generators 12, 67, we thus reach the result that, if 1, 2, 3, 4, 5, 6, 7, 8 be a general set of associated points, the line (123, 567) intersects the join of the two points (34, 678), (45, 812).

Ex. 3. If we then remark that this join lies on the plane 345, we see that this join is also met by the line (345, 781). Again, the line (234, 678) contains the point (34, 678), and the line (456, 812) contains the point (45, 812). Thus the four lines

(123, 567), (234, 678), (345, 781), (456, 812)

are all met by the line joining the points, (34, 678), (45, 812). These four lines are, however, only interchanged among themselves by cyclical interchange of the numbers; it follows that they are met also by the join of the points (45, 781), (56, 123), and so on, in all by eight such joining lines. Thus the four lines are generators of the same system of a quadric.

Ex. 4. Let 2, 3, 4, 5, 7, 8 be any six points, and 1 a further point. From the last point let the transversal be drawn to the lines 23, 57, meeting these, respectively, in P and P'. Similarly, let Q, on 78, and Q', on 34, be on a line through 1; and R, on 45, with R', on 82, be also on a line through 1. The lines QR', RP', PQ' are then generators of a quadric, of which $Q'R$, $R'P$, $P'Q$ are also generators. This quadric meets the lines 23, 34, 45, 57, 78, 82, respectively, in other points P_1, Q_1', R_1, P_1', Q_1, R_1'. It can be shewn that the three lines P_1P_1', Q_1Q_1', R_1R_1' meet in a point. Denoting this by 6, the points 1, 2, ..., 8 are eight associated points. The proof follows easily from Ex. 2.

Ex. 5. For the determination of the eighth point of an associated set when seven are given, we have, by what precedes, two theorems: (1), the cubic curves determined by the two sets of six points, A, B, C, D, A', C'; A, B, C, D, B', C' have, respectively, chords meeting in the eighth point, D', required. The chord of the first curve is that drawn from B', that of the second curve is that drawn from A'. Or, as we have seen (Ex. 18, p. 139, above) that a single cubic curve exists passing through five given points, having a given line as chord, we can regard D' as the common point of the various cubic curves constructed each to pass through five of the seven given points and have the join of the other two as chord. (2), if A, B, C, D be a self-polar tetrad in regard to a quadric, and every two of A', B', C' be conjugate in regard to this quadric, the point D' is the pole of the plane $A'B'C'$ in regard to this. Hesse has given a linear construction for D' founded on this last fact (see *Ges. Werke*, pp. 46, 48, 680. See also Cayley, *Papers*, I, p. 425 (1849), for another view of the problem); it depends upon a theorem of plane geometry: In a plane let A, B, C be a self-polar triad in regard to a conic, and P, U; Q, V; R, W be three pairs of conjugate points in regard to this conic; then the polar lines, respectively l, m, n, of U, V, W, can be linearly constructed. Let BU, AV meet in O; let PO meet AC in Y, and QO meet BC in X; further, let XV meet AQ in H, and YU meet BP in K. Also let AC meet HK in L, and BC meet HK in M. Then PL is the polar of U, and QM the polar of V. Similarly, the line n can be constructed.

This being assumed, and the points A, B, C, D, A', B', C' given as above, let the six lines DA', $B'C'$, DB', $C'A'$, DC', $A'B'$ meet the plane ABC, respectively, in U, P, V, Q, W, R. The triad ABC will be self-polar in regard to the conic in which the quadric meets the plane ABC, and the polar line of DA' will be a line, l, lying in this plane and in a plane which contains $B'C'$. Thus the polar line of U in regard to this conic will be the line l, and this will contain P. Similarly V, Q will be conjugate points in regard to this conic, the polar line, m, of V containing Q; and W, R will be such that the polar line, n, of W, contains R.

The lines l, m, n being constructed as explained, the point D', required, is the intersection of the planes $(l, B'C')$, $(m, C'A')$, $(n, A'B')$.

Ex. 6. If the curve of intersection of two general quadric surfaces be projected on to a plane from any point of itself, it becomes a cubic curve. Conversely, it can easily be shewn that a curve in a plane, expressed by the vanishing of a homogeneous cubic polynomial in the three coordinates, may be regarded as arising by the projection of the curve of intersection of two quadric surfaces. Bearing in mind that the latter curve meets every generator, of a quadric surface on which it lies, in two points, the theorem that seven points in space determine an eighth is at once seen to be in correspondence with the theorem, for a plane, that all general cubic curves with eight common points pass through a ninth. We may construct this ninth point as follows: let A, B, C, M, N and P, Q, R be eight points of a plane, and D a point not lying in this plane; let Ω be a quadric containing A, B, C and the lines DM, DN (other than the plane pair ABC, DMN); let DP, DQ, DR meet this quadric (beside at D) in P_1, Q_1, R_1. Now let the cubic curve in space, which contains the five points D, A, P_1, Q_1, R_1 and has BC for a chord, meet Ω again in O_1. Then DO_1 meets the plane in the ninth point required. For this problem see also Cayley, *Papers*, IV, pp. 495–504 (1862). Also p. 178, below.

Ex. 7. A further way of regarding the theorem that quadrics through seven points have an eighth common point should be referred to briefly. Taking five arbitrary points, of which no four lie in a plane, there are five linearly independent quadrics passing through these, say $U_1=0$, $U_2=0$, ..., $U_5=0$. If four of the points be the points of reference and the fifth be (1, 1, 1, 1), the functions $U_1, \dots, U_5$ are in fact arbitrary linear functions of the six functions

$$\xi=y(t-z),\quad \eta=z(t-x),\quad \zeta=x(t-y),$$
$$\xi'=(t-y)z,\quad \eta'=(t-z)x,\quad \zeta'=(t-x)y,$$

which are equivalent to five in virtue of the identity

$$\xi+\eta+\zeta=\xi'+\eta'+\zeta',$$

and are further connected by the relation $\xi\eta\zeta=\xi'\eta'\zeta'$. We may regard the ratios of any five independent linear functions of ξ, η, ζ, ξ', η', ζ' as coordinates of a point of space of four dimensions. Thereby, to any point of our original three-fold space, other than certain exceptional points for which all of $\xi, \eta, \dots, \zeta'$ are zero, there corresponds a point of the three-fold locus, Σ, lying in the four-fold space, for which $\xi\eta\zeta=\xi'\eta'\zeta'$; conversely, save for exceptional points, to any point of this three-fold locus, Σ, there corresponds the point of the original space given by

$$x/t=(\eta'-\zeta)/(\xi-\xi'),\quad y/t=(\zeta'-\xi)/(\eta-\eta'),\quad z/t=(\xi'-\eta)/(\zeta-\zeta').$$

To the general quadric of the original space which passes through the given five points there corresponds, then, in the four-fold space, the intersection of the locus Σ with the locus expressed by an equation of the form $A\xi+B\eta+C\zeta=A'\xi'+B'\eta'+C'\zeta'$, wherein the relation $\xi+\eta+\zeta=\xi'+\eta'+\zeta'$ is understood. Let such a three-fold locus, or space, expressed by a linear equation, be, for distinctness, denoted by σ. To the quadrics of our original space passing through seven given points, consisting of the five chosen fundamental points and two other points, say A and P, will correspond the spaces σ, in the four-fold space, which pass through two given points, say $(\alpha, \beta, \gamma, \alpha', \beta', \gamma')$ and $(\lambda, \mu, \nu, \lambda', \mu', \nu')$, of the locus Σ. These will contain all points of the line joining these two points of Σ; and, as we see by substituting expressions of the forms $\alpha+\phi\lambda, \dots, \gamma'+\phi\nu'$ for the coordinates in the equation of Σ, there is a third point of Σ lying on this line, through which, then, all these spaces σ pass. This is the point corresponding to the eighth intersection of the quadrics in the original space which pass through the seven given points.

The correspondence can be followed in detail. We limit ourselves to the result in the four-fold space which corresponds to the fact that the eighth point lies on the chord, drawn from P, to the cubic curve containing the five fundamental points and the point A. Let this point be (a, b, c, d); this cubic curve is then given by

$$x = a(\theta - a)^{-1}, \quad y = b(\theta - b)^{-1}, \quad z = c(\theta - c)^{-1}, \quad t = d(\theta - d)^{-1},$$

for varying values of θ, the points $(1, 1, 1, 1)$, (a, b, c, d) arising respectively for $\theta = 0$, $\theta = \infty$. It is easily seen that the locus in the four-fold space to which this corresponds is the line given by the three simultaneous equations $\xi/\alpha = \xi'/\alpha'$, $\eta/\beta = \eta'/\beta'$, $\zeta/\gamma = \zeta'/\gamma'$. This line passes through the point $(\alpha, \beta, \gamma, \alpha', \beta', \gamma')$, and lies entirely on the locus Σ. Through this line, and the point $(\lambda, \mu, \nu, \lambda', \mu', \nu')$, corresponding to P, there passes a plane; this plane meets the locus Σ, in fact, in a conic, as we see from the fact that any line meets the locus Σ in three points; the equations of the conic may easily be found. This conic is met by the line, given by the equations $\xi/\alpha = \xi'/\alpha'$, etc., in two points; it corresponds to the chord drawn from P in the original space, to meet the cubic curve; by its construction it contains the point $(\lambda, \mu, \nu, \lambda', \mu', \nu')$, and the line joining $(\alpha, \beta, \gamma, \alpha', \beta', \gamma')$ to this point meets the conic again in the point of Σ which corresponds to the eighth intersection of the quadrics in the original space.

The locus Σ will be found to be of great interest to us. If, instead of $\xi, \eta, \zeta, \xi', \eta', \zeta'$, we use coordinates

$$x_1 = \tfrac{1}{2}(\eta + \zeta - \xi), \qquad x_2 = \tfrac{1}{2}(\zeta + \xi - \eta), \ \ldots,$$
$$x_4 = \tfrac{1}{2}(\xi' - \eta' - \zeta'), \ \ldots, x_6 = \tfrac{1}{2}(\zeta' - \xi' - \eta'),$$

its equations take the forms $\Sigma x_r^3 = 0$, $\Sigma x_r = 0$, $r = 1, \ldots, 6$.

The set of eight associated points was considered by von Staudt, *Beiträge zur Geometrie der Lage*, III, 1860, pp. 372 ff. The theorem of Ex. 2, above, was given by Hesse; see *Ges. Werke*, p. 680, and various papers in *Crelle's J.* The theorem of Ex. 3 was given by Zeuthen; see *Acta Math.* XII, 1889, p. 363. See also Dobriner, *ibid.* p. 339; and Schroeter, *Acta Math.* XIV, 1890. The locus Σ considered in Ex. 7 was studied by Segre; see *Atti Acc. sc. Torino*, XXII, 1886, 7; p. 547.

CHAPTER IV

THE GENERAL CUBIC SURFACE; INTRODUCTORY THEOREMS

In this book we regard the theory of a cubic surface as best treated in connexion with a certain figure in space of four dimensions. But the preliminary theorems for a general cubic surface are so intimately related with other results included in this volume that it seems desirable to give some account of them.

The theorem of a double-six of lines. It is convenient to give at once an independent proof of a theorem which arises implicitly below. Suppose that a, b, c, d, e are five lines, no two meeting one another, which have a common transversal, f'. There is then, beside f', a common transversal of every four of the five lines. The theorem referred to is that the five transversals so arising have themselves a common transversal. Denote by e' the transversal of a, b, c, d, beside f', by d' the transversal of a, b, c, e beside f', and so on. We are to prove that the five lines a', b', c', d', e' are all met by a line. It is clear that no two of these lines intersect; if, for instance, a' and b' were in one plane, every two of c, d, e, all of which meet a' and b', would intersect.

We prove that a', b', c', d', e' have a common transversal by shewing that the common transversal of a', b', c', d', other than e, coincides with the common transversal, other than d, of a', b', c', e'. This we do by shewing that the common transversal, other than e, of a', b', c', d', meets a', b', c', respectively, in three points which can be constructed from the lines a, b, c, a', b', c', f' only. In fact, denoting the nine intersections,

$$(b', c),\ (b, c'),\ (c', a),\ (c, a'),\ (a', b),\ (a, b'),\ (a, f'),\ (b, f'),\ (c, f'),$$

respectively by

$$A,\ A',\ B,\ B',\ C,\ C',\ U,\ V,\ W,$$

we shew that the common transversal of a', b', c', d', other than e, meets a' on the plane (A, A', U), meets b' on the plane (B, B', V), and meets c' on the plane (C, C', W).

Let f denote the common transversal, other than e, of a', b', c', d', and let this meet the lines a', b', c', respectively, in X, Y, Z. Consider the two quadric surfaces (b, c, e) and (b', c', d'), having, respectively, as generators of the same system, the two triplets of lines indicated. As the line e meets b', c', d', it is a generator of the second quadric as well as of the first; as d' meets b, c, e, it is a generator of the first quadric as well as of the second. As these two quadrics have thus two intersecting lines as common generators, their remaining common points lie in a plane. Of such points, not lying on e or d', are the points A, or (b', c), and A', or (b, c'); so also the point U, or (a, f'), is such a point, since the line a, meeting b', c', d', is a generator of the second quadric, and f', meeting b, c, e, is a generator of the first quadric. Lastly, the point X, or (a', f), is common to the two quadrics, since a' meets b, c, e, and f meets b', c', d'. Thus X, where f meets a', lies on the plane (A, A', U). By considering the two quadrics (c, a, e) and (c', a', d'), we similarly shew that Y lies on the plane (B, B', V); and, by considering the two quadrics (a, b, e) and (a', b', d'), that Z lies on (C, C', W).

For the common transversal, other than d, of a', b', c', e', we proceed in the same way, using e', d instead of d', e, respectively. The planes (A, A', U), (B, B', V), (C, C', W) arise once more. The theorem is thus proved.

Such an aggregate of twelve lines

$$\begin{matrix} a, & b, & c, & d, & e, & f, \\ a', & b', & c', & d', & e', & f', \end{matrix}$$

consisting of two sextuples, wherein each line meets five lines of the sextuple to which it does not belong, but is skew to the other lines of its own sextuple, and is also skew to a corresponding line of the other sextuple, is called a double-six. We shall commonly speak of the lines of the double-six which form a sextuple as a *row* of the double-six.

From the twelve lines of the double-six, fifteen other lines can be defined, as follows: associating the lines $a, b, \ldots, f, a', b', \ldots, f'$, respectively, with the numbers $1, 2, \ldots, 6, 1', 2', \ldots, 6'$, let the line of intersection of the plane of a, b', with the plane of a', b, say, of the plane $[1, 2']$ with the plane $[1', 2]$, be denoted by c_{12}; there will be fifteen such lines, obtained by taking every pair of the numbers $1, 2, \ldots, 6$. Fifteen other lines can also be obtained from the double-six: we may join the point of intersection, $(1, 2')$, of the lines a, b', to the point of intersection, $(1', 2)$, of the lines a', b; this construction can be made in fifteen ways. We may denote the joining lines by symbols c_{rs}'.

It has incidentally been shewn above that the four points $(2, 3')$, $(2', 3)$, $(1, 6')$, $(1', 6)$ lie in one plane, this being the fact that the points A, A', U, X are in one plane. Thus the line c_{23}' intersects the line c_{16}'. By a precisely similar argument it follows that, if no two of the numbers r, s, i, j are the same, the lines c_{rs}', c_{ij}' intersect one another. Thence, by the dual argument, the plane of two intersecting lines being considered instead of their point of intersection, it follows, if no two of the numbers r, s, i, j are the same, that any two lines c_{rs}, c_{ij} intersect one another.

We have now two sets, each of (12 + 15, or) twenty-seven lines, one set consisting of $a, b, \ldots, f, a', b', \ldots, f'$, together with the lines c_{rs}, the other set consisting of the same twelve lines together with the lines c_{rs}'. Let us consider the former set. It is easy to see that the lines of this set are symmetrical as regards their intersections with one another: each line of the twenty-seven intersects ten others of the set, and these consist of five pairs of mutually intersecting lines, so that in the plane of any two intersecting lines of the set is a third line of the set. For instance, the line 1 (or a) is met by the ten lines

$$2', c_{12};\ 3', c_{13};\ 4', c_{14};\ 5', c_{15};\ 6', c_{16},$$

which consist of five pairs of intersecting lines. Similarly, the line c_{12} is met by the lines of the five pairs, each of two intersecting lines,

$$1, 2';\ 1', 2;\ c_{34}, c_{56};\ c_{35}, c_{64};\ c_{36}, c_{45}.$$

Further, it is possible to arrange the twenty-seven lines in two sets of, respectively, twelve and fifteen lines, in other than the original way, so that the twelve lines form a double-six, and the fifteen are deducible from these by the same rule as were the lines c_{rs} from the original double-six; there are in fact thirty-six such arrangements. Writing, for greater clearness, 23 instead of c_{23}, and so on, the following twelve lines

$$\begin{matrix} 1, & 1', & 23, & 24, & 25, & 26 \\ 2, & 2', & 13, & 14, & 15, & 16 \end{matrix}$$

are at once seen to form a double-six; further, the lines formed from these, as were the lines c_{rs} from the original double-six, are easily seen to be the other fifteen lines of the original twenty-seven. Such a double-six as this can be constructed in fifteen ways. Another double-six, typical of twenty double-sixes, is given by

$$\begin{matrix} 1, & 2, & 3, & 56, & 64, & 45 \\ 23, & 31, & 12, & 4', & 5', & 6', \end{matrix}$$

and the remaining fifteen lines arise from this by the same rule as before. We see then how to obtain 1 + 15 + 20, or thirty-six, double-sixes.

Reciprocity of the figure. Considering the original double-six, it can be shewn that there exists a quadric surface in regard to which the six lines 1, 2, ..., 6, of one row, are, respectively, the polar lines of the corresponding lines, 1′, 2′, ..., 6′, of the other row. In regard to this quadric surface, then, the line c_{rs} is the polar of c_{rs}'. To prove this, consider the fifteen triplets of lines each consisting of two lines of the first row of the double-six taken with that one of the lines c_{rs} which intersects both; such a triplet is given, for instance, by the three lines 1, 2, c_{12}. With these fifteen triplets consider also the similar triplets each formed from two lines of the second row of the double-six taken with that one of the lines c_{rs} which intersects both, such, for instance, as $3'$, $4'$, c_{34}. Then it can be seen that a definite quadric exists, possibly degenerating into two planes, containing the combination formed by any triplet of the first set of fifteen triplets, taken with any triplet of the second set. For instance, the two triplets 1, 2, c_{12} and $1'$, $2'$, c_{12} both lie in the plane-pair $[1, 2']$, $[1', 2]$, whose line of intersection is the line c_{12}; again, the two triplets 1, 2, c_{12} and $2'$, $3'$, c_{23} lie on the plane-pair of which one plane contains the lines 1, $2'$, c_{12} and the other plane contains the lines 2, $3'$, c_{23}; while two triplets such as 1, 2, c_{12} and $3'$, $4'$, c_{34} consist of three lines 1, 2, c_{34}, of which no two intersect, together with three other such lines, $3'$, $4'$, c_{12}, of which, however, each intersects all the first three, so that the six lines all lie on a quadric surface. Assuming the statement verified, there will be, in all, 15 . 15 or 225 quadrics; it is then, further, the case that the equations of these quadrics, expressed in point coordinates, are linear functions of *nine* of them. For there are three linearly independent quadrics passing through a triplet consisting of two skew lines and a transversal of these: Let P, Q, R, S denote four triplets each containing two lines of the first row of the double-six, and P', Q', R', S' denote four triplets each containing two lines of the second row of the double-six, and let (S, S') denote the quadric containing the triplets S and S', and so in general; then, if the quadrics (S, P'), (S, Q'), (S, R') be linearly independent, the quadric (S, S') is a linear function of these; if the quadrics (P', P), (P', Q), (P', R) be linearly independent, the quadric (S, P') is a linear function of these; similarly, with a like hypothesis, the quadric (S, Q') is expressible by (Q', P), (Q', Q), (Q', R), and the quadric (S, R') by (R', P), (R', Q), (R', R); finally, every one of the quadrics is thus seen to be expressible by the nine obtained by taking P, Q, R with P', Q', R', provided that, in every case, the three quadrics (S, P'), (S, Q'), (S, R') are linearly independent. A detailed scrutiny shews that this is so in general.

There is, however, a single quadric envelope which is inpolar to nine linearly independent quadrics (above, p. 52). Thus there exists a quadric envelope, in general unique, which is inpolar to the 225 quadrics spoken of. This we may denote by Σ; it will sometimes be spoken of as the Schur quadric associated with the double-six.

Now take the three pairs of triplets

$$1, 2, c_{12} \text{ and } 1', 2', c_{12};\quad 1, 2, c_{12} \text{ and } 2', 3', c_{23};\quad 1, 3, c_{13} \text{ and } 1', 2', c_{12},$$

lying, respectively, in the three plane-pairs

$$[1, 2', c_{12}], [1', 2, c_{12}];\quad [1, 2', c_{12}], [2, 3', c_{23}];\quad [1, 2', c_{12}], [1', 3, c_{13}];$$

each of the pairs of planes being conjugate to one another in regard to the quadric Σ, the pole of the plane $[1, 2']$ is seen to be the common point of the planes $[1', 2]$, $[2, 3']$, $[1', 3]$, namely, the point $(1', 2)$. Similarly, the pole of the plane $[1, 3']$ is the point $(1', 3)$. The two planes both contain the line 1, the two points both lie on the line $1'$. Thus the lines $1, 1'$ are polars of one another in regard to the quadric Σ, as are, similarly, 2 and $2'$, 3 and $3'$, etc.

The quadric Σ is in fact determined by the six lines 1, 2, 3, $1'$, $2'$, $3'$, only. These six lines are the edges of a skew hexagon, A, B', C, A', B, C', wherein A, A' are, respectively, the points (b', c), (b, c'), or $(2', 3)$, $(2, 3')$, etc., and the quadric Σ is such that opposite edges of this hexagon are polar lines of one another. Thus the point A, the intersection of the edges AB' and AC', is the pole of the plane $A'BC$, etc. Let the three planes $A'BC$, $B'CA$, $C'AB$ meet in the point D, so that AD is the intersection of the planes $AB'C$, $AC'B$, etc. Then D is the pole of the plane ABC, and A, B, C, D are a self-polar tetrad of points in regard to Σ; while A', B', C' are three points of which every two are conjugate to one another in regard to Σ. These two conditions determine the quadric. It will, however, be seen to be of advantage to have considered the quadric from the point of view we have taken.

Another determination of the double-six. It can be shewn that, if we have six lines, a, b', c, a', b, c', forming a skew hexagon, as here, and another line, d, which meets one set of alternate edges, a', b', c', of the hexagon, then a double-six is determined, which will, therefore, be that here discussed with the same notation for the lines. The proof of this is instructive, and may be given. Consider the aggregate of lines which meet the three skew lines a', b', c', these being the generators, of the other system from these, of the quadric determined by a', b', c'. Let us regard two of these lines, say (x) and (y), as *corresponding*, when they are both met by some transversal of the three other alternate edges, a, b, c, of the hexagon. We can then see that to any (x) there correspond two lines (y), and, to any (y), two lines (x); for when a line (x), meeting a', b', c', is taken, there are two transversals of the four lines (x), a, b, c; if one of these, say (z), be taken, there is a definite transversal (y), beside (x), of the four lines (z), a', b', c'; similarly when (y) is taken first. A line (x), meeting a', b', c', may be defined by a parameter, x, as, for instance, by lying in a definite plane, of equation $U + xV = 0$, passing through a'; the correspondence between the lines (x) and (y) may then be represented by an equation connecting two parameters, x and y; this equation, by the geometrical definition, will be rational, of the second order in each of the parameters, and symmetrical in regard to these. If y_1 and y_2 be the two values of y given by this equation, corresponding to a value of x, it may, or may not, happen, that the two values corresponding to the value, y_1, of x, are x and y_2; this will happen, however, for all values of x if it happen for a particular value. In such case the three values x, y_1, y_2 will be one set of a general involution of triads of values (Vol. II, pp. 135 ff.). If then we can shew that there exists one set of three transversals of a', b', c' with the property that every two of them are met by a transversal of a, b, c, it will follow that, if we take the line d, arbitrarily, to meet a', b', c', and then the lines e, f, also to meet a', b', c', by the condition that e meets the transversal, f', of a, b, c, d, and f meets the other transversal, e', of a, b, c, d, then e and f will also meet a transversal, d', of a, b, c. We shall then have constructed a double-six, clearly unique, from the lines a, b, c, a', b', c', d. It is, however, easy to find one set of three transversals of a', b', c' with the property that every two of them are met by a transversal of a, b, c. For, let O and ϖ be, respectively, a point and a plane which are pole and polar of one another in regard to both the quadrics (a, b, c), (a', b', c'), defined, respectively, by the generators indicated; then, through the point where the line a' meets the plane ϖ, there passes a generator, say a_1', of the quadric (a', b', c'), which meets b' and c', and is the harmonic image of a' in regard to O and ϖ (see above, p. 80); similarly, through the point where the line a meets ϖ, there passes a generator, say a_1, of the quadric (a, b, c), which meets b and c as well as a. With an analogous notation in general, since b' and c' both meet a, it follows that b_1' and c_1', which both meet a', b', c', also both meet a_1. Three transversals of a', b', c' which are such that every two of them are met by a transversal of a, b, c, are, therefore, given by a_1', b_1', c_1'. Thus the proof of the existence of the double-six is completed.

The Steiner trihedral pairs. It has been shewn above that the quadrics containing the pairs of triplets of lines such as r, s, c_{rs} and $r', s', c_{r's'}$ are linearly dependent from nine such quadrics. These may in fact be taken to be those arising from the lines 1, 2, 3, 1′, 2′, 3′, c_{23}, c_{31}, c_{12}, for which the nine quadrics are all plane-pairs. Let the triplets in question, namely

$$2, 3, c_{23};\ 3, 1, c_{31};\ 1, 2, c_{12};\ 2', 3', c_{23};\ 3', 1', c_{31};\ 1', 2', c_{12},$$

be denoted, respectively, by p, q, r, p', q', r', and the planes [2, 3′], [2′, 3], [3, 1′], [3′, 1], [1, 2′], [1′, 2] be denoted, respectively, by α, α', β, β', γ, γ'; the quadrics containing the pairs of triplets

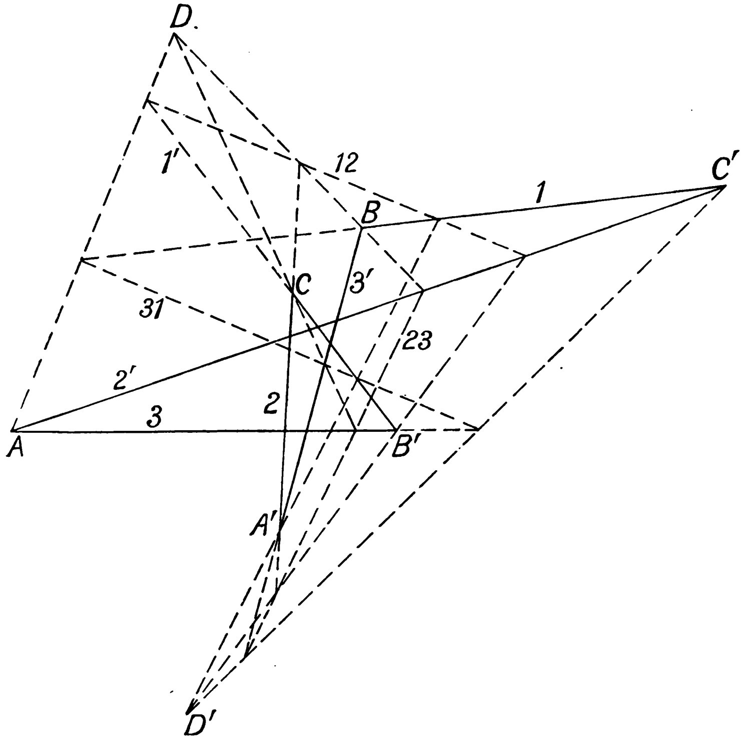
$$q, r';\ q', r;\ r, p';\ r', p;\ p, q';\ p', q;\ p, p';\ q, q';\ r, r'$$

are then, respectively, the plane-pairs

$$\beta, \gamma;\ \beta', \gamma';\ \gamma, \alpha;\ \gamma', \alpha';\ \alpha, \beta;\ \alpha', \beta';\ \alpha, \alpha';\ \beta, \beta';\ \gamma, \gamma'.$$

The nine lines are the intersections of the three planes α, β, γ

with the three planes α', β', γ'. If, as above, we introduce the point D, the intersection of the planes α, β, γ, and the lines DA, DB, DC, joining this to the points $(2', 3)$, $(3', 1)$, $(1', 2)$, respectively, and also introduce the point D', the intersection of the planes α', β', γ', and the lines $D'A'$, $D'B'$, $D'C'$, joining this, respectively, to the points $(2, 3')$, $(3, 1')$, $(1, 2')$, we shall in the aggregate obtain the figure consisting of all the intersections of the six planes α, β, γ, α', β', γ'. This contains twenty points, fifteen lines and six planes, of which each point lies in three of the lines and in three of the planes, each line contains four of the points and lies in two of the planes, while each plane contains ten of the points and five of the lines, so that the incidences can be denoted by the symbol



$$20\,(.,3,3)\,15\,(4,.,2)\,6\,(10,5,.).$$

The twenty points are the six points A, B', C, A', B, C', the points D, D', and the three sets of four points such as, for example, the intersections of c_{12} with 1, $2'$, $1'$, 2. The fifteen lines are the lines 2, $3'$, ..., c_{12}, originally considered, together with the six such as DA; each of these six lines contains three points of intersection of two of the nine original lines; for instance, DA contains the three points $(2', 3)$, $(1, c_{23})$, $(1', c_{12})$; and the nine lines consist of three coplanar triads all in perspective from D, and consist also of three coplanar triads in perspective from D'. The figure is a section, by a three-fold, of the figure in space of four dimensions considered on pp. 214, 215 of Vol. II.

Relatively to the nine original lines, the two triads of planes, α, β, γ, and α', β', γ', may be spoken of as a pair of *Steiner trihedrals.*

Examples of the configuration of twenty-seven lines. *Ex.* 1. It appears, from what has been said, that, from the twenty-seven lines, $a, b, \ldots, f, a', b', \ldots, f', c_{rs}$, a set of six lines can be chosen of which no two intersect, in seventy-two ways. Such a set of six lines being called a sextuple, it will be found that there are sixteen sextuples containing any one of the twenty-seven lines, but that no two sextuples have four lines in common. Conversely, any set of four lines, from the twenty-seven, of which no two intersect, lies in one of the sextuples.

Further, it will be found that two non-intersecting lines can be chosen from the twenty-seven in 216 ways, three lines of which no two intersect in 720 ways, four lines of which no two intersect in 1080 ways, and five lines of which no two intersect in 648 ways. Such a set of five skew lines has at least one common transversal, also one of the twenty-seven lines, and may have two such transversals. There are no sets of seven, or more, lines, among the twenty-seven, of which no two intersect.

Ex. 2. There are in all 135 points of intersection of two lines from the twenty-seven, and any two such intersecting lines are both met by a third line. Of such triads of three coplanar lines from the twenty-seven there are in all 45.

Ex. 3. The twenty-seven lines have been seen to arise from five non-intersecting lines with a common transversal. Now consider the surface which is represented by the vanishing of a general homogeneous polynomial of the third order in the space coordinates; this is called a cubic surface, being met by an arbitrary line in three points, the substitution of values of the forms $x_0 + \lambda x_1$, $y_0 + \lambda y_1$, etc., for the coordinates, leading to a cubic equation in λ. The conditions that a given line should lie entirely on the surface are four in number, all linear in the coefficients of the equation of the cubic surface; thus the conditions for the cubic surface, that it should contain one given line and five other skew lines which meet this are, in all, nineteen in number. The cubic surface, whose equation contains twenty terms, can thus be determined to contain these six lines. The cubic surface will then equally contain the other twenty-one lines constructed as above from these six, since each additional line is such as to meet four of those already taken.

Conversely, we may expect that any cubic surface, of general type, contains such a set of twenty-seven lines. For the figure of five non-intersecting lines with a common transversal is itself of amplitude nineteen, depends, that is, on nineteen constants, as does the equation of a general cubic surface. There are four constants to determine the transversal, five more to fix the points where the other lines meet this, and two more to determine each of these lines, say, by fixing the point where this meets an arbitrary plane. The coefficients in the equation of the cubic surface are then functions of the constants determining the figure; and we may expect that the latter can be chosen to correspond to arbitrary values of the former. But, for this to be so, the nineteen constants of the figure must enter as nineteen effectively independent constants in the expressions, in terms of them, of the coefficients in the equation of the cubic surface. For this it is sufficient that no change in the figure of the six lines, of arbitrarily limited magnitude, shall be possible without a change in the cubic surface.

We may approach the algebraical theorem thus suggested, that a cubic surface expressed by the vanishing of a general cubic polynomial contains twenty-seven lines, in a somewhat different way. There are four algebraic conditions to be satisfied for a line to lie entirely on the surface; and a line depends on four constants. Let us assume thus that the cubic surface contains at least one line; it is then easy to infer the existence of the other lines. Taking the one line to be given by $x=0$, $y=0$, a general plane through this, of equation $x+\lambda y=0$, will meet the cubic surface further in a conic; it is at once proved that the condition for this to break up into two lines is a quintic equation for λ. By the solution of this equation we then have ten further lines on the surface, and the proof of the remaining sixteen, and that there are no more, can be completed. Or, we may initiate the investigation by seeking a plane which meets the cubic surface in three lines; the elimination of one coordinate between the equation of the cubic surface and the equation of the plane leads to a cubic polynomial in the three remaining coordinates; the three coefficients in the equation of the plane are to be chosen so that this cubic polynomial breaks up into three linear factors. In such way it can be proved that for a cubic surface whose equation has real coefficients there are at least three lines whose equations have real coefficients.

It has been shewn that the twenty-seven lines can be constructed from the figure consisting of a skew hexagon together with a transversal of three alternate sides of this hexagon. This figure, we easily see, is also of amplitude nineteen, depending on nineteen constants.

Another figure depending on nineteen constants is that of four lines of which no two intersect together with a point of general position. For a cubic surface to contain this figure requires however only seventeen conditions for the coefficients in the equation of the surface.

Ex. 4. The proof of the reciprocity of the double-six can be obtained also as follows: Consider the figure consisting of three non-intersecting lines, say a, b, c, together with three other non-intersecting lines, say d', e', f', of which every one meets all of the first three. It can be proved that this figure is obtainable, by incidences only, from five suitably chosen points of the figure, or, also, from five suitably chosen planes of the figure. Hence it can be shewn that any two such figures can be regarded as related to one another (in the sense explained in Vol. I, p. 150) so that to every point of one corresponds a point of the other; or can be regarded also as related to one another in such a way that to every point of one figure corresponds a plane of the other figure (v. Staudt, *Beiträge z. Geom. d. Lage*, I, p. 6). When the two figures are formed by the lines (a, b, c, d', e', f') and (a', b', c', d, e, f), of a double-six, it can be shewn that they can be related in the latter of the two ways referred to, with the further limitation that the relation is involutory, a point of either figure being the pole in regard to a quadric surface of the corresponding plane of the other figure. (See E. Stenfors, *Die Schläflische Konfiguration von zwölf Geraden*, Helsingfors, 1921.)

Ex. 5. An interesting special double-six has been discussed by Dr W. Burnside (*Proc. Camb. Phil. Soc.*, XVI, 1911, p. 418). Let A, B, C, D, E be five general points, taken in a definite order, forming a skew pentagon in three dimensions. From each of these points let the transversal be drawn to meet the two lines constituted by, (a), the opposite edge of the pentagon, and, (b), the join of the two vertices of the pentagon which are contiguous to that vertex from which the transversal is drawn. It can be shewn that the five transversals so obtained are all met by two lines. It can further be shewn that if the five original points be taken in all possible orders, just six such pairs of lines, each meeting five transversals described as above, are obtained. And, then, that these six pairs of lines constitute a double-six. This double-six then has the property of being unaltered by a correspondence of the three-fold space to itself, of the kind described Vol. I, p. 150, determined by the fact that the five fundamental points correspond to these same points taken in a different order. It is essentially the only possible double-six unaltered by such a (1, 1) point correspondence, or *collineation*.

The fact that the five transversals spoken of, drawn one from each of the five given points, are all met by two lines, is deducible from the theorem (above, page 68, Ex. 26) that there exists a focal system in which each of the five given points is the pole of the plane containing this and the two contiguous vertices of the pentagon; for, by this theorem, there exists also another focal system in which each point is the pole of the plane joining this point to the opposite edge of the pentagon. Analytically, if the five points be represented by the symbols A, B, C, D, E, subject to

$$A+B+C+D+E=0,$$

and m, m' be the two real numbers for which $m+m'=1$ and $mm'=-1$, it will easily be found that the thirty points obtainable by all symbols of the form $mA+B+C$, which, in another order, are the same as those obtainable by the symbols $m'A+B+C$, lie in fives upon twelve lines forming the double-six in question.

If we also take the ten points whose symbols are the differences, such as $A-B$, of the original symbols, these can be regarded, in ten ways (Vol. II, p. 212), as consisting of two triads in perspective, together with their centre of perspective and three points lying on their axis of perspective. By joining each of these ten points, regarded as centre of perspective, to the three points lying on the corresponding axis of perspective, we obtain in all fifteen new lines. These are in fact the lines c_{rs}, of our preceding theory, to be associated with the double-six above obtained.

If we take four of these ten points, which do not lie in a plane, as fundamental points, X, Y, Z, T, defined by

$$5X=A-E,\quad 5Y=B-E,\quad 5Z=C-E,\quad 5T=D-E,$$

the original five points may be defined in terms of these, namely by

$$A=4X-Y-Z-T,\quad \ldots,\quad E+X+Y+Z+T=0.$$

With coordinates, x, y, z, t, referred to X, Y, Z, T, the twelve lines of the double-six may be shewn to be, respectively, those given by the symbols

$$\begin{gathered}
a\,(y, z, x;\ z, y, t),\quad b\,(z, x, y;\ x, z, t),\quad c\,(x, y, z;\ y, x, t),\\
d\,(t, x, z;\ x, t, y),\quad e\,(t, y, x;\ y, t, z),\quad f\,(t, z, y;\ z, t, x);\\
a'\,(t, x, y;\ x, t, z),\quad b'\,(t, y, z;\ y, t, x),\quad c'\,(t, z, x;\ z, t, y),\\
d'\,(y, z, t;\ z, y, x),\quad e'\,(z, x, t;\ x, z, y),\quad f'\,(x, y, t;\ y, x, z),
\end{gathered}$$

where, for example, the symbol $a\,(y, z, x;\ z, y, t)$ means the line given by the equations $my+z+x=0$, $mz+y+t=0$. If the first row of these be denoted by $1, 2, \ldots, 6$, and the second row by $1', 2', \ldots, 6'$, respectively, the other fifteen lines are then given, respectively, by

$$\begin{gathered}
c_{35}\,(x, y+z);\ c_{26}\,(t, y+z);\ c_{34}\,(t, z+x);\ c_{15}\,(t, x+y);\ c_{14}\,(y+z, x+t),\\
c_{16}\,(y, z+x);\ c_{45}\,(y, z+t);\ c_{56}\,(z, x+t);\ c_{46}\,(x, y+t);\ c_{25}\,(z+x, y+t),\\
c_{24}\,(z, x+y);\ c_{13}\,(z, y+t);\ c_{12}\,(x, z+t);\ c_{23}\,(y, x+t);\ c_{36}\,(x+y, z+t),
\end{gathered}$$

where, for example, the symbol $c_{35}(x, y+z)$ means the line given by

$$x=0,\quad y+z=0.$$

It is easy, now, to verify that these twenty-seven lines all lie on the locus given by the equation

$$x^3+y^3+z^3+t^3-(x+y+z+t)^3=0,$$

and that the lines, $1', \ldots, 6'$, of the second row of the double-six, are, respectively, the polar lines of the lines, $1, \ldots, 6$, of the first row of the double-six, in regard to the quadric whose equation is

$$x^2+y^2+z^2+t^2+(x+y+z+t)^2=0.$$

It may also be verified that one form of the equation of the cubic surface is

$$(my+z+t)(mz+x+t)(mx+y+t)$$
$$=(m'y+z+t)(m'z+x+t)(m'x+y+t).$$

The system of twenty-seven lines here considered is not the most general possible. The lines of the double-six meet in pairs in six points lying on a plane in ten different ways, these being the planes containing the sets of three of the five points A, B, C, D, E; the other fifteen lines meet in threes in ten points, as we have seen, the three concurrent lines lying in a plane. The cubic surface involved is that called by Clebsch the *diagonal* surface.

Geometrical definitions of a cubic surface. Suppose we are given any four lines, a, b, c, d, of which no two intersect, and a point, O, of general position. Let the lines be considered as two couples, a, b and c, d. If now a plane be drawn through O, and its intersections with the lines a, b be joined by a line, and its intersections with c, d be joined by another line, these two joining lines will intersect, in a point, Q, of the plane. We may consider the locus of this point Q for all possible planes drawn through the point O. The locus is in fact one of which there are three points upon an arbitrary line, l. For, consider the two quadrics (a, b, l) and (c, d, l); as they have a common generator, their common tangent planes, other than those containing the line l, form a cubic developable, of which, then, three planes pass through O. Let one of these three planes meet the line l in the point Q; we prove that this is a point of the locus spoken of. The plane in question, touching the quadric (a, b, l), contains a generator of this which meets the lines a, b, l, and, hence, passes through the point Q where the plane meets l. Similarly, a transversal of the lines c, d can be drawn, in this plane, passing through Q. Thus Q is a point of the locus. We thus obtain three points of the locus upon l, and, conversely, can shew that there are no others. When the line l, in place of being general, passes through the point O, two of the planes of the developable through O contain the line l; but there are still two points, Q, upon l, beside O, each an intersection of a line meeting a, b with a line meeting c, d. We may, thus, speak of the locus of Q as a cubic surface. Evidently this surface contains the four lines a, b, c, d; for, for instance, from any point of the line a, a transversal can be drawn to c and d, and the plane through O which contains this transversal will meet b in a point which may be joined to the point already taken on a. Also, the surface contains the transversal drawn from O to a and b; for, from any point of this, a line can be drawn to meet c and d, through which, and the former transversal, there passes a plane containing O. By a similar argument, the surface contains the transversal drawn from O to c and d.

Ex. The figure consisting of four non-intersecting lines and a point, depends on nineteen constants. If the four lines be divided into two pairs, and the two transversals be drawn from the point, one to each of these pairs, we have a new figure, depending on the same constants. And there are three such, corresponding to the three ways in which the four lines can be divided into two pairs.

The conditions that a homogeneous cubic polynomial in the four space coordinates should vanish for every point of each of the four given lines, and also for the given point, are only seventeen in number; but if the cubic polynomial is further to vanish at every point of either of the two transversals drawn from the given point to two pairs of the four given lines, two further conditions are necessary, and only one such cubic polynomial is possible. We expect then that upon the locus represented by the vanishing of such a cubic polynomial, the figure of four lines and two transversals of two pairs of these, will be obtained. We shall in fact identify this figure, below, as arising from the figure of twenty-seven lines previously discussed.

Next, suppose we are given five non-intersecting lines, a, b, c, d, e, which have a common transversal; this transversal may, for the present, be denoted by l; later it will be called f'. Then, the five lines being regarded as consisting of the two couples a, b and c, d, beside the line e, consider the two quadrics (a, b, e) and (c, d, e). As these have in common the two intersecting generators l and e, their common points, other than those on these generators, lie on a plane, and, therefore, on a conic; and their common tangent planes, other than those containing these generators, pass through a point, and, therefore, envelop a quadric cone. Let O be the vertex of this cone. Evidently the planes joining O to the six lines a, b, c, d, e, l are planes of this cone; further, the plane of the two transversals drawn from any point P, of the line e, one to the pair a, b, the other to the pair c, d, is a common tangent plane of the two quadrics, and passes through O; while, conversely, any tangent plane of the cone meets e in a definite point, P.

Now let any line, say m, be drawn through O. The two quadrics, (a, b, m) and (c, d, m), having common the generator m, meet also in a cubic curve, of which the lines a, b, c, d, as well as m, are chords. From any point, Q, of this curve, can be drawn a generator of the quadric (a, b, m), meeting the lines a, b, m, and also a generator of the quadric (c, d, m), meeting the lines c, d, m; thus Q can be constructed by drawing a plane through the line m, and, therein, joining the points where this plane meets a and b, and also the points where this plane meets c and d, and taking the intersection of these joins; the locus of such points, Q, for all such planes through m, is the cubic curve in question. As, however, the line m passes through the vertex, O, of the quadric cone above found, there are two planes through m which touch this cone; and, in each of these, by what has been said, the point Q, so obtained, is a point, P, of the line e. The cubic curve which arises from the line m has, therefore, beside a, b, c, d, m, also the line e as chord.

We thus obtain an infinite number of cubic curves having the given lines a, b, c, d, e as chords, each having as chord also a particular line, m, drawn through a point O, this point being constructed from a, b, c, d, e by a certain procedure. The aggregate of the ∞^2 points, Q, of all these cubic curves is evidently that found by drawing an arbitrary plane through O and, therein, finding the intersection of the line, joining the points where a, b meet the plane, and the line joining the points where c, d meet the plane. It is thus a cubic surface, Ω, containing a, b, c, d, the point O, and the transversals drawn from O, to meet a, b, and to meet c, d. The cubic curves obtained, having a, b, c, d and e as chords, all lie on this cubic surface, Ω; moreover, since, in any plane through O, an infinite number of lines, m, can be drawn through O, there will be an infinite number of these cubic curves passing through the point, Q, determined as above by this plane. Also, the surface Ω contains the line e, because, as we have shewn, through every point, P, of this line, there passes a plane, also containing O, for which P satisfies the condition by which points Q are determined. The surface also contains the line l, every point of which satisfies the condition of being the point Q for the plane joining O to this line.

Every four of the five lines a, b, c, d, e has, beside l, another transversal; we prove now that all these lie on the surface Ω. For the transversal, e', of a, b, c, d, this is clear, all points of this line satisfying the condition for the point Q of the plane (O, e'). Consider the transversal, d', of a, b, c, e: from the point, P, where this meets e, draw the transversal to c and d, meeting d in D; then, the join of any point, Q, of d', to D, meets c as well as d, and the point

Q lies on the line d' which meets a and b. Thus, this point Q satisfies the condition for the point Q of the plane (D, d'); and this plane passes through O because it contains the transversals from P to a, b and to c, d; by the construction made, this plane contains the line c. Denoting, similarly, by a', b', c' the transversals, beside l, respectively of (b, c, d, e), (c, a, d, e), (a, b, d, e), the point O is thus incidentally shewn to lie on the four planes $[a, b']$, $[a', b]$, $[c, d']$, $[c', d]$, which, therefore, meet in a point; these planes are in fact all tangent planes of both the quadrics (a, b, e) and (c, d, e). The line of intersection of the planes $[a, b']$, $[a', b]$, which we may denote by c_{12}, is also on the surface Ω, being the transversal drawn from O to a and b; so is the line of intersection, c_{34} say, of the planes $[c, d']$, $[c', d]$. Thus O may be defined, when c_{12}, c_{34} are given, as the intersection of these lines.

We have constructed the point O, and the cubic surface Ω, from the four lines a, b, c, d, a transversal, l, of these, and a further line, e, which meets l. Conversely, suppose a, b, c, d, and the point O, to be given, and l to be one of the transversals of a, b, c, d. Then the quadric cone, having O for vertex, which touches the five planes joining O to a, b, c, d, l, is definite; thence the quadric surface having this cone as enveloping cone and containing the two lines a, b as generators is also definite (just as, dually, the quadric containing a given conic and also two non-intersecting lines each meeting the conic once, is definite); so also, the quadric having the specified cone as enveloping cone and containing the two lines c, d as generators, is definite. Of both these quadrics the line l is a generator; these quadrics will then have common another generator, meeting l. This is the line e, which is thus constructed when a, b, c, d and O are given. However, the lines a, b, c, d have, beside l, another common transversal, already named, e'. With this, and a, b, c, d, O, we then find a further line, say f, which meets e'. As then we proceeded from a, b, c, d, e, with the common transversal l, to find O, and the cubic surface, so we can construct O, and the surface, from a, b, c, d, f, with the common transversal e'; it is easy to see that the same surface is found, and that the lines a', b', c', d', before defined, as meeting, respectively, (b, c, d, e), (c, a, d, e), (a, b, d, e), (a, b, c, e), all meet f. Thus a', b', c', d', e' have a common transversal, and, incidentally, the theorem of the double-six is obtained.

In the construction of O, and the cubic surface, from the lines a, b, c, d, e, and their common transversal, l, we have proceeded in an unsymmetrical manner in two respects, first in separating e from a, b, c, d, and then in taking the two pairs a, b and c, d from these. There are in all $5 . 3$, or fifteen, ways in which we may proceed; these lead to fifteen points O, but the cubic surface finally obtained is the same in all cases, there being only one such surface which contains the six lines a, b, c, d, e and their common transversal l, when these are general. For these involve the existence of fifteen other lines on the surface, which can be constructed from these lines alone, and the common points, of two cubic surfaces, lying in a general plane cannot be more than nine in number. If, now denoting the line l by f', we associate the lines $a, b, \ldots, e, f$; $a', b', \ldots, e', f'$, respectively, with the numbers $1, 2, \ldots, 5, 6$; $1', 2', \ldots, 5', 6'$, and denote the line of intersection of the planes $[1, 2']$, $[1', 2]$ by c_{12}, and so on, the fifteen points O will be the various points of intersection (c_{rs}, c_{ij}), where r, s, i, j are four different numbers from $1, 2, \ldots, 6$.

Ex. 1. Considering any plane through the line c_{12}, drawn to contain two further intersecting lines of the cubic surface, and any plane through the line c_{34}, drawn to contain two further intersecting lines of the cubic surface, it is the fact that either of the two former lines, meeting c_{12}, is met by one of the two latter lines, meeting c_{34}. For, otherwise, the line of intersection of these two planes, already meeting the cubic surface in the point (c_{12}, c_{34}), would meet the surface in more than three points. For instance, the plane drawn through c_{12} may contain the lines $1'$, 2, and the plane drawn through c_{34} may contain the lines 3, $4'$; then the lines $1'$, 3 meet, as also do the lines 2, $4'$. Any line of the surface meeting c_{12}, other than the lines c_{34}, c_{56}, say, for instance, the line 2, is thus met by four of the lines, other than c_{12} and c_{56}, which meet c_{34}; and the other line, $1'$, lying in the plane $[2, c_{12}]$, is met by the other four lines, beside c_{12} and c_{56}, which meet c_{34}; further, these two ranges of each four points, respectively on the lines 2 and $1'$, are in perspective from the point (c_{12}, c_{34}).

Prove that there are in all 1080 such pairs of ranges of four points of intersection, in perspective from a point of intersection of two lines of the cubic surface.

Ex. 2. Prove further that, upon the line containing the three points (c_{12}, c_{34}), $(1', 3)$, $(2, 4')$, there is a point at which intersect the planes containing, respectively, the three sets of lines $(2, 1', c_{12})$, $(4', 3, c_{34})$, (c_{24}, c_{13}, c_{56}). These nine lines, arranged in the three sets $(2, 4', c_{24})$, $(1', 3, c_{13})$, (c_{12}, c_{34}, c_{56}), lie in three other planes, making with the three former planes a pair of Steiner trihedrals. Shew also that of such lines as that containing the three intersections (c_{12}, c_{34}) $(1', 3)$, $(2, 4')$, each containing three intersections, there are, in all, 720.

Ex. 3. Prove that there exist 120 pairs of Steiner trihedrals.

The definition of a cubic surface in general. The preceding geometrical definition of a cubic surface, which has led us to the figure of twenty-seven lines previously discussed, forms a sufficient basis for the development of all the properties. Greater freedom of argument will however be available in some cases if it may be assumed that the surface so obtained has the generality of the locus expressed by the vanishing of a complete homogeneous cubic polynomial in the four coordinates of a point. We have given reasons for expecting this to be so; in what follows we shall assume that it is so. But it may be well to recognise explicitly that in so doing we omit an algebraical discussion which should logically be given.

The cubic curves of the surface which belong to a particular double-six. In the preceding discussion we have obtained a system of cubic curves lying on the cubic surface, each the intersection of two quadrics (a, b, m), (c, d, m), where m is an arbitrary line passing through the point (c_{12}, c_{34}), which was called O. Through an arbitrary point, Q, of the surface, there pass, we have seen, infinitely many such curves, these corresponding to lines, m, lying in the plane through O which contains the transversals from Q, respectively to a, b and to c, d. Through two points, Q and Q', of the surface, each of which determines such a plane, there passes one such cubic curve, corresponding to the line of intersection of these two planes. Thus two of these cubic curves intersect in one point only.

The line c_{12}, meeting a and b, and meeting the line m at O, is a generator of the quadric (a, b, m); thus, through the lines a, b, c_{12}, and any one of the cubic curves, there can be described a quadric surface. Conversely, any quadric containing a, b, c_{12} has, at O, a generator, m, of the same system as a, b, and this quadric therefore meets the cubic surface again in one of the cubic curves, which, again, lies on the quadric (c, d, m). It is clear, if we employ the algebraic symbols, that the points common to a quadric surface and a cubic surface lie on a sextic curve, that is, a curve meeting an arbitrary plane in six points; for the quadric meets the plane in a conic, of which the points are expressible by quadratic functions of a parameter, and the cubic surface meets the plane in a cubic curve, from the equation of which, by substitution of quadratic polynomials for the coordinates, a sextic equation results. Thus, when a quadric surface is drawn through the three lines a, b, c_{12}, the cubic curve in which this quadric further meets the cubic surface constitutes the whole of the residual intersection. By a similar argument, a quadric surface can be drawn through this cubic curve whose residual intersection with the cubic surface consists of the lines c, d, c_{34}. From this, by the symmetry between the lines of the cubic surface, we infer that, if r and s denote any particular two of the six lines a, b, ..., e, f, the cubic curves which we have obtained on the cubic surface are all obtainable as the residual intersections with the surface of the quadric surfaces, drawn through the three lines r, s, c_{rs}. Thence it appears, from what has been said (p. 162 above), that we are to regard the sets of three lines such as r', s', $c_{r's'}$, consisting of any two of the lines a', b', ..., e', f', and their associated line $c_{r's'}$, as particular forms of the cubic curves under discussion. But then, as the lines a', b', ..., f' are quite similar to the lines a, b, ..., f, it follows that there exists on the cubic surface another system of cubic curves, each the residual intersection with the surface of a quadric drawn, say, through the three lines $1'$, $2'$, c_{12}.

This new system of cubic curves is, however, obtainable from the former system; for it is the case that any cubic curve of the former system and any cubic curve of the latter system are, together, the complete intersection of the cubic surface with a quadric. To prove this, it is sufficient, after what has been said, to prove that, if we take the cubic curves γ and γ', of which γ is the residual intersection with the cubic surface of any quadric drawn through the lines $1'$, $2'$, c_{12}, and γ' is the residual intersection with the cubic surface of any quadric drawn through the lines 1, 2, c_{12}, then the curves γ, γ' lie on a quadric surface. This will follow if we shew that γ, γ' have five points in common, other than those on the specified lines; for, then, the quadric surface described to contain these five points, and also two other points of each of the curves, γ, γ', as then meeting each of the curves in seven points, will contain both these curves. Now, the common points of γ, γ' are the points of the cubic surface which lie on the common curve of the two general quadrics described as above, respectively through 1, 2, c_{12} and through $1'$, $2'$, c_{12}. These quadrics, having the line c_{12} in common, meet otherwise in a cubic curve; this curve passes through the two points $(1, 2')$, $(1', 2)$, which are on both quadrics, and also meets the common generator c_{12} in two points; beside the four points given by these, which lie on the cubic surface, the cubic curve will meet the cubic surface in five other points, not lying, when the quadrics drawn through the lines 1, 2, c_{12} and $1'$, $2'$, c_{12} are not special, on any of these lines. This proves the result enunciated.

From this we see that, given a single cubic curve, γ, of either system, the curves of the other system are obtainable by drawing the most general quadric surface through the curve γ. Such a quadric is identified by two points of the cubic surface not lying on γ, which also, we have seen, identify a cubic curve of the other system.

It follows now, as in a previous section (above, p. 162), that the quadric surfaces whose intersection with the cubic surface breaks up into cubic curves, one of each system, are, when expressed in point coordinates, linearly deducible from nine of them, which may be taken to be the same nine as those taken in the section referred to. These quadrics are then all outpolar to the same quadric, Σ, that, namely, in regard to which the six pairs of lines, (1, 1′), ..., (6, 6′), are polar lines of one another; and, by what we have seen, this is the same statement as that any quadric containing any cubic curve of either system is outpolar to Σ.

A particular consequence is that the five points above shewn to be common to two of the cubic curves, γ and γ', of different systems, are such that the plane which contains any three of them has, for its pole in regard to Σ, a point lying on the join of the other two points; or, in a phraseology previously employed (above, p. 37), that these five points are a self-conjugate pentad in regard to Σ. To prove this, consider the general quadric surface passing through these five points; it is a linear aggregate of five such quadrics, when expressed by its equation in point-coordinates; these may then be taken to consist of two quadrics through each of the two cubic curves which intersect in the five points, together with the quadric which contains both these curves, there being, as we know, three linearly independent quadrics through any cubic curve in space. We thus infer that every quadric through the five points is outpolar to the quadric Σ. This leads to the statement made, since a particular quadric through the five points is the plane-pair consisting of the plane through three of these points taken with any plane whatever through the other two.

Ex. 1. For the case of two degenerate cubic curves of the same system constituted, respectively, by the lines a, b, c_{12}, and by the lines c, d, c_{12}, we saw that, if a plane be drawn through the point O, or (c_{12}, c_{34}), which is common to these degenerate cubics, and the join of the two points where this plane meets the lines a, b be taken, as also the join of the two points where this plane meets the lines c, d, then these two joins meet in a point of the cubic surface, all points of the surface being obtainable by varying the plane drawn through O. We consider now a theorem which is a generalisation of this result: If any two cubic curves in space, of the cubic surface, belonging to the same system, be taken, intersecting in a point, Q, of the surface, and a variable plane be drawn through Q, meeting one of these curves again, say, in M and N, and the other in M' and N', then the lines MN, $M'N'$ meet in a point of the cubic surface, all points of which are thus obtainable by varying the plane. We base this theorem upon a property of the *plane* cubic curve in which the cubic surface meets an arbitrary plane, of which we give the proof immediately (Ex. 2); this property is that, if A, B, C, Q be any four fixed points of this plane cubic curve, and any conic be drawn through these points, meeting the plane cubic again in the two points M and N, then the third point in which the line MN meets the plane cubic again is the same whatever conic be taken. Assuming this result, let ω denote, in the theorem enunciated for the cubic curves in space on the cubic surface, the plane cubic curve in which the cubic surface is met by the plane which is drawn through Q; and let A, B, C be the points in which this plane curve ω is met by the lines a, b, c_{12}, of the cubic surface. The quadric surface containing these three lines, and also one of the two cubic curves considered, say γ, which pass through Q, will meet the plane in a conic containing the points Q, A, B, C, and also containing the two points, M and N, in which the plane meets the curve γ, beside Q. All these points are on the curve ω. Let K be the third intersection of the line MN with the curve ω. By the property of a plane cubic curve which we have assumed, this point K lies also on the line $M'N'$. Conversely, through any point, K, of the cubic surface, a single chord can be drawn of any assigned cubic curve in space, lying on the cubic surface, which passes through Q. This chord and the line KQ determine a plane. The theorem enunciated is therefore proved.

Ex. 2. Of the property, for a plane cubic curve, assumed in Ex. 1, which is a very particular case of a general theorem for plane curves, we may here give the following proof. The plane curve which is the section of the cubic surface by a plane, is met by an arbitrary line of that plane in three points; it can thus be represented by the vanishing of a homogeneous cubic polynomial in the three coordinates of a point on that plane. We have assumed that the cubic surface is that given by the vanishing of a general cubic polynomial in the four space coordinates; the plane curve will, therefore, if the plane be general, be expressed by the vanishing of a quite general cubic polynomial in the three coordinates, containing, homogeneously, ten independent coefficients. Let this equation be $f=0$, and let U, V be two other cubic polynomials in the three coordinates which both vanish at eight points of the curve $f=0$. The equation $U+\lambda V=0$ then represents a cubic curve, in the plane, passing through these eight points. We assume that the common points of the curves $U=0$, $V=0$ are nine in number, an assumption, moreover, easily verified in the application of the theorem made below. These curves will, therefore, intersect in a further point beside the given eight points, and the curve $U+\lambda V=0$ will pass through this for all values of λ. The value of λ is however particularised when a point, other than the specified ninth point, is assigned upon the curve $U+\lambda V=0$, and this curve is then uniquely determined; in particular, by taking this assigned point to lie on $f=0$, we see that the curve $f=0$ can be represented in the form $U+\lambda V=0$, if λ be properly chosen. (Cf. Ex. 6, p. 156.)

Now, suppose that through the four points A, B, C, Q, of the cubic curve $f=0$, two conics $S_1=0$, $S_2=0$ are drawn, meeting $f=0$ again, respectively, in the points M_1, N_1 and the points

M_2, N_2; let $P_1=0$, $P_2=0$ be the respective equations of the lines M_1N_1 and M_2N_2. Then the cubic polynomials S_1P_2 and S_2P_1 both vanish at the eight points A, B, C, Q, M_1, N_1, M_2, N_2 of the curve $f=0$. Thus, by what has been said, there is an identity of the form $f=\mu S_1P_2+\nu S_2P_1$, in which μ, ν are constants. This shews, however, that the lines $P_1=0$, $P_2=0$ meet on the curve $f=0$, which proves the property in question.

The general property, of which the above is a particular case, may be enunciated for any plane curve, $F=0$, which has no multiple points, as follows: let A, B, C, ..., T be any set of points on $F=0$; let $S_1=0$, $S_2=0$ be any two curves, in this plane, of the same order, both of which contain this set of points and meet the curve $F=0$, respectively, in the further points M_1, N_1, ..., U_1 and M_2, N_2, ..., U_2, the number of points in these two further sets being in fact the same. Now, let $P_1=0$ be any curve whatever drawn through the points M_1, N_1, ..., U_1, having with the curve $F=0$ the further intersections H, K, ... The property then is that there exists a curve, of the same order as $P_1=0$, whose complete intersection with $F=0$ consists of the two sets of points

$$M_2, N_2, \ldots, U_2, \ H, K, \ldots.$$

Each of the two sets $(M_1, N_1, \ldots, U_1)$ and $(M_2, N_2, \ldots, U_2)$ is said to be a *residual* of the first set, $(A, B, C, \ldots, T)$, and these two sets are therefore said to be *coresidual*. The set $(H, K, \ldots)$ is then a residual of the set $(M_1, N_1, \ldots, U_1)$. The property may then be stated by saying that any residual of one of two coresidual sets is equally a residual of the other.

Ex. 3. The property for plane curves just explained has an analogue for surfaces, in which a set of points of the plane curve is replaced by a curve on the surface, and residual sets of points by residual curves on the fundamental surface, that is, curves which, together, are the complete intersection of this surface with a further surface. We first illustrate this by considering a particular case for curves on the cubic surface. We denote the equation of the cubic surface by $F=0$. Through any line of this surface let two planes be drawn, $S_1=0$, $S_2=0$; the residual intersections, in general, conics, may be denoted by M_1, M_2, respectively. Let an arbitrary quadric, say $P_1=0$, be drawn through the conic M_1, and the residual intersection of this quadric with the cubic surface be denoted by H. Then it is the case that this curve H forms, with the conic M_2, the complete intersection of the cubic surface with another quadric, say $P_2=0$. In general terms, the curve H, which is a residual of one of the two coresidual conics M_1, M_2, is equally a residual of the other.

To prove this, remark, first, that the curve H is a quartic curve, meeting an arbitrary plane in four points; for the aggregate of this curve and the conic M_1, being the intersection of a quadric surface and a cubic surface, meets an arbitrary plane in six points. Next, this quartic curve, H, meets every generator of the quadric $P_1=0$ in two points; these, with the point where the generator meets the conic M_1, are the three intersections of the line with the cubic surface, when this does not contain the line entirely. A quartic curve, on a quadric, meeting every generator in two points, is however the complete intersection of this quadric with another quadric, and a quadric can be drawn through the curve and an arbitrary point. Assuming this fact, which is proved below, consider the four intersections of the quartic curve with the plane of the conic M_2; as the curve is on the cubic surface these intersections, if not all on the conic M_2, can only be on the line of intersection of the planes of the two conics M_1 and M_2, and, therefore, as the curve is on the quadric $P_1=0$, can only be where the conic M_1 meets this line, which requires a particular quadric P_1. Thus, in general, the curve will meet the conic M_2 in four points. Therefore a quadric can be drawn through the quartic curve to contain also the conic M_2; for, we have only to describe a quadric through the quartic curve which shall meet this conic in a fifth point other than those four in which the quartic curve already meets the conic.

To prove the fact stated, that if a quartic curve, H, lying on a quadric surface, P, meet every generator of the quadric in two points, then a quadric can be drawn through the curve and any other arbitrary point, we may argue as follows: Let the arbitrary point be O, and take eight points, $A_1, A_2, \ldots, A_8$, of general position, upon the quartic curve; describe the quadric surface, P', through O and these eight points; this will meet the quadric P in a quartic curve, H'. We prove that this coincides with the curve H. For, first, this curve H' meets every generator of the quadric P in two points, as we see by considering how many points of this curve, not on this generator, lie on an arbitrary plane drawn through this; this plane meets the quadric P, further, in a line, and meets the quadric P' in a conic. Wherefore, if we project the two curves H, H', on to an arbitrary plane, from one of the eight points, $A_1, \ldots, A_8$, which are common to both curves, say from A_1, we obtain two plane cubic curves having nine points in common, namely the projections of the seven points $A_2, \ldots, A_8$, and the points where the generators of the quadric P, at the point A_1, meet this plane. We have proved above (Ex. 2) that, of the nine intersections of a given plane cubic curve (here the projection of the curve H) with another such curve, only eight can be taken arbitrarily upon the first curve, the remaining one being then determinate. In our present case, by retaining the same positions for $A_1, A_2, \ldots, A_7$, and changing the position of A_8, we can, if the curve

H' is distinct from H, assume the ninth intersection of two such plane cubic curves quite arbitrarily upon one of them. We infer therefore that H' coincides with H. The fact stated is then proved.

Ex. 4. The general property referred to, at the beginning of Ex. 3, may be stated for a cubic surface (to which however it is not restricted) as follows: Suppose that, through any curve, l, on the cubic surface, there pass two surfaces of equal order, $S_1 = 0$, $S_2 = 0$, whose residual intersections with the cubic surface are, respectively, the curves M_1 and M_2; let any surface whatever, $P_1 = 0$, be drawn through the curve M_1, having, as its residual intersection with the cubic surface, a curve H; then a surface, of the same order, exists, whose complete intersection with the cubic surface consists of the curves H and M_2. It seems desirable to enunciate this property; but we give only indications of the proof. This depends on the fact that, if $F = 0$ be the equation of the cubic surface, and $S = 0$ the equation of another surface, then any surface containing the complete intersection of $F = 0$ and $S = 0$ has an equation of the form $\Theta F + PS = 0$; here Θ, P are homogeneous polynomials in the coordinates, of respective orders such as to make the left side of the equation of the order of the surface which is to be expressed. In our case take for S the surface $S_1 = 0$, whose intersection with the cubic surface consists of the curves l and M_1; consider the composite surface consisting of the surfaces $S_2 = 0$ and $P_1 = 0$, with equation $S_2 P_1 = 0$; as $S_2 = 0$ contains the curve l, as well as the curve M_2, and $P_1 = 0$ contains the curve M_1, as well as the curve H, this surface $S_2 P_1 = 0$ contains the intersection, (l, M_1), of the surfaces $F = 0$, $S_1 = 0$; there is thus, by what we have stated, an identity of the form $S_2 P_1 = \Theta F + P_2 S_1$, wherein Θ, P_2 are appropriate polynomials. The surface expressed by $P_2 = 0$ thus meets the cubic surface, $F = 0$, on the portion of the intersection of this with $S_2 P_1 = 0$ which does not lie on $S_1 = 0$. Wherefore, the curves M_2 and H lie on the surface $P_2 = 0$; it was the existence of such a surface which was to be proved.

The development of the properties of coresidual curves on a cubic surface is of great importance, but would carry us too far. The reader may consult a paper, *Proc. Lond. Math. Soc.* XI, 1912, p. 287.

Ex. 5. The quadrics which pass through the curve of intersection of two given quadrics meet an arbitrary line in pairs of points of an involution. From the result of Ex. 3, it follows that the conics in which the cubic surface is met by the planes drawn through a line of the surface, say l, meet this line in pairs of points of an involution. Of this result another proof arises below. The double points of the involution are two important points of the line; in fact it will be found below that the line touches at these two points the quartic surface known as the Hessian of the cubic surface.

Ex. 6. The theorem stated in Ex. 5 is easily obtained analytically; and another result which includes this as a particular case may be obtained at the same time. Let $F=0$ be the equation of the cubic surface, and x_1, y_1, z_1, t_1 be the coordinates of any particular point, P_1. The quadric surface whose equation is

$$[x_1\partial/\partial x + y_1\partial/\partial y + z_1\partial/\partial z + t_1\partial/\partial t]F = 0$$

is called the polar quadric of the point P_1 in regard to the cubic surface. It is such that the line joining P_1 to any point, P, of the curve of intersection of the cubic surface with this polar quadric of P_1, meets the cubic surface in two coincident points at P, as we may easily see by considering the equation in λ obtained by substituting in $F=0$, for the coordinates, the values

$$x+\lambda x_1,\ y+\lambda y_1, \text{ etc.}$$

The general result referred to is that, if we take any particular line lying on the cubic surface, the ∞^3 quadrics constituted by the polar quadrics of all points P_1 meet this line in pairs of points of an involution. That this involution includes the pairs of points of intersection, with the line, of conics lying on the cubic surface, in planes passing through the line, is clear; for a point, P, where such a conic meets the line, arises twice over in the intersections with the cubic surface of any line through P lying in the plane of the conic. To prove the result, let the coordinates be so taken that the line of the cubic surface which is considered is that given by $x=0$, $y=0$; the equation of the cubic surface is then of the form $xU+yV=0$, where $U=0$, $V=0$ represent quadric surfaces. The polar quadric, by the form of its equation, is unchanged by any particular choice of coordinates (cf. Vol. II, p. 104). In the present case, the equation of the polar quadric of P_1 is

$$x_1U+y_1V+xDU+yDV=0,$$

where D represents the operator by which the polar quadric, $DF=0$, is formed. The polar quadric thus meets the line $x=0$, $y=0$ in the pair of points given by $x_1(U)+y_1(V)=0$, where (U), (V), containing terms in z^2, zt, t^2, represent the result of putting $x=0$, $y=0$ in U and V. We know that the pairs of points given by this equation, when x_1, y_1 vary, belong to an involution (Vol. II, p. 111, Ex. 3). The general plane through the line $x=0$, $y=0$, say $y-\lambda x=0$, meets the cubic surface on the quadric cone expressed by $[U]+\lambda[V]=0$, where $[U]$, $[V]$ are obtained from U, V respectively, by substituting λx for y. This cone meets $x=0$, $y=0$ in a pair of points given by $(U)+\lambda(V)=0$, belonging to the same involution as before.

The double points of the involution, being harmonic in regard to the intersections of the line with a polar quadric, are conjugate to one another in regard to all polar quadrics. But there exist pairs of points with this property not lying on a line of the cubic surface, as we shall see (see below, under *Hessian surface*).

Ex. 7. A result given above suggests another way in which we may approach the theory of a cubic surface and the lines lying thereon. Suppose that we are given two cubic curves, γ and γ', in three dimensions, having a point in common, say O. An arbitrary plane, drawn through O, will meet these curves both in two further points, say, respectively, A, B, and A', B'. We may consider the locus of the point of intersection, P, of the two lines AB, $A'B'$, as the plane drawn through O varies. It follows from what has preceded that the locus is a cubic surface containing the curves γ, γ'. But this may be proved directly. For, take nine points, other than O, on each of these cubic curves. The nineteen points thus obtained suffice to determine a cubic surface, defined as the locus expressed by a cubic polynomial in the four space coordinates. This surface will contain both the cubic curves, as meeting each in ten points, nine being the number of intersections of a cubic surface with a cubic curve. There are, in general, ten common chords of two cubic curves in space, as has been seen (above, p. 141); the quadric cones projecting the cubic curves γ and γ' from O have four common generators, which are among these ten. There remain, then, six other common chords of these two cubic curves, say, a, b, c, d, e, f; and each of these chords, as meeting the cubic surface in four points, will lie entirely thereon. It can be shewn that, taking two of these common chords, say a and b, there is a single line meeting both, and also meeting each of the curves γ, γ', in such a way that the four points of meeting are distinct. This line will then also lie on the cubic surface. In general, four curves in space, of respective orders m, n, p, q, are met by $2mnpq$ lines (see below); this would give eighteen lines meeting both a and b and also meeting each of the curves γ, γ' once. We can, however, with more careful examination, see that seventeen of these lines are such as to meet the cubic surface in less than four points; it cannot, therefore, be inferred that these lie on the surface. For, let the line a meet the curves γ and γ', respectively, in the points A_1, A_2 and A_1', A_2', and the line b meet γ and γ' respectively, in B_1, B_2 and B_1', B_2'. Then, one of the seventeen lines is the transversal from O to a and b; two more are the joins of A_1 to B_1' and B_2', and there are eight such lines in all; if the quadric be described containing the curve γ' and its two chords, a, b, there will be a generator of this through A_1, of the opposite system from these, which will meet the curve γ', as well as a, b and the curve γ; this is another of the seventeen lines, and there are four such, respectively through A_1, A_2, B_1, B_2. There are four similar lines definable by the quadric containing the curve γ and its chords a, b. Seventeen lines are thus accounted for, each of which meets the cubic surface in three points only. There is, thus, as stated, one line meeting the curves γ, γ' and the lines a, b, in four distinct points, and, therefore, lying on the cubic surface. We may denote this by c_{12}. By taking every couple of the six lines $a, b, \ldots, e, f$, we obtain in all fifteen such lines of the cubic surface; the theory of the surface can then be developed from this point.

To prove that there are $2mnpq$ lines each meeting four given curves, of respective orders m, n, p, q, we may assume that a surface of order N is met by a curve in space, of order k, in Nk points. If the surface and curve are defined by algebraic equations this is an algebraic theorem, which needs proof. Assuming this, however, consider first the particular case of the result under discussion which asserts that there are $2m$ lines meeting one curve of order m and three lines. The transversals of these three lines generate a quadric surface, which, by the assumption made, meets the curve of order m in $2m$ points; from each of these there is one of the lines desired, meeting the curve of order m and the three given lines. Hence we have the result that the lines meeting a curve of order m, and also meeting two lines, generate a surface of order $2m$. By the assumption made, this surface will meet a curve of order n in $2mn$ points; this is, then, the number of lines meeting two given curves of orders m and n, and also meeting two given lines. Wherefore, the lines meeting two given curves of orders m and n, and also meeting a line, generate a surface of order $2mn$. By the assumption made, this surface will meet a curve of order p in $2mnp$ points; this is, then, the order of the surface formed by the lines meeting three given curves of respective orders m, n, p. Hence, this surface meeting a curve of order q in $2mnpq$ points, there are $2mnpq$ lines meeting four curves of respective orders m, n, p, q.

Definition of a cubic surface by three related star-figures. We have explained in Vol. I (p. 148) what is meant by two related plane systems, wherein, to any point of one plane there corresponds a point of the other, and to a range of points in one plane there corresponds a related range of points of the other. Suppose the points and lines of one of these planes are joined to a point, O, not lying in this plane, respectively by lines and planes; and, similarly, that the points and lines of the other plane are joined to a point, O', not lying in this plane, respectively by lines and planes. We then obtain two star-figures, or central-systems, with vertices, or centres, respectively at O and O', which are said to be related to one another, any line, or flat pencil of lines, passing through O, corresponding to a line, or related flat pencil of lines, passing through O', and conversely.

Such a relation between two star-figures can be set up by means of a cubic curve which contains the two vertices O and O'. It is only necessary to make correspond to any plane through O, which will meet the cubic curve in two further points, the plane joining O' to the chord of the cubic curve which contains these points; then, any line through O, which meets an infinite number of chords of the curve, whose ends are pairs of an involution thereon, will correspond to the line through O' which meets all these chords. It may be proved that any flat pencil of lines through O gives rise in this way to a related flat pencil of lines through O'; and, conversely, that any two related star-systems may be regarded as arising in this way from a cubic curve in space.

Now suppose we have three star-systems, of vertices O, O' and O'', of which any two are related to one another, so that, to any plane through O, there corresponds a definite plane through O' and a definite plane through O''. We may then consider the locus of the point of intersection of three such related planes. By what has been said, this comes to supposing that we have two cubic curves which meet in O, one of these containing O', the other containing O'', and that we draw through O an arbitrary plane, meeting the first cubic curve in the further points A', B' and the second curve in the further points A'', B'', and then consider the locus of the intersection of the lines $A'B'$ and $A''B''$. We are thus brought back to the definition of a cubic surface which has been considered (Ex. 7, p. 183); and it appears, since it has been shewn that, on a cubic surface, there can be drawn one cubic curve of a definite system through two arbitrary given points, that a cubic surface can be generated by the intersection of corresponding planes of three related star-systems in which the vertices, O, O', O'', are any three points of the surface.

By choosing a proper system of coordinates, related to a cubic curve containing the points O and O', the corresponding planes through these points, intersecting in a chord of this curve, can (above, p. 131) be supposed to have the equations

$$x-y(\theta+\phi+\omega)+z(\theta\omega+\phi\omega+\theta\phi)-t\theta\phi\omega=0,$$
$$x-y(\theta+\phi+\omega')+z(\theta\omega'+\phi\omega'+\theta\phi)-t\theta\phi\omega'=0,$$

or say $\quad \xi u+\eta v+\zeta w=0, \quad \xi u'+\eta v'+\zeta w'=0,$

wherein $\xi:\eta:\zeta, =1:\theta+\phi:\theta\phi$, have ratios which vary as these planes vary, but $u, =x-y\omega$; $v, =-y+z\omega$; $w, =z-t\omega$; $u', =x-y\omega'$, etc., are fixed. The planes $u=0$, $v=0$, $w=0$, of the star-figure of vertex O, correspond then, respectively, to the planes $u'=0$, $v'=0$, $w'=0$, of the star-figure of vertex O'. When we take any general system of coordinates the equations of corresponding planes of the star-figures (O), (O') will remain of the forms $\xi u+\eta v+\zeta w=0$,

$\xi u' + \eta v' + \zeta w' = 0$, and the plane of the star-figure (O'') which corresponds to these will be of the form $\xi u'' + \eta v'' + \zeta w'' = 0$, where u'', v'', w'' are fixed planes through O'', corresponding respectively to u, v, w. The equation of the cubic surface is thus

$$\begin{vmatrix} u, & v, & w \\ u', & v', & w' \\ u'', & v'', & w'' \end{vmatrix} = 0.$$

This form gives rise to several remarks. In the first place, considering the three quadrics which are represented by $vw' - v'w = 0$, $wu' - w'u = 0$, $uv' - u'v = 0$, the last two of these have in common the line given by $u = 0$, $u' = 0$, and, beside this, intersect in a cubic curve which lies on the first. Thus this cubic curve lies on the cubic surface. It is evidently the cubic curve joining the points O and O'. Similarly, the cubic curve of the surface joining the points O and O'' is that common to the three quadrics $vw'' - v''w = 0$, $wu'' - w''u = 0$, $uv'' - u''v = 0$. We may, however, without altering the equation of the cubic surface, replace u, v, w, respectively, by $au + bu' + cu''$, $av + bv' + cv''$, $aw + bw' + cw''$, where a, b, c are any constants; and at the same time make similar replacements for u', v', w', and for u'', v'', w''. Thereby we obtain an infinite number of cubic curves lying on the surface; it may be seen that these are such as those previously described as belonging to one system. Any one of these curves is obtained by taking two of the rows of the modified determinantal equation of the cubic surface; by dealing similarly with the *columns* of the determinant, another system of cubic curves of the surface is obtained. Moreover, as any minor of the determinant, of two rows and columns, belongs as well to two rows as to two columns, we see that any cubic curve of the first system and any cubic curve of the second system are together the complete intersection of the cubic surface with a quadric, as was previously proved. Further, the equations of all quadric surfaces so arising are linear functions of those nine of them which correspond to the nine minors of the determinant, of two rows and columns, as also has been shewn above.

Ex. 1. The six lines which form one row of the double-six associated with the present way of writing the equation of the cubic surface are the common chords of one system of cubic curves. To find them we are to express that the planes $\xi u + \eta v + \zeta w = 0$, $\xi u' + \eta v' + \zeta w' = 0$, $\xi u'' + \eta v'' + \zeta w'' = 0$, meet in a line; this requires an identity, in regard to the coordinates, of the form $\Sigma \xi (\lambda u + \lambda' u' + \lambda'' u'') = 0$, in which the three parameters λ, λ', λ'' are independent of the coordinates; this again, leads to four equations all linear both in ξ, η, ζ and in λ, λ', λ''. By elimination of λ, λ', λ'', from each set of three of these equations, we thence obtain cubic polynomials in ξ, η, ζ; the values of these for which these polynomials vanish solve the problem. The other row of the double-six is to be similarly found from the columns of the determinant.

Ex. 2. The nine independent quadrics, each containing a cubic curve, on the cubic surface, of each of the two systems, are outpolar to a single quadric, Σ; in regard to this quadric, as has been seen, the lines of one row of the double-six are polar lines of those of the other row, respectively. This quadric, Σ, is inpolar to any quadric which, expressed in point coordinates, is a linear function of the nine quadrics. Now, the cubic surface being $F=0$, let $DF=0$ be the polar quadric (above, p. 182) of any point (x_1, y_1, z_1, t_1), where the operator D is a sum of such terms as $x_1\partial/\partial x$. This is a linear function of the nine quadrics referred to; for, with the above determinant form for F,

$$DF=\begin{vmatrix} Du, & Dv, & Dw \\ u', & v', & w' \\ u'', & v'', & w'' \end{vmatrix} + \begin{vmatrix} u, & v, & w \\ Du', & Dv', & Dw' \\ u'', & v'', & w'' \end{vmatrix} + \begin{vmatrix} u, & v, & w \\ u', & v', & w' \\ Du'', & Dv'', & Dw'' \end{vmatrix},$$

and each of Du, Dv, etc., is a constant, being the values of u, v, etc. for the point (x_1, y_1, z_1, t_1); the minors, in the determinants, multiplying these constants, are the nine quadrics in question.

We infer, therefore, that the quadric Σ is inpolar to every polar quadric. The expression for F by which we have deduced this is connected with one of the double-sixes of the lines on the cubic surface, and the two systems of cubic curves associated therewith; the quadric Σ is also related to this double-six. There is such a quadric for every one of the double-sixes, and, therefore, there are in all thirty-six such Schur quadrics. All these will then be inpolar to the polar quadrics, that is, inpolar to the four quadrics

$$\partial F/\partial x=0, \ \ldots, \ \partial F/\partial t=0.$$

Hence, the *tangential* equations of the Schur quadrics are all linear functions of at most six of them.

We have already (above, p. 182) considered pairs of points which are conjugate to one another in regard to all the polar quadrics of the cubic surface. These form, in fact, pairs of so-called corresponding points of a certain quartic surface, the Hessian of the cubic surface. Each such pair may be regarded, tangentially, as a degenerate quadric which is inpolar to the polar quadrics; thus the tangential equations of all such point-pairs may be expressed linearly by those of six of them. The Schur quadrics, in tangential form, may then be expressed by such six point-pairs.

Ex. 3. For the cubic surface whose equation is expressed by

$$ax^3+by^3+cz^3+dt^3+eu^3=0,$$

where u is expressible in terms of x, y, z, t by means of the relation

$$ax + by + cz + dt + eu = 0,$$

the general polar quadric is at once seen to be expressible as a linear function of the four $x^2 - u^2 = 0$, $y^2 - u^2 = 0$, $z^2 - u^2 = 0$, $t^2 - u^2 = 0$, namely to be of the form

$$Ax^2 + By^2 + Cz^2 + Dt^2 + Eu^2 = 0,$$

with $A + B + C + D + E = 0$. Thus a pair of points, (x, y, z, t, u), $(x_1, y_1, z_1, t_1, u_1)$, which are conjugate to one another in regard to all these quadrics must be such that

$$xx_1 = yy_1 = zz_1 = tt_1 = uu_1;$$

they must, therefore, be such that both of them satisfy the equation

$$ax^{-1} + by^{-1} + cz^{-1} + dt^{-1} + eu^{-1} = 0,$$

which, conversely, is also a sufficient condition. It may easily be verified that the polar quadric of either of the two points, in regard to the cubic surface, is a quadric cone whose vertex is at the other point; this, as may easily be seen, is the same thing as that the two points lie on a surface whose equation can be expressed by the vanishing of a determinant of four rows and columns in which the elements of the first row are $\partial^2 F/\partial x^2$, $\partial^2 F/\partial x \partial y$, etc., those of the second row are $\partial^2 F/\partial y \partial x$, $\partial^2 F/\partial y^2$, etc., and so on. For the form of F under discussion, this equation reduces to that given, $ax^{-1} +$ etc. $= 0$. As has been said, the surface is called the Hessian. With this form for F, the equation of the Hessian can be seen to be capable, when u is expressed in terms of x, y, z, t, of the form

$$\lambda + bcX + adP + caY + bdQ + abZ + cdR = 0,$$

where

$X = yz^{-1} + y^{-1}z$, $P = xt^{-1} + x^{-1}t$, etc., and $\lambda = a^2 + b^2 + c^2 + d^2 - e^2$. This shews, however, that any seven points of the Hessian, of coordinates (x_r, y_r, z_r, t_r), for $r = 1, \ldots, 7$, are connected, when $A_1, \ldots, A_7$ are suitably chosen, by the equation

$$\sum_{r=1}^{7} A_r (ux_r + vy_r + wz_r + pt_r)(ux_r^{-1} + vy_r^{-1} + wz_r^{-1} + pt_r^{-1}) = 0,$$

holding for all values of u, v, w, p. This is the equation connecting the tangential equations of any seven pairs of corresponding points on the Hessian.

It may also be proved that the tangential equation of a general quadric which is inpolar to all the polar quadrics of the cubic surface is a linear function of the six quadrics such as

$$u^2 + v^2 + w^2 + p^2 - \lambda vw/bc = 0, \ldots, \; u^2 + v^2 + w^2 + p^2 - \lambda up/ad = 0,$$

where λ has the same value as above. Every Schur quadric is thus expressible by these six quadrics.

The representation of the cubic surface on a plane. In the case of curves we have distinguished between those, such as the conic and the cubic curve in space, of which the coordinates of a point are expressible by rational functions of a parameter, and those, much the larger class, for which this is not so. The examples of the latter class which we have met with most often are the cubic curve in a plane, and the quartic curve which is the intersection of two quadrics. In the case of surfaces a similar distinction is observable: there are surfaces of which the coordinates of a point are expressible as rational functions of two parameters, these parameters being themselves definable each as a rational function of the coordinates of a point of the surface; but for the majority of surfaces this is not possible; nor is it easy, as it is for curves, to give a general criterion sufficient to ensure its possibility. A quadric is a surface of which any point is given by the intersection of two generators, each of which is determined by a single parameter, and the expression in question is thence possible. We now proceed to remark on the fact that a cubic surface also has this character. In general, the two parameters, in terms of which the points of such a surface are expressible, may be interpreted as ratios of the coordinates of a point in a plane; but it is possible, in an infinite number of ways, to set up a correspondence, between any point of a plane and some other point and conversely, expressible by rational equations. Thus, when a surface is representable on a plane in one way, it is so representable in an infinite number of ways. In general, any such representation must be expected to have *singular* elements; a point of the surface may correspond, not to a point, but to a curve, of the plane; for instance, when a quadric is projected on to a plane from a point of the quadric, the point gives rise to a line of the plane; or, a curve of the surface may lead only to a point in the plane, as we shall see in the case of the cubic surface. The various representations possible for a given surface are to be distinguished by the character of these singular elements.

The generation of the cubic surface by the intersection of corresponding planes of three related star-systems leads at once to a representation of the surface upon a plane. For we may regard the planes of one, and therefore of all, of the star-systems, as being related to the points of a plane. With symbols, the cubic surface being obtained, as above, by the locus of the intersection of three planes $\xi u + \eta v + \zeta w = 0$, $\xi u' + \text{etc.} = 0$, $\xi u'' + \text{etc.} = 0$, we may represent this intersection by a point of coordinates ξ, η, ζ, in a plane. These are then proportional to quadric functions of the coordinates, x, y, z, t, of the point of the cubic surface; conversely, x, y, z, t, obtained from the three equations such as $\xi u + \text{etc.} = 0$, are proportional to cubic polynomials in ξ, η, ζ, say, respectively, $\vartheta, \phi, \psi, \chi$.

The correspondence between the planes $\xi u + \text{etc.} = 0$, $\xi u' + \text{etc.} = 0$, was obtained by the fact that these intersect in a chord of a certain cubic curve, say γ, each point of the curve being an intersection of corresponding rays of two star-systems; through each point of this curve there pass then an infinite number of pairs of corresponding planes of these two star-systems, and the cubic curve is the locus common to the three quadric surfaces $vw' - v'w = 0$, $wu' - w'u = 0$, $uv' - u'v = 0$. Another cubic curve, γ', common to $vw'' - v''w = 0$, $wu'' - w''u = 0$, $uv'' - u''v = 0$, determines the correspondence between the planes $\xi u + \text{etc.} = 0$, $\xi u'' + \text{etc.} = 0$. These curves meet in a point, O, where $u = 0$, $v = 0$, $w = 0$. From any general point, P, of the cubic surface, a chord can be drawn to each of the curves γ, γ'; the plane of these chords is the plane $\xi u + \text{etc.} = 0$, passing through the point O, and this determines the two corresponding planes of the other two systems, and the ratios $\xi : \eta : \zeta$. In particular, when P is on the curve γ, the chord of γ' drawn from P determines the plane $\xi u + \text{etc.} = 0$, and this determines the chord of the curve γ through which the plane $\xi u' + \text{etc.} = 0$ also passes. Thus, any point of the cubic surface determines a single determinate point, (ξ, η, ζ), of the plane. But, conversely, when P is on a line which is a common chord, not passing through O, of the curves γ, γ', the point (ξ, η, ζ) arises equally well from any point of this chord. We have already remarked that there are six such common chords (above, p. 183); thus there are six points of the plane (ξ, η, ζ) which correspond to lines, say a, b, c, d, e, f, of the cubic surface. This result is obtainable also by considering the sections of the cubic surface by planes which pass through a line, say l; if one such plane have the equation $Ax + By + Cz + Dt = 0$, its section with the cubic surface corresponds to the plane curve

$$A\vartheta + B\phi + C\psi + D\chi = 0,$$

which contains the three points of the plane corresponding to the intersections of the line l with the surface. A point of the plane (ξ, η, ζ), other than one of these three points, which is common to two such plane curves $A\vartheta + \text{etc.} = 0$, $A'\vartheta + \text{etc.} = 0$, corresponds, therefore, to *two* different points of the cubic surface, lying respectively on the planes $Ax + \text{etc.} = 0$, $A'x + \text{etc.} = 0$. Two plane cubic curves have, in fact, nine common points. Thus the four curves $\vartheta = 0$, $\phi = 0$, $\psi = 0$, $\chi = 0$ have six points in common; these are the six points referred to.

The loci in the plane (ξ, η, ζ) which correspond to the known loci of the cubic surface can now be enumerated. If, through the point O, there be drawn an arbitrary line, and $\xi_1 u + \eta_1 v + \zeta_1 w = 0$, $\xi_2 u + \eta_2 v + \zeta_2 w = 0$ be two planes which contain this, the corresponding lines of the other two star-systems are determined; to any plane through the first line correspond definite planes through the two other corresponding lines, and the locus of the intersection of these three planes, when the first plane varies, is a cubic curve. The points of this correspond to the points $(\xi_1 + \theta\xi_2, \eta_1 + \theta\eta_2, \zeta_1 + \theta\zeta_2)$, of the plane (ξ, η, ζ), obtained by varying θ. Such cubic curves of the cubic surface, of which, for instance, one particular case is the curve common to the three quadrics $uv' - u'v = 0$, $uv'' - u''v = 0$, $u'v'' - u''v' = 0$, thus correspond to the lines of the plane (ξ, η, ζ). The cubic curves of the cubic surface which are of the same family as the curves γ, γ', on which the vertices of the star-systems lie, meet the cubic curves just obtained, each in five points, and, moreover, meet each of the lines $a, b, \ldots, f$ in two points. The cubics of the cubic surface of the family of γ and γ' thus correspond to curves, in the plane (ξ, η, ζ), which are of the fifth order and have a double point at each of the six singular points of this plane. A particular case of a cubic of the same family as γ, γ' is the aggregate of the lines a', b', c_{12}; a line a' meets five of the lines a, b, c, d, e, f, and is a chord of cubics of the family complementary to γ, γ'. Thus the line a' corresponds to a curve, in the plane (ξ, η, ζ), which contains the five singular points corresponding to b, c, d, e, f, and meets a line of this plane in two points; namely, this curve is the conic containing the five singular points. The line c_{12}, which meets a, b and also a', b', corresponds to the join of the two singular points (a), (b); the degenerate quintic curve corresponding to (a', b', c_{12}) consists of two conics and this line. The fifteen lines c_{rs} thus correspond to the joins of the six singular points.

More generally, it appears that, if we use the symbol U to denote, either an arbitrary line in the plane (ξ, η, ζ), or the corresponding curve of the cubic surface, of the family not meeting any of the lines a, b, c, d, e, f, and use the symbols $A_1, A_2, \ldots, A_6$ to denote, either the six singular points of the plane, or the corresponding lines $a, b, \ldots, f$ of the cubic surface, then a curve of order λ, in the plane, which has a general multiple point of order λ_r at the point A_r $(r = 1, \ldots, 6)$, may be associated with the symbol

$$\lambda U - \lambda_1 A_1 - \ldots - \lambda_6 A_6;$$

and that this will denote then, equally, a curve of the cubic surface of order $3\lambda - \lambda_1 - \ldots - \lambda_6$. It is necessary to prove (see below, Ex. 5), but it is stated here for clearness, that this curve is obtainable by the following process: Draw, through a set of λ cubic curves of the cubic surface, chosen arbitrarily from among those of the family to which U belongs, any surface, Ω, of sufficiently high order to contain these, and consider the curve which is the residual intersection of this surface with the cubic surface; through this residual curve draw the general surface, Ω', of the same order as Ω, which contains the line a as a λ_1-fold line, the line b as a λ_2-fold line, and so on; the remaining intersection of this second surface, Ω', with the cubic surface, is a curve which is represented by the symbol $\lambda U - \lambda_1 A_1 - \ldots - \lambda_6 A_6$; and there is a family of such curves when the conditions for the surface Ω' do not determine it uniquely. The curves of the family U are the simplest example of the statement, these being determined, as we have seen, by quadric surfaces all passing through an arbitrary cubic curve of the complementary family. The lines of the cubic surface such as c_{12} form another example; on the plane (ξ, η, ζ) this line, passing through A_1 and A_2, is representable by $U - A_1 - A_2$; on the cubic surface, we have seen, the aggregate (c_{12}, a, b) form a particular curve of the family of curves U. The representation of a conic, on the plane, passing through $A_2, A_3, \ldots, A_6$, will be $2U - s + A_1$, where s denotes $A_1 + \ldots + A_6$; it has been seen that this conic represents the line a' of the cubic surface. That this follows from the rule stated above we may see by drawing quadrics through two of the curves U, and considering a quartic surface through the residual intersection of these quadrics with the cubic surface; this residual intersection consists of two cubic curves of the complementary system; the quartic surface through these two cubic curves, and through the lines b, c, d, e, f, will further meet the cubic surface in a locus of order $3 . 4 - 2 . 3 - 5$, that is, in a line. This is then the line a', which, meeting the quartic surface in the five points in which it meets the lines b, c, d, e, f, lies entirely thereon. The representation, upon the plane (ξ, η, ζ), of a plane section of the cubic surface, being by a cubic curve through the singular points, will be associated with the symbol $3U - s$. This is the same as

$$(U - A_1 - A_2) + (2U + A_1 - s) + A_2,$$

in accordance with the fact that, on the cubic surface, the lines c_{12}, a', b form a particular plane section. We may easily interpret the symbol $3U - s$ directly, on the cubic surface, in accordance with the rule given above; for instance by using a sextic surface passing through three cubic curves of the family complementary to U.

Ex. 1. With some loss of symmetry we may obtain the representation of a cubic surface upon a plane in what is perhaps a more natural way, as follows. Assume that the surface possesses two non-intersecting lines; then, from any point, P, of the surface, a definite transversal can be drawn to these two lines, and this will meet an assumed fixed plane in a definite point, Q; conversely, from Q we can in general pass back to P without ambiguity, also by drawing a transversal, and considering its third intersection with the cubic surface. In this representation, all the points of the cubic surface which lie on a line, lying on the cubic surface, which is a transversal of the two given lines, correspond to the same point, Q, of the plane. Through either of the two assumed lines there pass five planes whose further intersection with the cubic surface consists of two lines, as has been remarked; the other of the two assumed lines thus meets at least one of each of these five pairs of coplanar lines. That is, there are five lines on the cubic surface meeting both the two assumed lines. Denote the two assumed lines by a' and b', and one of the five lines meeting both these by c_{12}; take coordinates so that the line a' is $x=0$, $y=0$, the line b' is $z=0$, $t=0$, and the line c_{12} is $y=0$, $t=0$; these leave a certain arbitrariness in x and z. It can then be shewn that the equation of the cubic surface is of the form

$$x\{z(ht-h'y)+t(gt-a'x-g'y)\}$$
$$+y\{z(bz+ft-f'y)+t(ct-c'y)\}=0.$$

Now take a point (ξ, η, ζ), in a plane, such that

$$\xi:\eta:\zeta=xt:yz:yt;$$

this point then corresponds to a definite line meeting the lines a', b', and so to a definite point of the cubic surface; and points of a line, $l\xi+m\eta+n\zeta=0$, correspond to the points on a cubic curve of the cubic surface, lying on a quadric $lxt+myz+nyt=0$, which is the general quadric containing the lines a', b', c_{12}. Conversely, we find, for the point (x, y, z, t) of the cubic surface,

$$x:y:z:t=\xi\phi:\zeta\phi:\eta\psi:\zeta\psi,$$

where $\phi=0$, $\psi=0$ represent conics in the plane (ξ, η, ζ). Thus a plane section of the cubic surface corresponds to a cubic curve, in the plane (ξ, η, ζ), with the equation

$$(A\xi+B\zeta)\phi+(C\eta+D\zeta)\psi=0.$$

This, whatever A, B, C, D may be, has six definite points: the intersections of the conics $\phi=0$, $\psi=0$; and the two points, $\xi=0$, $\zeta=0$, on $\psi=0$, and $\eta=0$, $\zeta=0$, on $\phi=0$. The representation can now be compared in detail with that given above.

Ex. 2. The symbol, for a cubic curve of the cubic surface, of the family complementary to U, represented on the plane by a quintic curve having a double point at each of the singular points, is $5U-2s$. We have $5U-2s+U=2(3U-s)$, in accord with the fact that two complementary cubic curves are together the intersection of the cubic surface with a quadric.

Ex. 3. A conic on the cubic surface obtained by a plane drawn through the line a, is associated with the symbol $3U-s-A_1$, and leads, in the plane (ξ, η, ζ), to a cubic curve passing through all the singular points, but having a double point at A_1. A conic, on the cubic surface, in a plane drawn through the line a', is associated with the symbol $U - A_1$, and corresponds to a line, in the plane (ξ, η, ζ), passing through the point A_1.

Ex. 4. On the cubic surface there are seventy-two families of cubic curves, each having as chords the six lines of one row of one of the double-sixes. For the row consisting of the lines $4', 5', 6', c_{23}, c_{31}, c_{12}$ (see above, p. 161), the corresponding family of cubic curves is represented by $2U - A_4 - A_5 - A_6$, giving, in the plane (ξ, η, ζ), conics passing through the three singular points A_4, A_5, A_6. For the row consisting of $1, 2, 3, c_{56}, c_{64}, c_{45}$, the cubic curves are represented by $4U - s - A_1 - A_2 - A_3$. For the row consisting of $2, 2', c_{13}, c_{14}, c_{15}, c_{16}$, the cubic curves are represented by $3U - s + A_1 - A_2$. All other cases are easily deducible from these.

Ex. 5. Two curves of the cubic surface associated, respectively, with the symbols $\lambda U - \Sigma\lambda_r A_r$, $\mu U - \Sigma\mu_r A_r$, meet one another in $\lambda\mu - \Sigma\lambda_r\mu_r$ points. Further, a curve of the preceding symbol is one of a family of which each curve is identified by the assignment of $\frac{1}{2}(n + m)$ points of it, so that the family is said to be of this *freedom*. Also the curves of this family are of *genus* $1 + \frac{1}{2}(n - m)$. Here $n = \lambda^2 - \Sigma\lambda_r^2$, $m = 3\lambda - \Sigma\lambda_r$, and the genus, π, of a curve, without actual multiple points, may be defined by saying that, of the intersections of a surface therewith, if the surface be of sufficiently high order, all but π can be chosen at will. For these matters, and the establishment of the general ideas, reference may again be made to a paper, *Proc. Lond. Math. Soc.* XI, 1912, p. 287; but see, also, Clebsch, *Die Geometrie auf der Flächen dritter Ordnung*, *Crelle's J.*, LXV, 1866.

Ex. 6. In the preceding theory, the cubic curves in the plane (ξ, η, ζ) which represent the plane sections of the cubic surface have been supposed to arise from the cubic surface. We may, however, start with six quite arbitrary points of the plane, and, taking the general cubic curve passing through these, whose equation will be of the form $A\vartheta + B\phi + C\psi + D\chi = 0$, consider the locus of a point in three dimensions whose coordinates are given by

$$x : y : z : t = \vartheta : \phi : \psi : \chi.$$

This locus will be a cubic surface, as the point (ξ, η, ζ), by which $\vartheta, \ldots, \chi$ are expressed, describes the plane. For $\vartheta, \phi, \psi, \chi$ we may then take any four particular cubic polynomials vanishing in the six given points, which are linearly independent of one another, the consequent modification of x, y, z, t being only a linear transformation of these. A particular case arose in Ex. 1 above, where the cubic curves were formed with the help of conics. Another case arises by remarking that there are two cubic curves passing through five of the given points which both have a double point at the remaining point. If we take ξ, η so that these both vanish at this sixth point, but not at any of the other five, the equations of these two cubic curves may be supposed to be $f=0$, $f_1=0$, where $f=a\xi^2+2h\xi\eta+b\eta^2$, and $f_1=a_1\xi^2+2h_1\xi\eta+b_1\eta^2$, in which a, h, b, a_1, h_1, b_1 are all linear homogeneous polynomials in ξ, η, and the third coordinate, ζ. From these we deduce two other cubic polynomials, $(af_1-a_1f)/\eta$ and $(fb_1-f_1b)/\xi$, which, equated to zero, represent cubic curves passing simply through all the six points. The four cubics are linearly independent, since an identity

$$A(af_1-a_1f)/\eta+B(fb_1-f_1b)/\xi-Cf_1+Df=0,$$

in which A, B, C, D are constants, involving the identity

$$f/f_1=(Aa\xi-Bb\eta-C\xi\eta)/(Aa_1\xi-Bb_1\eta-D\xi\eta),$$

would require f, f_1 to have a common factor linear in ξ, η, ζ. We thus obtain the cubic surface expressed by the formulae

$$x=(af_1-a_1f)/\eta, \quad y=(fb_1-f_1b)/\xi, \quad z=-f_1, \quad t=f,$$

the point, (ξ, η, ζ), corresponding to any point, (x, y, z, t), of this, being obtainable by solving the equations

$$az+a_1t+\eta x=0, \quad bz+b_1t-\xi y=0,$$

which are linear in ξ, η, ζ.

Ex. 7. Given seven lines of which no two intersect, having a common transversal, there exists a single point such that the planes joining this to the eight lines touch a quadric cone (p. 150, above, Ex. 4). Given six skew lines with a common transversal, the locus of a point, such that the planes joining it to the seven lines touch a quadric cone, is a cubic curve, having the six lines as chords but not meeting the transversal (above, p. 136). Given five skew lines with a common transversal, the locus of a point, such that the planes joining it to the six lines touch a quadric cone, is a cubic surface on which the six lines lie. The analytical proof of this leads naturally to the formulae of Ex. 6.

Let the common transversal be taken for $z=0$, $t=0$, the planes zxy, txy being any planes drawn through this. A quadric cone which touches the line $z=0$, $t=0$ will meet the planes zxy, txy in two conics touching one another on this line, say at the point $(\eta, -\xi, 0, 0)$. The equation of a plane being $lx+my+nz+pt=0$, the tangential equations of these conics are of the respective forms

$$n(l\eta-m\xi)-(al^2+2hlm+bm^2)=0,$$
$$p(l\eta-m\xi)-(a_1l^2+2h_1lm+b_1m^2)=0;$$

thus, if we denote $al^2+2hlm+bm^2$, and $a_1l^2+2h_1lm+b_1m^2$, respectively, by $\phi(l, m)$ and $\phi_1(l, m)$, and denote $\phi(\xi, \eta)$ and $\phi_1(\xi, \eta)$, respectively, by f and f_1, the coordinates, l, m, n, p, of the general tangent plane of the quadric cone which touches the line $z=0$, $t=0$ at the point $(\eta, -\xi, 0, 0)$, satisfy the relation

$$(l\eta - m\xi)(nf_1 - pf) - [\phi(l, m)f_1 - \phi_1(l, m)f] = 0.$$

This, however, breaks up into the equation $l\eta - m\xi = 0$, and the equation

$$l\frac{af_1 - a_1f}{\eta} + m\frac{fb_1 - f_1b}{\xi} - nf_1 + pf = 0,$$

which is thus the equation of the vertex of the cone. Herein the quantities $\xi, \eta, a, h, b, a_1, h_1, b_1$ enter homogeneously to the third order in the aggregate, the expression $(af_1 - a_1f)/\eta$, for example, being of the first order in ξ and η, and of the second order in the other six parameters.

Now, any line meeting the transversal $z=0$, $t=0$ is given by two planes $px+qy+rz=0$ and $px+qy+st=0$, so that the coordinates of the general plane containing this line are of the forms $(\lambda+\mu)p$, $(\lambda+\mu)q$, λr, μs. For this to be a tangent plane of the quadric cone we require

$$\lambda r(p\eta - q\xi) - (\lambda+\mu)\phi(p, q) = 0, \quad \mu s(p\eta - q\xi) - (\lambda+\mu)\phi_1(p, q) = 0;$$

thus, the condition for the cone to touch the line is

$$-p\eta + q\xi + \frac{1}{r}\phi(p, q) + \frac{1}{s}\phi_1(p, q) = 0.$$

This is a linear condition for the parameters $\xi, \eta, a, h, b, a_1, h_1, b_1$. Thus, when the cone is to touch seven such lines, beside their transversal, it is determinate, in general. When the cone is to touch six such lines, and their transversal, the six parameters, $a, h, \ldots, b_1$ are, in general, definite linear homogeneous functions of ξ, η; and the vertex of the cone, whose coordinates are then homogeneous cubic polynomials in ξ, η, describes a cubic curve. It may be shewn that this line has the six skew lines as chords, but does not meet their transversal; it has already been remarked (Ex. 8, p. 135) that the chords of a cubic curve which meet a line are projected, from a point of the curve, by planes which touch a quadric cone touching the line. Lastly, when the cone is to touch five skew lines and their common transversal, the six parameters $a, h, \ldots, b_1$ are expressible linearly by ξ, η and a third parameter, say ζ; the vertex of the cone then describes a cubic surface, upon which the five lines and their transversal may be shewn to lie.

Derivation of a plane quartic curve from a cubic surface. The converse of the result of the preceding example (7) is that, with the notation we have employed, the six planes joining an arbitrary point of a cubic surface to the lines b, c, d, e, f, of one row of a double-six, and to the line, a', of the other row, which meets all these, touch a quadric cone. This result finds its proper place in the considerations to which we now pass.

First, it must be made clear what is meant by the *tangent plane* of the cubic surface at any point, and by the *inflexional lines* of the surface at this point. If the equation of the surface be $f=0$, the three points in which the line joining two points (x_0, y_0, z_0, t_0), (x, y, z, t), meets the surface, are obtainable by solving the cubic equation in λ which arises by substituting in the equation $f=0$, for the coordinates, respectively $x_0+\lambda x$, $y_0+\lambda y$, etc. If D denote the operator $x\partial/\partial x_0 + y\partial/\partial y_0 + z\partial/\partial z_0 + t\partial/\partial t_0$, and f_0 denote what f becomes when x_0, y_0, z_0, t_0 are put for the coordinates, this equation is $f_0 + \lambda D f_0 + \frac{1}{2}\lambda^2 D^2 f_0 + \frac{1}{6}\lambda^3 D^3 f_0 = 0$. If (x_0, y_0, z_0, t_0) be on the cubic surface, or $f_0=0$, one root of this cubic equation is zero, for all points (x, y, z, t); namely, every line through (x_0, y_0, z_0, t_0) meets the surface once at that point. If (x, y, z, t) lie on the plane whose equation is $Df_0=0$, every line drawn in this plane, through the point (x_0, y_0, z_0, t_0), meets the surface twice at this point. This is the plane which is called the tangent plane of the surface at this point; the curve in which it meets the cubic surface has a double point at this point. Now consider the quadric surface whose equation is $D^2 f_0 = 0$; it is easy to prove that it passes through the point (x_0, y_0, z_0, t_0), and has, for tangent plane at this point, the tangent plane of the cubic surface. This plane therefore contains two lines of this quadric. But when a point, (x, y, z, t), satisfies both $Df_0=0$ and $D^2 f_0=0$, the above cubic equation in λ has three zero roots. We see thence that the generators at (x_0, y_0, z_0, t_0), of the quadric $D^2 f_0 = 0$, meet the cubic surface in three coincident points at (x_0, y_0, z_0, t_0); these are then the tangent lines at this point of the two branches of the section of the cubic surface by its tangent plane. They are the lines called the inflexional lines of the surface at (x_0, y_0, z_0, t_0); they lie in the tangent plane at this point. More generally, when (x_0, y_0, z_0, t_0) is not necessarily a point of the cubic surface, the plane $Df_0=0$ is called the polar plane of (x_0, y_0, z_0, t_0) in regard to the cubic surface, and the quadric $D^2 f_0 = 0$ is called the polar quadric; it is easy to see that, if Δ denote what the operator D becomes when x, y, z, t are interchanged, respectively, with x_0, y_0, z_0, t_0, the polar plane can be given by $\Delta^2 f=0$, and the polar quadric by $\Delta f=0$; thus, if a point lie on the polar plane of another point, this lies on the polar quadric of the first. In particular, the polar quadric of a point (x_0, y_0, z_0, t_0) meets the cubic surface in points at which the tangent plane passes through (x_0, y_0, z_0, t_0). Further, it may be remarked that if two curves on a cubic surface intersect in a point O, the plane determined by the tangent lines of these curves at O is the tangent plane of the surface.

We take now a point, O, of the cubic surface, not lying on any of the lines of the surface. Then we consider the curve of the surface which is the locus of points, P, of the surface, whereat the tangent plane passes through O; as we have seen, this is the intersection of the cubic surface with the polar quadric of O; moreover, this polar quadric passes through O, has the same tangent plane as the cubic surface at O, and contains the two inflexional lines of the surface at O. The curve in question, being the intersection of the cubic surface with a quadric, is of the sixth order; by what is said, it passes through O, having there a double point, its two tangent lines at this point being the inflexional lines of the cubic surface. Thus an arbitrary plane through O meets the curve in four other points, and the curve is projected from O, on to an arbitrary plane, into a quartic curve. Conversely, it may be stated, any general quartic curve in a plane can be shewn to be capable of being thus derived. We shall denote the sextic curve on the cubic surface by ϑ.

If an arbitrary quadric cone be drawn with vertex O, four of its twelve points of intersection with ϑ will be at O, and there will be eight others; it may happen that these eight other points coincide in pairs, the quadric cone touching the curve ϑ in four points, not at O. When this is so, we may, for brevity, speak of the cone as a contact cone. In such case, if a further arbitrary quadric cone be drawn, with vertex at O, to pass through the four points of contact, with the curve ϑ, of the contact cone in question, the remaining four intersections, with ϑ, of this further cone, are also points of contact with ϑ, of a contact cone; this we speak of as being of the same *system* as the former. There are in all sixty-three different systems of contact cones, with the same vertex, O. In particular such a contact cone may consist of two planes; then either it consists of the tangent plane of the cubic surface at O, taken with the plane joining O to one of the twenty-seven lines of the surface; or it consists of the planes joining O to two non-intersecting lines of the surface. There are 216 pairs of non-intersecting lines of the surface, but it will be seen that these arrange themselves in sets of six pairs giving degenerate contact cones of the same system.

We approach the proof of these statements by considering, first, degenerate contact cones consisting of the tangent plane at O taken with the plane joining O to a line of the surface. When the curve ϑ is projected from O on to a plane, ϖ, the tangent line of the resulting quartic curve, at any point, is evidently the intersection with ϖ of the tangent plane of the cubic surface at the corresponding point, P, of the curve ϑ, this tangent plane, by hypothesis, passing through O. In particular, by taking P at O, the tangent plane of the cubic surface at O gives rise to a tangent line of the quartic curve; but there are two ways of approach of P to O, along the two branches at O of the curve ϑ; thus the tangent plane of the cubic surface at O touches the plane quartic curve in two points, lying, namely, on the inflexional lines of the cubic surface at O. The plane joining O to any one, say l, of the lines of the cubic surface, equally gives a double-tangent of the plane quartic curve; the points of contact are the projections of the two points of the line l at which the plane Ol is a tangent plane of the cubic surface, namely the points in which l is met by the conic in which the plane Ol cuts the surface. We thus see that the plane quartic curve has twenty-eight double-tangents. Now, let any plane be drawn through the line l, meeting the cubic surface also in a conic, say σ. The six intersections of this plane with the curve ϑ will contain the two points of this we have just found lying on the line l, which do not lie on σ, in general; and there will be four other points, which will lie on the conic σ. We have remarked that, when two curves of the cubic surface have distinct tangent lines at a point where the curves intersect, the plane of these lines is the tangent plane of the surface. Thus, the tangent plane of the cubic surface at any one of the four intersections of the curve ϑ and the conic σ, touches both these curves; while, by definition of ϑ, this plane passes through the point O. The quadric cone joining O to the conic σ is thus a contact cone, touching the curve ϑ in four points. This cone will meet the plane ϖ in a conic having four points of contact with the plane quartic curve, and, therefore, no further intersections with this. We have remarked that, in general, the conic σ does not contain the two points where the curve ϑ meets the line l; the curve ϑ, however, lies on a quadric, the polar quadric of O; the section of this quadric by the plane of σ is a conic; this conic contains the two points where ϑ meets l, and the four points where ϑ meets σ. This conic also meets the two generators at O of the polar quadric of O. Thus, on projection to the plane ϖ, the four points of contact of the conic arising by projection of σ, with the plane quartic curve, lie on a conic whose other four intersections with the quartic are the points of contact with this of two of its double-tangents. Of the contact cones, $O\sigma$, joining O to a conic σ, there is an infinite number, each defined by a plane through the line l; and, as an arbitrary line through O meets the cubic surface again in two points, two such cones pass through this line. In particular, there are five planes through the line l for which the conic σ breaks up into two lines, and the cone $O\sigma$ becomes two planes; we may also consider the plane-pair consisting of the plane Ol and the tangent plane at O as a sixth degenerate contact cone. Thus, in the plane ϖ, for the plane quartic curve, the result is that two of the contact conics, of the system derived from the line l, pass through an arbitrary point of the plane, and six of them break up into two lines, each a bitangent of the plane quartic curve. This system of contact conics may remind us of the conics in a plane which touch four given lines, which is indeed a particular case, arising when the quartic curve breaks up into four lines. In the particular case, all the conics are inpolar to any conic passing through three particular points, which form a triad self-polar in regard to all the conics touching the four lines. In the general case now before us, it is also true that the contact conics of the system considered are all inpolar to a conic, which is unique; in special this is true of the six contact conics which break up into two lines. Thus, as a pair of lines inpolar to a conic intersect thereon, we have the result that the six points of intersection of the pairs of bitangents which are particular contact conics of the system, lie upon a conic, to which all the proper contact conics of the system are inpolar. Such a set of six pairs of bitangents is called a Steiner system; there are evidently twenty-seven systems arising in this way. The proof of several of the statements here made has not been given; but the character of this proof will be clear after the consideration of the thirty-six cases of contact conics associated with pairs of non-intersecting lines of the cubic surface, to which we now pass.

Consider one of the thirty-six double-sixes of lines of the cubic surface; with this, as we have seen, are associated two families of cubic curves on the surface. Through the point O, and an arbitrary point, say H, of the curve ϑ, a definite curve of one of these families can be drawn; this curve is projected from O by a quadric cone, whose residual intersection with the cubic surface is, as we have seen, a cubic curve of the other family; and these two curves cross one another at five points, as was also proved. Of these five points, O is evidently one; at any other point of crossing of these curves, which lie both on the cone and on the cubic surface, the plane of the tangent lines of the two curves is as well a tangent plane of the cone, passing through O, and a tangent plane of the cubic surface; thus the point of crossing lies on the curve ϑ. Wherefore, the quadric cone touches the cubic surface, and the curve ϑ, at the assumed point H, and also at three other points, say P, Q and R, and is such a contact cone as was in view. It may be remarked, too, that, in virtue of what has previously been proved (above, p. 177), the polar line of OH, in regard to the Schur quadric belonging to the double-six under consideration, lies in the plane PQR, the five points O, H, P, Q, R forming a self-conjugate pentad in regard to this quadric, while the contact cone is outpolar to this quadric. The system of contact cones, of vertex O, of the curve ϑ, obtained in this way, consists of the cones projecting from O the cubic curves, through O, of either of the two families belonging to the double-six; and, since an arbitrary line through O meets the cubic surface in two further points, and a cubic curve of the family is determined by O and another point of the surface, we see that there are two such cones containing, as generator, an arbitrary line drawn through O. Now, suppose that a and a' are two lines of different rows of the double-six, not intersecting one another; then, one cubic curve, of those associated with the double-six, consists of the line a', together with the conic in which an arbitrary plane drawn through the other line, a, meets the cubic surface, other than a itself; a degenerate cubic of the complementary family is, similarly, constituted by the line a taken with a conic of the cubic surface lying in a plane through a'. Hence, a degenerate contact cone is constituted by the two planes Oa, Oa'. Also, if the conics in the planes Oa, Oa' meet a and a', respectively, in A, B and A', B', it is easily seen, in accordance with a remark made above, that A, B, A', B' form a self-polar tetrad in regard to the Schur quadric belonging to the double-six. On the other hand, the contact cones from O are all inpolar to a definite quadric cone with O as vertex. For, such a contact cone is determined by one of the cubic curves, associated with the double-six, which pass through O; and this curve is determined by its tangent line at O. The equation of the cone thus contains rationally a parameter, determining this tangent line in the tangent plane at O of the cubic surface. We have remarked, however, that there are two of these contact cones possible, containing an arbitrary line drawn through O. The parameter thus enters to the second order in the equation of the tangent cone; this equation is, therefore, of the form $\lambda^2 U + \lambda V + W = 0$, where λ is the parameter, and U, V, W are cones with vertex at O. By considering the tangential equation of this cone, we see that there is a single definite cone, with O as vertex, which is outpolar to all the contact cones. In particular, this single cone, say Ω, is outpolar to all the plane-pairs such as Oa, Oa'. Hence we have the result that if a, a'; b, b'; ..., f, f' be the pairs of lines in the six *columns* of a double-six, and O be an arbitrary point of the cubic surface, the six transversals from O, to a and a'; to b and b'; etc., lie upon a quadric cone, Ω.

Ex. 1. A similar argument is applicable to the case of the contact cones obtained by joining O to the conics of the cubic surface lying in planes through a line, l, of the surface. Hence we have the result that, if C_1, C_2, ..., C_5 be the points of intersection of the five pairs of lines of the cubic surface, of which a pair lie in a plane through the line l, then the quadric cone containing the five lines OC_r contains also the line in which the plane Ol meets the tangent plane at O. It will be recalled that it has been proved that the five planes joining O to one from each of the five pairs of intersecting lines meeting l, touch a quadric cone which touches the plane Ol (above, p. 195).

It is known, too, that the lines joining the pairs of the five points C_r, and the planes containing the threes of these, meet an arbitrary plane in ten points, and ten lines, of which each point is the pole of one of the lines in regard to a certain conic in that plane (Vol. II, p. 218). When the plane is any plane through the line l, the conic in question is the conic of the cubic surface which lies in this plane; and any cubic curve through the five points C_r meets this plane in points which form a self-conjugate triad in regard to this conic (A. C. Dixon, *Quart. J. of Math.*, XXIII, 1889, p. 343).

Ex. 2. We may deal with the theory of the contact cones of the curve ϑ with analysis. It will be sufficient here to consider the case of contact cones associated with a double-six. As before, let O be any point of the cubic surface, and a, a' be two non-intersecting lines of the surface. Let the conics of the surface which lie in the planes Oa, Oa' meet the lines a, a', respectively, in A, B and A', B'. Choose coordinates so that the planes Oa, Oa', OAA' are, respectively, $y=0$, $z=0$, $x=0$, the plane $t=0$ being any plane through the line AA'. The line a, in the plane $y=0$, will have an equation $x+\lambda t=0$; as it does not intersect the line a', it must intersect the conic of the cubic surface which lies in the plane Oa', or $z=0$, the point of intersection being on the line $y=0$, $z=0$; this conic may then be taken to have the equations

$$z=0, \quad x^2+\lambda xt+mxy+nyt=0.$$

The line a' being, similarly, $z=0$, $x+\mu t=0$, the conic in the plane Oa has equations of the forms $y=0$, $x^2+\mu xt+rxz+kzt=0$. Hence we find, for the equation of the plane OBB', $\xi=0$, where $\xi=(\lambda-\mu)x+y(n-m\mu)+z(r\lambda-k)$; and, for the equation of the tangent plane of the cubic surface at O, $P=0$, where

$$P=\lambda\mu x+n\mu y+k\lambda z.$$

Then the equation of the cubic surface is $C=0$, where

$$C=t^2P+tQ+R,$$

in which

$$Q=(\lambda+\mu)x^2+(n+m\mu)xy+(k+r\lambda)xz+2fyz,$$

$$R=x^2(x+my+rz)+yz(ux+vy+wz),$$

f, u, v, w being constants. Taking, then, $U=2tP+Q$, so that $U=0$ is the polar quadric of O, we can verify the identity

$$4PC=U^2-x^2\xi^2+4yz\psi,$$

where

$$\psi=x^2(n-m\lambda)(r\mu-k)+P(ux+vy+wz)-fQ+f^2yz.$$

This identity is the same as

$$4PC = U^2 - \Phi^2 + 4yz\Psi,$$

wherein $\Phi = x\xi + 2\lambda yz$, $\Psi = \psi + \lambda x\xi + \lambda^2 yz$, and λ is an arbitrary parameter. The curve ϑ, for which $C = 0$, $U = 0$, thus lies on the quartic cone, of vertex O, given by

$$\Phi^2 - 4yz\Psi = 0, \text{ or } x^2\xi^2 - 4yz\psi = 0,$$

and $\Phi = 0$ represents the general quadric cone, of vertex O, containing the points A, B, A', B'. A general contact cone is therefore given by $\Psi = 0$.

It is clear from the first form of the identity that the points of the curve given by the intersection of the quadrics

$$U + x\xi + 2\lambda yz = 0, \quad U - x\xi - 2\lambda^{-1}\psi = 0$$

lie either on the cubic surface, or on the tangent plane, $P = 0$. It can be seen that these quadrics have in common a line, through O, lying in the tangent plane, variable with λ. The common curve of these quadrics, however, lies on the cone $\Psi = 0$, which thus contains a cubic curve, of the cubic surface, passing through O. Another such cubic curve is obtained from the quadrics

$$U - x\xi - 2\lambda yz = 0, \quad U + x\xi + 2\lambda^{-1}\psi = 0.$$

Further elementary results will be found in papers, *Proc. Lond. Math. Soc.*, IX, 1910, p. 145, and p. 205, the latter of which gives valuable references to the literature. The theory of the contact cones was originally obtained with the help of multiple theta functions, and belongs to any curve whatever which is not rational or elliptic. See Clebsch, *Crelle's J.*, LXIII, 1864, p. 189; and, for a general introduction, the writer's *Abel's Theorem* (Cambridge, 1897), pp. 377—392. The result we have proved that, of the points of contact, H, P, Q, R, of a contact cone with the curve ϑ, the three latter are determined when the first is given arbitrarily, arises from the fact that the curve ϑ is of *genus* 3 (see above, p. 194). The number 4, of points of contact, is the value of $2p-2$ when $p=3$; the number 63, of systems of contact cones, is the value of $2^{2p}-1$ when $p=3$; the number 6, of degenerate contact cones of any system is the value of $2^{p-2}(2^{p-1}-1)$ when $p=3$. For a general sextic curve obtained by the intersection of any cubic surface with any quadric surface, there are, similarly, quadrics which touch the curve in six points, the value of the genus, p, in this case, being 4. An interesting geometrical introduction to this case is given by Milne, *Proc. Lond. Math. Soc.*, XXI, 1922, p. 373; see also P. Roth, *Monatsh. f. Math. u. Phys.*, XXII, 1911, pp. 64—88.

The equation of the cubic surface referred to two Steiner trihedrals. Consider a cubic surface defined by the vanishing of a general cubic polynomial in the coordinates x, y, z, t, and assume that this surface contains at least one line, and thence that there are five planes through this line whose further intersection with the surface consists of a pair of lines (as above, p. 167); let the coordinates be taken, with the point $x = 0$, $y = 0$, $z = 0$ on the surface, so that one line of the surface is $x = 0$, $t = 0$, so that another pair of lines of the surface which meet this are $t=0$, $y=0$ and $t=0$, $z=0$, and so that a further plane, containing a pair of lines beside $x=0$, $t=0$, is given by $t+x=0$, these lines being, respectively, $t+x=0$, $v=0$, and $t+x=0$, $w=0$, where v, w are homogeneous polynomials in x, y, z. Then the equation of the cubic surface is necessarily of the form $t^2P+t\phi+xyz=0$, where ϕ is a homogeneous quadratic polynomial in x, y, z, and P is linear in these; and, as $t+x=0$ intersects the surface in the lines for which $v=0$, $w=0$, we have $\phi=xP+yz-vw$. The equation is, therefore, $t^2P+t(xP+yz-vw)+xyz=0$. It is at once seen, however, that this is identically the same as

$$(t+x)(t+by)(t+cz)=t(t+x+qv)(t+x+rw),$$

in which b, c, q, r are constants, provided that these constants can be so chosen that $bc=qr$, and also so that there is the identity

$$x+qv+rw-by-cz+bcP=0\,;$$

if we assume general values for v, w, P, as linear functions of x, y, z, write $b=\lambda q$, $c=\lambda^{-1}r$, and equate coefficients of x, y, z in this identity, two of the resulting equations determine q and r uniquely in terms of λ, and the substitution of these in the third equation leads to an equation for λ of the fourth order. Thus the form in question is possible. In more general terms, the equation of the cubic surface is reducible to the form $UVW=U'V'W'$, in which $U=0, \dots$ are six planes. By considering the geometrical meaning of this (as will appear more particularly in a moment), we see that these are the planes of a Steiner trihedral pair, previously explained (above, pp. 164, 174); so that there are 120 ways in which the equation of the cubic surface can be reduced to this form.

Now assume this form; and let $U_0, V_0, \dots$ be the values of $U, V, \dots$, respectively, at an arbitrary general point, (x_0, y_0, z_0, t_0), of the surface, which does not lie on a line of the surface; put $u=U/U_0$, $v=V/V_0$, etc.; then, in virtue of $U_0V_0W_0=U_0'V_0'W_0'$, we can suppose the equation of the surface to be $uvw=u'v'w'$. The six planes $u=0$, $v=0$, ... must be expressible by four of them; thus we can suppose the existence of two identities of the forms

$$a_1u+b_1v+c_1w=a_1'u'+b_1'v'+c_1'w',$$
$$a_2u+b_2v+c_2w=a_2'u'+b_2'v'+c_2'w',$$

wherein, since $u, v, \dots$ reduce to unity at (x_0, y_0, z_0, t_0), the constants are such that

$$a_1+b_1+c_1=a_1'+b_1'+c_1',\quad a_2+b_2+c_2=a_2'+b_2'+c_2',$$

and, therefore, such that

$$(a_1+\sigma a_2)+(b_1+\sigma b_2)+(c_1+\sigma c_2)=(a_1'+\sigma a_2')+(b_1'+\sigma b_2')+(c_1'+\sigma c_2'),$$

whatever σ may be. We may, however, in three ways, choose σ so that

$$(a_1 + \sigma a_2)(b_1 + \sigma b_2)(c_1 + \sigma c_2) = (a_1' + \sigma a_2')(b_1' + \sigma b_2')(c_1' + \sigma c_2').$$

But, when we have six quantities $\lambda, \mu, \nu, \lambda', \mu', \nu'$ which satisfy the two relations $\lambda + \mu + \nu = \lambda' + \mu' + \nu'$, and $\lambda\mu\nu = \lambda'\mu'\nu'$, if we put

$$\alpha = (\mu' - \nu)/(\lambda - \lambda'), \quad \beta = (\nu' - \lambda)/(\mu - \mu'), \quad \gamma = (\lambda' - \mu)/(\nu - \nu'),$$

and, then, $\alpha' = 1 - \alpha$, $\beta' = 1 - \beta$, $\gamma' = 1 - \gamma$, it can at once be verified that $\lambda, \mu, \nu, \lambda', \mu', \nu'$ are, respectively, proportional to $\beta\gamma', \gamma\alpha', \alpha\beta', \beta'\gamma, \gamma'\alpha, \alpha'\beta$. Hence, in our case, the identities connecting $u, v, \ldots$ are capable of the forms

$$\beta_r\gamma_r'u + \gamma_r\alpha_r'v + \alpha_r\beta_r'w = \beta_r'\gamma_r u' + \gamma_r'\alpha_r v' + \alpha_r'\beta_r w',$$

for $r = 1, 2, 3$, these being equivalent to two independent equations. If, then, we put

$$\xi_r = \beta_r\gamma_r'u, \quad \eta_r = \gamma_r\alpha_r'v, \quad \zeta_r = \alpha_r\beta_r'w,$$
$$\xi_r' = \beta_r'\gamma_r u', \quad \eta_r' = \gamma_r'\alpha_r v', \quad \zeta_r' = \alpha_r'\beta_r w',$$

the equation of the cubic surface is capable of the forms

$$\xi_r\eta_r\zeta_r = \xi_r'\eta_r'\zeta_r',$$

where $\xi_r, \eta_r, \ldots$ are subject to two linear identities, of which one is

$$\xi_r + \eta_r + \zeta_r = \xi_r' + \eta_r' + \zeta_r'.$$

With these equations we can at once specify the equations of the twenty-seven lines of the cubic surface. In the first place, the line of intersection of any one of the planes $\xi_r = 0$, $\eta_r = 0$, $\zeta_r = 0$ with any one of the planes $\xi_r' = 0$, $\eta_r' = 0$, $\zeta_r' = 0$ is evidently a line of the surface, the same line for the three values of the suffix r, since the plane $\xi_r = 0$ is the same as $u = 0$, etc. Denoting such a line by $\xi\xi'$, $\xi\eta'$, etc., we may represent these lines, respectively, with a notation previously employed, by the scheme

$$\begin{array}{lllccc} \xi\xi', & \xi\eta', & \xi\zeta' \equiv & c_{12}, & 1, & 2' \\ \eta\xi', & \eta\eta', & \eta\zeta' & 1', & c_{31}, & 3 \\ \zeta\xi', & \zeta\eta', & \zeta\zeta' & 2, & 3', & c_{23} \end{array}$$

and may thence recover the original definition of the trihedral pair. In the next place, if X_r', Y_r', Z_r', respectively, denote $\xi_r', \eta_r', \zeta_r'$, in some order, the line given by $\xi_r = X_r'$ and $\eta_r = Y_r'$ is, by the identity connecting the six planes, also on the plane $\zeta_r = Z_r'$; and thus lies on the surface. This line may be represented by $(X', Y', Z')_r$; by taking all three values of r, and all permutations for X_r', Y_r', Z_r', so that, for example, $(\xi', \zeta', \eta')_r$ stands for $\xi_r = \xi_r'$, $\eta_r = \zeta_r'$, $\zeta_r = \eta_r'$, we obtain eighteen lines. With the previous notation they may be identified as follows:

$(\eta', \xi', \zeta')_r \equiv c_{14}, c_{15}, c_{16}$; $(\zeta', \eta', \xi')_r \equiv c_{24}, c_{25}, c_{26}$; $(\xi', \zeta', \eta')_r \equiv c_{34}, c_{35}, c_{36}$
$(\xi', \eta', \zeta')_r \equiv c_{56}, c_{64}, c_{45}$; $(\zeta', \xi', \eta')_r \equiv 4, 5, 6$; $(\eta', \zeta', \xi')_r \equiv 4', 5', 6'$,
where the meaning is, that, in each case, the three lines on the right arise, respectively, for $r = 1, 2, 3$.

The Cremona form of the equation of the cubic surface. Remarking the identity

$$(x + y + z)^3 = x^3 + y^3 + z^3 + 3(y + z)(z + x)(x + y),$$

and putting

$$\xi = x_2 + x_3, \quad \eta = x_3 + x_1, \quad \zeta = x_1 + x_2,$$
$$\xi' = -(x_5 + x_6), \quad \eta' = -(x_6 + x_4), \quad \zeta' = -(x_4 + x_5),$$

or

$$2x_1 = \eta + \zeta - \xi, \; \ldots, \; 2x_4 = \xi' - \eta' - \zeta', \; \ldots,$$

the two equations $\xi\eta\zeta = \xi'\eta'\zeta'$, $\xi + \eta + \zeta = \xi' + \eta' + \zeta'$, lead to the two

$$x_1^3 + x_2^3 + x_3^3 + x_4^3 + x_5^3 + x_6^3 = 0,$$
$$x_1 + x_2 + x_3 + x_4 + x_5 + x_6 = 0.$$

The cubic surface may then be supposed to be given by these two equations, taken with another necessary linear equation connecting $x_1, \ldots, x_6$. (Cremona, *Math. Annal.*, XIII, 1878.)

The planes $x_1 = 0, \ldots, x_6 = 0$, save for permutations, are determinate, in association with a particular double-six of lines of the cubic surface. For fifteen of the lines of the surface are given each by a set of three planes such as $x_1 + x_2 = 0$, $x_3 + x_4 = 0$, $x_5 + x_6 = 0$. The other twelve lines, which are $5, 5', c_{6m}$ and $6, 6', c_{5m}$ (for $m = 1, 2, 3, 4$), form a double-six, and can be found in terms of the coefficients in the remaining equation connecting $x_1, \ldots, x_6$, by the solution of a quadratic equation.

The Sylvester form of the equation of the cubic surface. The Cremona form may be regarded as a particular case of a form $\Sigma a_r x_r^3 = 0$, subject to the relation $\Sigma x_r = 0$, with another linear relation connecting $x_1, \ldots, x_6$; that namely in which the coefficients $a_1, \ldots, a_6$ are equal. As Reye has shewn (*Crelle's J.*, LXXVIII, 1874), there exists a set of six planes $x_1 = 0, \ldots$, corresponding to any arbitrary line, for which the more general form is possible. We assume this form, in order to reach a remarkable form, as a sum of *five* cubes, due to Sylvester (1851; *Math. Papers*, I, p. 195); the method we follow can in particular be carried out starting from the Cremona form. It will be seen that it is supposed that the cubic surface is quite general.

We assume, that is, the cubic surface given by the equations

$$\sum_{r=1}^{6} a_r x_r^3 = 0, \quad \sum_{r=1}^{6} x_r = 0, \quad \sum_{r=1}^{6} h_r x_r = 0,$$

of which the last is the second necessary condition connecting $x_1, x_2, \ldots$; in this we may, evidently, replace $h_1, h_2, \ldots$ by $h_1+\lambda$, $h_2+\lambda, \ldots$, where λ is arbitrary. We take the most general case possible, assuming that no two of $h_1, h_2, \ldots, h_6$ are equal; this is necessary for the method we employ. Then, $\phi(\sigma)$ denoting the product of the six factors $\sigma-h_r$, and $\phi'(\sigma)=d\phi(\sigma)/d\sigma$, none of the quantities $\phi'(h_r)$ is zero. We can also suppose that the sum, of six terms, $\Sigma a_r^{-1}\phi'(h_r)$, does not vanish. For, the quintic polynomial in λ expressed by $\Sigma a_r^{-1}\phi'(h_r+\lambda)$ vanishes only for five values of λ, unless it vanish identically—and that is not so; this we see by equating to zero the coefficients of the various powers of λ, and eliminating, from the six resulting equations, the six coefficients a_r^{-1}; the result is the product of the differences of $h_1, \ldots, h_6$. To ensure that $\Sigma a_r^{-1}\phi'(h_r)$ does not vanish we have, then, only to increase each of $h_1, h_2, \ldots$ by a suitable value of λ; this we suppose to be done. Now we consider the expression

$$\psi(\sigma), = -\phi(\sigma)\sum_{r=1}^{6}\frac{a_r^{-1}\phi'(h_r)}{\sigma-h_r};$$

by the condition just secured, this is a quintic polynomial in σ; let its roots be $k_1, \ldots, k_5$. It is necessary for the method we employ to assume that *no two of these roots are equal, nor any of them equal to any of* $h_1, \ldots, h_6$.

Next, let
$$F(\sigma)=\phi(\sigma)\sum_{r=1}^{6}\frac{x_r}{\sigma-h_r},$$

so that, by the conditions connecting $x_1, \ldots, x_6$, this is a cubic polynomial in σ. The equation $F(\sigma)=0$, when $x_1, \ldots, x_6$, as well as σ, are variable, is the equation of a plane of a cubic developable; as $F(h_r)=\phi'(h_r)x_r$, this is the cubic developable of which $x_1=0$, $x_2=0, \ldots, x_6=0$ are planes.

Now consider, as depending upon σ, the fraction

$$[F(\sigma)]^3/\phi(\sigma)\psi(\sigma),$$

of which the numerator is of the ninth order, and the denominator is of the eleventh order, and has its roots all different. Expressing this in partial fractions we can infer that

$$\sum_{r=1}^{6}\frac{F^3(h_r)}{\phi'(h_r)\psi(h_r)}+\sum_{s=1}^{5}\frac{F^3(k_s)}{\phi(k_s)\psi'(k_s)}=0;$$

as $F(h_r)=\phi'(h_r)x_r$ and $\psi(h_r)=-a_r^{-1}[\phi'(h_r)]^2$, the first sum is $-\Sigma a_r x_r^3$. If we put

$$\xi_s=[\phi(k_s)]^{\frac{1}{3}}\sum_{r=1}^{6}\frac{x_r}{k_s-h_r},$$

so that $\xi_s = 0$ represents one of five particular planes of the cubic developable containing the six planes $x_r = 0$, and also put

$$\mu_s = [\phi(k_s)]^{\frac{1}{2}}/\psi'(k_s),$$

we are finally able to infer that

$$\sum_{r=1}^{6} a_r x_r^3 = \sum_{s=1}^{5} \mu_s \xi_s^3,$$

where also $\sum_{s=1}^{5} \mu_s \xi_s = 0$; for

$$\sum_{s=1}^{5} \mu_s \xi_s = \sum_s \frac{\phi(k_s)}{\psi'(k_s)} \sum_r \frac{x_r}{k_s - h_r}, \; = \sum x_r \sum_s \frac{\phi(k_s)}{\psi'(k_s)(k_s - h_r)},$$

and we have only to consider the expression of $F(\sigma)/\psi(\sigma)$ in partial fractions, regarded as depending on σ. The relation $\Sigma \mu_s \xi_s = 0$ is the only necessary relation among the five planes $\xi_s = 0$.

This method of deducing Sylvester's form was given by Beltrami (*Rendic. Lomb.*, Milan, XII, 1879, p. 24). Sylvester's own enunciation was accompanied by indications of a proof, depending on the properties of the Hessian surface, which has been developed by Clebsch (*Crelle's J.*, LIX, 1861, p. 193); the nature of this proof will be understood from the properties of the Hessian developed below on the basis of Sylvester's form. The reader may also consult Gordan, *Math. Annal.*, V, 1872, p. 341. Also Segre and Sturm, *Archiv d. Math. u. Phys.*, X, 1906, pp. 209, 216. And, generally, Steiner, *Gesamm. Werke*, II, p. 657; Sturm, *Synthetische Untersuch. ü. Fl. dr. Ordn.*, Leipzig, 1867; Cremona, *Mémoire de géom. pure sur les surf. d. trois. ordre, Crelle's J.*, LXVIII, 1868, and Grassmann, *Crelle's J.*, XLIX, 1855, p. 37.

The polars in regard to a cubic surface. The Hessian surface. We have already explained (above, p. 182) what is meant by the polar quadric, and by the polar plane, of a point in regard to a cubic surface. In regard to the polar quadrics, it is convenient to notice here, (*a*), that the polar quadrics of all points of a line are a system of quadrics all passing through the curve of intersection of any two of them, as is clear because the polar quadric of a point is expressed by an equation which is linear in the coordinates of this point; and, (*b*), that the polar quadrics of all points of a plane have common the eight points of intersection of any three of these quadrics. When the polar quadric of one point passes through another point the polar plane of this other passes through the first point; there are thus eight points of which a given plane is the polar plane. In regard to polar planes, we consider similarly, (*a*), the envelope of the polar planes of the points of a given line. These planes are expressed by an equation of the form

$$[(\lambda x_1 + \mu x_2)\partial/\partial x + \ldots]^2 f = 0,$$

that is, of the form $\lambda^2 P + 2\lambda\mu Q + \mu^2 R = 0$, where P, Q, R are linear in the current coordinates x, y, z, t. These are the tangent planes of a quadric cone, whose equation is $RP = Q^2$. But it may happen, as will be seen, that the cone degenerates, all these polar planes having a line in common. Further, (b), we consider the envelope of the polar planes of the points of a given plane, say ϖ. It is clear that the *coordinates* of such a polar plane are homogeneous quadratic functions of *three* variable parameters. From this it follows (as will be seen below, p. 222) that these polar planes all touch a particular surface of the third order, which has four double points. The polar quadrics of the points of this cubic surface, taken in regard to the original cubic surface, can then be proved to touch the plane, ϖ, from which we began.

The polar quadric of a point, (x_0, y_0, z_0, t_0), may be a cone, of vertex (x_1, y_1, z_1, t_1). The condition for this is the coexistence of four equations, linear both in regard to (x_0, y_0, z_0, t_0), and in regard to (x_1, y_1, z_1, t_1), as we easily see; and these equations are symmetrical in regard to both these points. If we denote the values, at (x_1, y_1, z_1, t_1), of $\partial^2 f/\partial x^2, \partial^2 f/\partial x \partial y, \ldots, \partial^2 f/\partial t^2$, wherein $f=0$ is the equation of the cubic surface, respectively by $f_{11}, f_{12}, \ldots, f_{44}$, these four equations are $x_0 f_{r1} + y_0 f_{r2} + z_0 f_{r3} + t_0 f_{r4} = 0$, for $r = 1, \ldots, 4$. We infer, then, that the necessary and sufficient condition is that both (x_0, y_0, z_0, t) and (x_1, y_1, z_1, t_1) should be points of a quartic surface whose equation is expressible by the vanishing of the determinant, of four rows and columns, whose general element is f_{rs}. This is the Hessian surface of the cubic surface, of which (x_0, y_0, z_0, t_0) and (x_1, y_1, z_1, t_1) are then said to be *corresponding* points. (Cf. p. 188, above.) It is important to recognise that this surface is independent of the choice of coordinates by which it is expressed.

The Hessian may be formed by the rule for any cubic surface, however special. When the surface is sufficiently general to be expressible in Sylvester's form

$$ax^3 + by^3 + cz^3 + dt^3 + eu^3 = 0,$$

with the condition

$$ax + by + cz + dt + eu = 0,$$

the polar plane of a point (X, Y, Z, T, U), where also

$$aX + \ldots + eU = 0,$$

is easily found to be

$$aX^2x + bY^2y + cZ^2z + dT^2t + eU^2u = 0;$$

and this equation is also that of the polar quadric of (x, y, z, t, u) when $X, Y, \ldots$ are regarded as current coordinates. Hence the equation of the Hessian surface is

$$ax^{-1} + by^{-1} + cz^{-1} + dt^{-1} + eu^{-1} = 0,$$

the relation connecting corresponding points being

$$x_0x_1 = y_0y_1 = z_0z_1 = t_0t_1 = u_0u_1.$$

If $F = 0$ denote the Hessian, the tangent plane, at any point $(x_0, y_0, \ldots)$ of this Hessian, calculated by the formula

$$[x\partial/\partial x_0 + y\partial/\partial y_0 + z\partial/\partial z_0 + t\partial/\partial t_0]F = 0,$$

where, in F, the coordinate u_0 has been replaced by

$$-e^{-1}(ax_0 + by_0 + cz_0 + dt_0),$$

may easily be seen to be

$$axx_0^{-2} + \ldots + dtt_0^{-2} + euu_0^{-2} = 0.$$

If $(x_1, y_1, \ldots)$ be the point corresponding to $(x_0, y_0, \ldots)$, this equation is the same as $axx_1^2 + \ldots + dtt_1^2 + euu_1^2 = 0$. Thus the tangent plane of the Hessian surface at any point is the polar plane, in regard to the cubic surface, of the corresponding point of the Hessian. This result may be obtained without the special form.

Now consider the relations of the five Sylvester planes, $x = 0, \ldots, u = 0$, to the Hessian surface. If these are clear, since the Hessian may be formed from the original form of the cubic surface, the method of reduction of this to the Sylvester form may be inferred. The five planes, $x = 0, \ldots, u = 0$, meet in threes in ten points. It is easily seen that every line drawn through one of these meets the Hessian in two coincident points there. The Hessian has, therefore, these ten points as double points. The five planes also meet in pairs in ten lines, each of which, evidently, contains three of these double points; these ten lines lie wholly on the Hessian. In any one of the ten planes there are four of the lines, and six of the double points, lying at the intersections of the lines. The polar quadric, in regard to the cubic surface, of any one of the ten points, breaks up into two planes, containing the line of intersection of two of the five planes and harmonic therewith. For instance, the polar quadric of the point $x = 0$, $y = 0$, $z = 0$, is $dT^2t + eU^2u = 0$. By this condition the ten points are definable directly from the equation of the cubic surface.

Ex. 1. Prove that the vertices of a pair of Steiner trihedrals (above, p. 204) are corresponding points of the Hessian surface.

Ex. 2. It has been seen that there are eight points of which a given general plane is the polar plane, in regard to the cubic surface. Prove that, upon the line joining any two of these eight points, there is an infinite number of pairs of points, forming an involution, such that the polar planes, in regard to the cubic surface, of the two points of a pair, are the same. Also, that the polar planes of all points of such a joining line pass through another line; the axial pencil of these planes, taken twice over, is then a degenerate form of the quadric cone in general obtained by the envelope of the polar planes of the points of a line. Prove also that, if the polar planes of all points of a line, with respect to the cubic surface, pass through another line, then two of the four intersections of the first line with the Hessian surface are corresponding points of this surface.

Ex. 3. Let P, P' be any pair of corresponding points of the Hessian, and let the line joining these meet the Hessian again in the points M and N. Let M', N' be the points of the Hessian respectively corresponding to M and N. Prove, (1), that the line $M'N'$ is the intersection of the tangent planes of the Hessian at P and P'; (2), that the polar plane of every point of the line PP', with respect to the cubic surface, contains the line $M'N'$, and (3), that the line $M'N'$ touches the Hessian at M' and N'.

Ex. 4. The cubic surface which is the envelope of the polar planes, in regard to the cubic surface, of the points of a plane, touches the Hessian at the points of a sextic curve. This curve is the locus of the points corresponding to the points of the plane curve in which the given plane cuts the Hessian.

Ex. 5. Let an arbitrary line meet the Hessian in points P, Q, R, S; and let P', Q', R', S' be the points respectively corresponding to these. The polar quadrics of P', Q', R', S', with respect to the cubic surface, are cones, with vertices respectively at P, Q, R, S. Prove that there are two planes, through the line $PQRS$, which are conjugate to one another in regard to each of these four cones. Then, that these two planes, taken with the four planes each containing three of the points P', Q', R', S', are six planes, say $\chi_r = 0$, in terms of which the equation of the cubic surface is expressible in the form $\Sigma c_r \chi_r^3 = 0$, $(r = 1, 2, \ldots, 6)$. (Reye, *Crelle's J.*, LXXVIII, 1874.)

Ex. 6. Every line of the cubic surface touches the Hessian in two points; these are corresponding points; and the twenty-four points thus arising from the lines of a double-six are the intersections, of the Schur quadric associated with the double-six, with the curve, of order twelve, which is the intersection of the cubic surface and its Hessian. When the cubic surface is $\Sigma a x^3 = 0$, with $\Sigma a x = 0$, in Sylvester's form, the fifty-four points so arising satisfy the equation $\Sigma a x^{-3} = 0$.

Ex. 7. If $u = ax + by + cz + dt$, $v = lx + my + nz + pt$, the Hessian of the cubic surface whose equation is $x^3 + y^3 + z^3 + t^3 + u^3 + v^3 = 0$, is given by

$$\begin{aligned} xyzt + uxyzt\,\Sigma\, a^2 x^{-1} + vxyzt\,\Sigma\, l^2 x^{-1} & \\ + uv\,[\Sigma\,(dl - ap)^2 yz + \Sigma\,(bn - cm)^2 xt] &= 0. \end{aligned}$$

When $d = 0$, so that the four planes $x = 0$, $y = 0$, $z = 0$, $u = 0$ meet in a point, if we put X, Y, Z, U, V, respectively, for $p^2 x$, $p^2 y$, $p^2 z$, $p^2 u$, $p^2 v$, this reduces to the form

$$tV\,[\Sigma\, l^2 YZ + U\Sigma X\,(bn - cm)^2] + (t + V)\,[XYZ + U\Sigma a^2 YZ] = 0.$$

The six common generators of the two cones obtained by equating to zero the coefficients of tV and $t+V$, in this equation, which have a common vertex, are then six intersecting lines lying on the Hessian surface. We infer that the cubic surface in question is not general enough to be given by the Sylvester form, as a sum of five distinct cubes. The line $V=0$, $t=0$ also lies on this Hessian.

Reduced forms for twenty-three cases of cubic surfaces are given by Cayley, *Papers*, VI, p. 359. It may be a curious problem for the reader to enquire what is the fewest number of cubes by which these forms can severally be represented. That any cubic polynomial, in x, y, z, t, may be represented as a sum of cubes only, each of a linear function of x, y, z, t, with proper coefficients, is clear; as a very particular case it may be shewn there is always an unique representation by a selection from the following twenty cubes: four cubes such as x^3; four cubes such as $(y+z+t)^3$; six cubes such as $(y+z)^3$ and six cubes such as $(y-z)^3$.

The representation of a general cubic surface upon a quadric surface. As both a cubic surface and a quadric surface may be represented upon a plane, it follows that a cubic surface can be represented on a quadric surface. Let A, B, C, D, E be five points of a quadric; these lie in threes in ten planes, giving, in all, ten conics lying on the quadric; there are two generators of the quadric at each of the five points; there are also two cubic curves lying on the quadric, containing the five points (above, p. 129). The representation of the cubic surface upon the quadric can be made in such a way that the twenty-seven lines of the cubic surface correspond to the twenty-seven elements of the quadric which we have enumerated, namely 5 points, 10 conics, 10 generators and 2 cubic curves.

For let the cubic surface be given by $\xi\eta\zeta=\xi'\eta'\zeta'$, where ξ, η, ζ are such that $\xi+\eta+\zeta=\xi'+\eta'+\zeta'$ and $a\xi+b\eta+c\zeta=a'\xi'+b'\eta'+c'\zeta'$. Then, for any σ, we have the relation

$$(a+\sigma)\xi+(b+\sigma)\eta+(c+\sigma)\zeta=(a'+\sigma)\xi'+(b'+\sigma)\eta'+(c'+\sigma)\zeta'.$$

There are two values of σ for which

$$(a+\sigma)(b+\sigma)(c+\sigma)=(a'+\sigma)(b'+\sigma)(c'+\sigma);$$

let these be σ_1 and σ_2; put $\xi_1=(a+\sigma_1)\xi$, and $\xi_2=(a+\sigma_2)\xi$, etc. We then have $\xi_r\eta_r\zeta_r=\xi_r'\eta_r'\zeta_r'$, $\xi_r+\eta_r+\zeta_r=\xi_r'+\eta_r'+\zeta_r'$, for $r=1$ and $r=2$. Now take x, y, z, t by the definitions

$$x/t=(\eta'-\zeta)/(\xi-\xi'),\quad y/t=(\zeta'-\xi)/(\eta-\eta'),\quad z/t=(\xi'-\eta)/(\zeta-\zeta'),$$

and let $x'=t-x$, $y'=t-y$, $z'=t-z$. We easily verify that

$$\xi:\eta:\zeta:\xi':\eta':\zeta'=yz':zx':xy':y'z:z'x:x'y,$$

which involve the two relations $\xi\eta\zeta=\xi'\eta'\zeta'$, $\xi+\eta+\zeta=\xi'+\eta'+\zeta'$. The remaining relation which limits $\xi, \eta, \ldots$ requires, however, that

$$ayz'+bzx'+cxy'=a'y'z+b'z'x+c'x'y,$$

and expresses that the point (x, y, z, t) lies on a quadric surface containing the five points $(1, 0, 0, 0)$, $(0, 1, 0, 0)$, $(0, 0, 1, 0)$, $(0, 0, 0, 1)$, $(1, 1, 1, 1)$.

Denote these points, respectively, by A, B, C, D, E, the generators of one system of the quadric which contains these points, respectively, by a_1, b_1, c_1, d_1, e_1, and those of the other system, through these points, respectively, by a_2, b_2, c_2, d_2, e_2. Further, let the cubic curve lying on the quadric, passing through the five points, which meets the generators of the first system each in *one* point be denoted by γ_1, and the cubic curve on the surface, through the five points, which meets the generators of the second system each in one point, be denoted by γ_2. Then, denoting the line of the cubic surface for which $\xi = 0$, $\xi' = 0$ by (ξ, ξ'), etc., the line which lies on the planes $\xi = \xi'$, $\eta = \eta'$, $\zeta = \zeta'$ by (ξ', η', ζ'), that which lies on the planes $\xi_1 = \xi_1'$, $\eta_1 = \eta_1'$, $\zeta_1 = \zeta_1'$ by $(\xi', \eta', \zeta')_1$, and so on, it may be verified that the twenty-seven lines of the cubic surface correspond to the twenty-seven elements of the quadric surface which have been specified, in accordance with the following scheme:

(ξ, ξ'), the point A ; (ξ', η), the plane ABD ;
(ζ, ξ'), the plane CAE ; (ξ, η'), the plane ABE ;
(η, η'), the point B ; (η', ζ), the plane BCD ;
(ζ', ξ), the plane CAD; (η, ζ'), the plane BCE ;
(ζ, ζ'), the point C.

(ξ', η', ζ'), ABC ; (η', ζ', ξ'), E ; (ζ', ξ', η'), D; (ξ', ζ', η'), ADE;
(ζ', η', ξ'), BDE ; (η', ξ', ζ'), CDE ; $(\xi', \eta', \zeta')_1, \gamma_2$; $(\eta', \zeta', \xi')_1, d_2$;
$(\zeta', \xi', \eta')_1, e_2$; $(\xi', \zeta', \eta')_1, a_1$; $(\zeta', \eta', \xi')_1, b_1$; $(\eta', \xi', \zeta')_1, c_1$;
$(\xi', \eta', \zeta')_2, \gamma_1$; $(\eta', \zeta', \xi')_2, d_1$; $(\zeta', \xi', \eta')_2, e_1$; $(\xi', \zeta', \eta')_2, a_2$;
$(\zeta', \eta', \xi')_2, b_2$; $(\eta', \xi', \zeta')_2, c_2$.

A particular double-six of lines of the cubic surface corresponds then to the two rows of elements on the quadric surface given by

$$\begin{array}{cccccc} A, & B, & C, & D, & e_2, & e_1 \\ BCD, & CAD, & ABD, & ABC, & \gamma_2, & \gamma_1\,; \end{array}$$

and, if the two rows of lines of this double-six be denoted, respectively, by $l_1, \ldots, l_6$ and $m_1, \ldots, m_6$, and the line which meets the two l_r, m_s, and the two l_s, m_r, be denoted by n_{rs}, the respective elements $n_{1h}\,(h = 2 \ldots 6)$, $n_{2k}\,(k = 3 \ldots 6)$, $n_{3r}\,(r = 4 \ldots 6)$, $n_{4s}\,(s = 5, 6)$, n_{56}, are given by

ABE, CAE, ADE, a_1, a_2; BCE, BDE, b_1, b_2; CDE, c_1, c_2; d_1, d_2; E.

Further, the cubic curve of the cubic surface, obtained by the intersection of this with the general quadric containing the lines m_2, m_3, n_{23} (see above, p. 176), is found to correspond to the conic on the quadric surface given by $Px' + Qy' + Rz' = 0$, that is, to the general conic of the quadric surface passing through the point $(1, 1, 1, 1)$. While, the cubic curve of the cubic surface which is the intersection of this with the general quadric containing the lines l_2, l_3, n_{23} corresponds to the sextic curve on the quadric given by its intersection with the cubic surface $Lx'yz + My'zx + Nz'xy = 0$, or, what is the same thing, with the cubic surface given by $Lx^{-1} + My^{-1} + Nz^{-1} + Kt^{-1} = 0$, wherein $L + M + N + K = 0$. As is seen in the following note, this is the general cubic surface with four double points, at the points A, B, C, D, which contains the point $(1, 1, 1, 1)$.

Ex. Determine the representation on the quadric of the other cubic curves of the cubic surface.

Note on the cubic surface with four double points. The present chapter has been devoted to the fundamental properties of the general cubic surface. Many special cubic surfaces have interesting properties; but there seems special reason for devoting some remarks to that surface which has, in fact, the greatest number of possible double points—as it presents itself in various ways. The surface was first studied by Cayley, *Papers*, I, p. 183 (1844).

The equation $x^{-1} + y^{-1} + z^{-1} + t^{-1} = 0$ clearly represents a cubic surface having each of the four points such as $(1, 0, 0, 0)$ as a double point. The six lines joining the pairs of these points lie entirely on the surface; and there are three other lines, each meeting an opposite pair of these six lines, which also lie on the surface. For instance, one of these three lines is given by $y + z = 0$, $x + t = 0$; the plane $x + t = 0$ meets the surface in this line, and in the line $x = 0$, $t = 0$ counting doubly. The three new lines lie in the plane $x+y+z+t=0$; and are the joins of the three pairs of opposite intersections of the four lines in which this plane meets the four fundamental planes, $x = 0$, etc. The surface contains no other lines than the nine which have been mentioned; if each of the six lines joining two of the double points be counted four times, these nine lines count as twenty-seven.

If we take three quantities, ξ, η, ζ, which we may regard as coordinates in a plane, defined by

$$\xi : \eta : \zeta = x(y+z) : y(z+x) : z(x+y),$$

where x, y, z, t are the coordinates of a point of the cubic surface, so that, as we may easily verify

$$\xi^{-1} : \eta^{-1} : \zeta^{-1} = tx - yz : ty - zx : tz - xy,$$

then we deduce

$$x^{-1} : y^{-1} : z^{-1} : t^{-1} = \xi - \eta - \zeta : \eta - \zeta - \xi : \zeta - \xi - \eta : \xi + \eta + \zeta,$$

which evidently satisfy the equation of the cubic surface. By these formulae, there is established a birational correspondence between the points of the cubic surface and the points of the plane (ξ, η, ζ). In this plane there are four lines $\xi \pm \eta \pm \zeta = 0$, each of which corresponds to one of the double points of the cubic surface, while the lines $\xi = 0$, $\eta = 0$, $\zeta = 0$ may be regarded as corresponding to the three lines of the surface lying in the plane $x + y + z + t = 0$. In general, to the plane cubic curve in which the surface is met by the plane $Ax + By + Cz + Dt = 0$, there corresponds, in the plane, the cubic curve $AYZT + \ldots + DXYZ = 0$, where X, Y, Z, T are, for brevity, written for $\xi - \eta - \zeta, \ldots, \xi + \eta + \zeta$. This latter is the general cubic curve passing through the six intersections of the four lines $X = 0$, $Y = 0, \ldots$. Conversely, to a general line of the plane, $u\xi + v\eta + w\zeta = 0$, there corresponds, on the cubic surface, the curve in which this is met by the quadric cone

$$(v + w)yz + (w + u)zx + (u + v)xy = 0;$$

this curve lies on the cubic surface

$$ux^{-1} + vy^{-1} + wz^{-1} + (u + v + w)t^{-1} = 0,$$

which is another cubic surface having the same four double points as the original. The curve of intersection of the original cubic surface with that represented by $ax^{-1} + by^{-1} + cz^{-1} + dt^{-1} = 0$ corresponds to the line, in the plane, given by

$$(d + a - b - c)\xi + (d + b - c - a)\eta + (d + c - a - b)\zeta = 0,$$

that is to say, the portion of this curve of intersection other than the six joins of the four fundamental points, so corresponds. It may be convenient to describe as the fundamental cubic curves, of the original cubic surface, these cubic curves, which are thus given by its intersection with other cubic surfaces having the same double points. Two of these curves have one common point, other than the four double points, through which they all pass; and one of these curves can be drawn through two arbitrary points of the original surface.

There is, upon any one of these fundamental cubic curves, a particular point; in fact the tangent planes of the cubic surface at all points of this curve meet the curve again in the same point, which is the point in question. For the curve given by the intersection of the cubic surface with the surface

$$ux^{-1} + vy^{-1} + wz^{-1} + (u + v + w)t^{-1} = 0,$$

this particular point is of coordinates $(x_0, y_0, z_0, 1)$, where

$$x_0 = (w - u)(u - v)/(w + u)(u + v),$$

etc.; and, with this, the statement may be verified directly, the equation of the tangent plane of the surface at (X, Y, Z, T) being $xX^{-2} + \ldots + tT^{-2} = 0$. But the fact will appear from the argument below. Assuming the truth of this, it follows that the quadric cone of vertex $(x_0, y_0, z_0, 1)$, which projects the cubic curve from this point, touches the cubic surface at every point of this curve. Moreover, as x_0, y_0, z_0, are clearly unchanged by the substitution of u^{-1}, v^{-1}, w^{-1}, respectively, for u, v, w, there is another quadric cone of vertex $(x_0, y_0, z_0, 1)$ which touches the cubic surface along a cubic curve, this being the curve lying on the surface

$$u^{-1}x^{-1} + \ldots + (u^{-1} + v^{-1} + w^{-1})\, t^{-1} = 0.$$

These two cubic curves, together, constitute the complete locus of points of the cubic surface whereat the tangent planes pass through $(x_0, y_0, z_0, 1)$, and may be spoken of as *conjugate* fundamental curves. The point $(x_0, y_0, z_0, 1)$ may be taken to be any point of the cubic surface, the ratios of u, v, w being then determinable from the equations

$$u(1 + x_0^{-1}) + v(1 + y_0^{-1}) + w(1 + z_0^{-1}) = 0,$$
$$u^{-1}(1 + x_0^{-1}) + v^{-1}(1 + y_0^{-1}) + w^{-1}(1 + z_0^{-1}) = 0.$$

The cubic surface is, therefore, such that the tangent cone, of order four, drawn to it from any general point of itself, breaks up into two quadric cones, each meeting the surface in a cubic curve.

The cubic surface contains also another important system of curves, those, namely, which correspond to the conics, in the plane (ξ, η, ζ), which touch the four lines $\xi \pm \eta \pm \zeta = 0$. The equation of such a conic is $a^{-1}\xi^2 + b^{-1}\eta^2 + c^{-1}\zeta^2 = 0$, where a, b, c are any constants for which $a + b + c = 0$. The corresponding curve on the cubic surface satisfies the equation

$$a^{-1}x^2(y + z)^2 + b^{-1}y^2(z + x)^2 + c^{-1}z^2(x + y)^2 = 0\,;$$

or, as $tx(y + z) = -yz(x + t)$, the curve satisfies the equation

$$a^{-1}(y + z)(x + t) + b^{-1}(z + x)(y + t) + c^{-1}(x + y)(z + t) = 0,$$

equivalent with $a^2(yz + xt) + b^2(zx + yt) + c^2(xy + zt) = 0$. This equation represents a quadric surface, passing through the four double points of the cubic surface, and touching the four lines in which the plane $x + y + z + t = 0$ meets the planes $x = 0, \ldots, t = 0$. The curves in which these quadric surfaces meet the cubic surface are then sextic curves, with four double points (at the fundamental points). Two of these curves pass through an arbitrary point of the cubic surface. These curves have the property, as will appear below, or may be verified directly, that the tangent line of the curve, at any point of the curve, is one of the inflexional lines of the surface at this point (see above, p. 197); it meets the surface at this point in three coincident points, and does not meet the surface at any other point. They are, therefore, called inflexional curves; and there are no other inflexional curves on the surface than these.

Consider, now, the relation of three points of the cubic surface which lie on a line. The third of these is such that all plane sections of the surface which contain the first two equally contain the third. A plane section of the cubic surface, however, corresponds, in the plane (ξ, η, ζ), to a cubic curve through the six points of intersection of the lines $\xi \pm \eta \pm \zeta = 0$. Thus, three points of the cubic surface which are in line correspond to three points of the plane, say P, Q, R, which have the property that all cubic curves through the six fundamental points, and through P, Q, necessarily pass through R; the existence of such a property for plane cubic curves has already been remarked (pp. 156, 178). Of such cubic curves, however, a degenerate one consists of the line $\xi + \eta + \zeta = 0$ taken with the conic defined by P, Q and the three intersections of the other three fundamental lines; and there are three other such degenerate cubic curves. The point R is thus the point through which pass the four conics each defined as passing through the three intersections of three of the fundamental lines, and also through P and Q. With a phraseology previously employed, in which P and Q are taken as Absolute points, and the conics are described as circles, R is the focus of the parabola touching the four fundamental lines (Vol. II, p. 82). That is, if the unique conic, of the form $a^{-1}\xi^2 + b^{-1}\eta^2 + c^{-1}\zeta^2 = 0$, touching the four fundamental lines, which touches PQ, be taken, R is the intersection of the two other tangents drawn to this conic, one from P and one from Q. A particular case, which we employ here, is that if P and Q coincide on the line PQ, the cubic curves considered touching this line at the point of coincidence, then R is the point of contact, with the conic touched by the line PQ, of the other tangent drawn to this conic from the point of coincidence. For distinctness, let the conic, of the form $a^{-1}\xi^2 + b^{-1}\eta^2 + c^{-1}\zeta^2 = 0$, (with $a + b + c = 0$), which touches a given line PQ, be called the conic *corresponding* to this line. There is then, upon the line, a particular point, the point of contact of the line with its corresponding conic; and, when P and Q coincide at this point, the point R also coincides with these. Thus we see that, upon any one of the fundamental cubic curves of the cubic surface, there is a particular point, at which the tangent line of the curve meets the surface in three coincident points; this point lies on a particular one of those sextic curves of the surface, previously spoken of, which correspond to the conics $a^{-1}\xi^2 + \text{etc.} = 0$ $(a + b + c = 0)$, and touches this curve at this point. Moreover, through any point of such a sextic curve, there passes a fundamental cubic curve of the cubic surface, touching the sextic curve at this point. That these sextics are inflexional curves, in the sense explained, is clear. We see, also, that, if we consider the third point of intersection, with the cubic surface, of the tangent line of a fundamental cubic curve, at any point of this, the locus of this third point is the inflexional curve of the cubic surface which touches this cubic curve. Denoting the point of a cubic curve of the surface where it touches an inflexional curve as the inflexional point of the curve, and recalling that, through any point of the plane, two conics of the set

$$a^{-1}\xi^2 + \text{etc.} = 0 \quad (a+b+c=0)$$

can be drawn, we see that two of the fundamental cubic curves of the cubic surface can be drawn through any point of the surface to have this point as their inflexional point. In the plane, the two tangents of the conics in question which pass through any point, are conjugate lines in regard to all these conics; and, if their equations be $u\xi + v\eta + w\zeta = 0$, and $u_1\xi + v_1\eta + w_1\zeta = 0$, we have $uu_1 = vv_1 = ww_1$. This relation then holds for the cubic curves in question through any point of the surface; and these curves may be spoken of as conjugate.

To any point, P, of the plane (ξ, η, ζ), there corresponds a cubic curve, passing through the six intersections of the four fundamental lines, which has a double point at P. For, if we determine the locus of the points of contact of the tangents from P to all the conics $a^{-1}\xi^2 + \text{etc.} = 0$ $(a+b+c=0)$, we find, by elimination of u, v, w from the equations

$$u\xi + v\eta + w\zeta = 0, \quad u\xi_0 + v\eta_0 + w\zeta_0 = 0, \quad u^{-1}\xi + v^{-1}\eta + w^{-1}\zeta = 0,$$

wherein (ξ_0, η_0, ζ_0) are the coordinates of P, the equation

$$\xi(\eta\zeta_0 - \eta_0\zeta)^{-1} + \eta(\zeta\xi_0 - \zeta_0\xi)^{-1} + \zeta(\xi\eta_0 - \xi_0\eta)^{-1} = 0,$$

which represents the curve in question, as is easily verified. If P moves on a line, the various cubic curves so found all pass then through the point where the line touches the conic which corresponds to it. Now, such a cubic curve corresponds to a plane section of the cubic surface having a double point, that is, to the section of the cubic surface by a tangent plane. We can thus infer that the tangent planes of the cubic surface, at all the points of one of its fundamental cubic curves, pass through the inflexional point of the curve, as was stated above.

Ex. Another result may be referred to. To any point, (ξ_0, η_0, ζ_0), of the plane, there is associated a conic which is the envelope of the polar lines of the point in regard to all the conics

$$a^{-1}\xi^2 + \text{etc.} = 0 \quad (a+b+c=0);$$

in particular, this conic touches the two lines through (ξ_0, η_0, ζ_0) which are conjugate to one another in regard to all these conics, these being the tangents at (ξ_0, η_0, ζ_0) of the two of these conics which pass through this point. The equation of this conic is

$$(\xi_0\xi)^{\frac{1}{2}} + (\eta_0\eta)^{\frac{1}{2}} + (\zeta_0\zeta)^{\frac{1}{2}} = 0;$$

it may be referred to, here, as *the envelope conic* for this point. Correspondingly, on the cubic surface, there is associated to any point, (x_0, y_0, z_0, t_0), a locus given by the equation

$$[\xi_0 x(y+z)]^{\frac{1}{2}} + \text{etc.} = 0.$$

The rational form of this, if we use the relations

$$tx^2(y+z) = -xyz(x+t) \text{ and } tyz(x+y)(x+z) = xyz(tx-yz),$$

which follow from the equation of the cubic surface, is at once found to be

$$yz(\eta_0 - \zeta_0)^2 + xt(\eta_0 + \zeta_0)^2 + \text{etc.} = 0.$$

This is the same as $PT = U^2$, where

$$P = x(\eta_0 + \zeta_0)^2 + y(\zeta_0 + \xi_0)^2 + z(\xi_0 + \eta_0)^2, \quad T = x + y + z + t,$$
$$U = x(\eta_0 + \zeta_0) + y(\zeta_0 + \xi_0) + z(\xi_0 + \eta_0);$$

the equation, therefore, represents a quadric cone, passing through the double points of the cubic surface, whose vertex is on the plane $T = 0$, which, moreover, touches this plane. The vertex of the cone is given by

$$xt^{-1} = \frac{(\zeta_0+\xi_0)(\xi_0+\eta_0)}{(\zeta_0-\xi_0)(\xi_0-\eta_0)}, \; yt^{-1} = \frac{(\xi_0+\eta_0)(\eta_0+\zeta_0)}{(\xi_0-\eta_0)(\eta_0-\zeta_0)}, \; zt^{-1} = \frac{(\eta_0+\zeta_0)(\zeta_0+\xi_0)}{(\eta_0-\zeta_0)(\zeta_0-\xi_0)}.$$

Two cones can be drawn to touch the plane $T = 0$, passing through the four double points, with vertex at this point; the other is evidently obtainable by writing ξ_0^{-1}, η_0^{-1}, ζ_0^{-1} for ξ_0, η_0, ζ_0, respectively. The cone meets the cubic surface in a sextic curve with a double point at each of the four double points of the surface; indeed, such a sextic can similarly be shewn to arise from any conic of the plane. The particular sextic in question touches the three lines of the cubic surface which lie in the plane $T = 0$; and, also, touches the two fundamental cubic curves of the cubic surface lying on the enveloping quadric cones drawn to the surface from (x_0, y_0, z_0, t_0). Let this sextic be described, here, as the envelope sextic associated with this point, and these two cubic curves as the associated cubic curves.

From any point, (x_1, y_1, z_1, t_1), of the cubic surface, there can be drawn four lines, each to meet both these cubic curves, other than the four lines to the double points of the surface, and the one line to the point (x_0, y_0, z_0, t_0); for, these two cubic curves are projected from (x_1, y_1, z_1, t_1) by cubic cones, having, in all, nine common generators. It can be shewn, now, that, when (x_1, y_1, z_1, t_1) is on the sextic associated with (x_0, y_0, z_0, t_0), these four lines become two pairs of coincident lines, each of which then meets these cubic curves, respectively, in two points with the property that the tangent lines of these curves at these points lie in a plane. This plane is then a plane of the developable formed by the common tangent planes of the two associated cubic curves; it meets the cubic surface in a plane cubic curve which touches both these cubic curves; this plane cubic section also passes through (x_1, y_1, z_1, t_1), and touches the associated sextic at (x_1, y_1, z_1, t_1). If the tangent line be drawn at any point, *H*, of one of the two associated cubic curves, there are, we know, four tangent lines of the other cubic curve which meet the former tangent line; the plane determined by the former tangent line and one of these four other tangent lines of the associated cubic curve, meets the cubic surface in a plane cubic curve which, as the point *H* of the first cubic varies, envelops the associated sextic.

To prove this result, consider, in the plane (ξ, η, ζ), the points, say (ξ_0, η_0, ζ_0) and (ξ_1, η_1, ζ_1), corresponding, respectively, to the points (x_0, y_0, z_0, t_0), (x_1, y_1, z_1, t_1) of the cubic surface, of which the latter is, at first, taken quite arbitrarily. There are two conics of the system $a^{-1}\xi^2 + \text{etc.} = 0\ (a+b+c=0)$ in regard to both of which the points (ξ_0, η_0, ζ_0), (ξ_1, η_1, ζ_1) are conjugate to one another. For, if we consider the conic associated with the point (ξ_1, η_1, ζ_1), whose equation is $(\xi_1\xi)^{\frac{1}{2}} + (\eta_1\eta)^{\frac{1}{2}} + (\zeta_1\zeta)^{\frac{1}{2}} = 0$, there are two tangents of this conic passing through the point (ξ_0, η_0, ζ_0); and, $u\xi + v\eta + w\zeta = 0$ being one of these, there is a particular conic of the system $a^{-1}\xi^2 + \text{etc.} = 0\ (a+b+c=0)$ for which this line is the polar of (ξ_1, η_1, ζ_1), namely $\xi_1^{-1}u\xi^2 + \eta_1^{-1}v\eta^2 + \zeta_1^{-1}w\zeta^2 = 0$. Consider one of these two conics, of the system in question, in regard to which (ξ_0, η_0, ζ_0) and (ξ_1, η_1, ζ_1) are conjugate: denote this by Σ_1. The polar of (ξ_0, η_0, ζ_0) in regard to Σ_1, taken with the two lines through (ξ_0, η_0, ζ_0), say l and l', which are conjugate to one another in regard to all the conics $a^{-1}\xi^2 + \text{etc.} = 0\ (a+b+c=0)$, determine a self-polar triad in regard to Σ_1; if then the two tangents be drawn to Σ_1 from (ξ_1, η_1, ζ_1), meeting the line l, say, in *P* and *M*, and meeting the line l' in *Q* and *N*, it is easily seen that the two lines *PQ* and *MN* are tangents of Σ_1, which, by the construction, touches *PN* and *QM* (see Vol. II, Ex. 31, p. 58, and Ex. 5, p. 28). The three points, (ξ_1, η_1, ζ_1), *P*, *Q*, thus correspond, on the cubic surface, to a line drawn from (x_1, y_1, z_1, t_1) to meet the two conjugate cubic curves of the cubic surface associated with (x_0, y_0, z_0, t_0), as, likewise, do the three points, (ξ_1, η_1, ζ_1), *M*, *N*. The two other such transversals drawn from (x_1, y_1, z_1, t_1) similarly arise from the other conic, Σ_2, in regard to which (ξ_0, η_0, ζ_0) and (ξ_1, η_1, ζ_1) are conjugate. Now, it may happen that the conics Σ_1, Σ_2 coincide; namely, when the envelope conic associated with (ξ_1, η_1, ζ_1) contains (ξ_0, η_0, ζ_0), that is, when $(\xi_0\xi_1)^{\frac{1}{2}} + (\eta_0\eta_1)^{\frac{1}{2}} + (\zeta_0\zeta_1)^{\frac{1}{2}} = 0$. Then the conics Σ_1, Σ_2 become the same conic, $\alpha^{-1}\xi^2 + \beta^{-1}\eta^2 + \gamma^{-1}\zeta^2 = 0$, with $\alpha = (\xi_0\xi_1)^{\frac{1}{2}}$, etc., as is easily seen. When this is so, the point (ξ_1, η_1, ζ_1)

is on the envelope conic arising from (ξ_0, η_0, ζ_0), and the point (x_1, y_1, z_1, t_1) is on the sextic curve associated with (x_0, y_0, z_0, t_0). This establishes the result which has been stated.

The theorem that the tangent line of a cubic curve on the cubic surface meets the surface again on the inflexional curve touching the cubic curve, proved above, was given by Laguerre, *Nouv. Ann.*, XI, 1872, p. 342 (*Oeuvres*, II, pp. 275, 281). The representation of the inflexional curves by conics touching four lines was remarked by Lie (see *Geom. d. Berührungstransf.*, I, 1896, p. 342). The theorem given in the example above is derived from F. Morley (*An extension of Feuerbach's theorem, Nat. Ac. of Sc., U.S.A.*, 1916 (2), p. 171). For further references in regard to the cubic surface with four double points, the reader may consult the author's *Multiply-periodic functions* (Cambridge, 1907), pp. 139—151, where the surface arises as touching the Kummer surface at every point of its intersection with it; also Neuberg, *Arch. d. Math. u. Phys.*, XI, 1907, p. 228, and Servais, *Bull. Sc. Acad. r. de Belgique*, VIII, 1922, pp. 50—66 and 103—123.

The Steiner quartic surface. We may consider the surface which is dual to the cubic surface just discussed. As the equation of the tangent plane of the cubic surface is $x_0^{-2}x + y_0^{-2}y + \ldots = 0$, the tangential equation of this cubic surface is $l^{\frac{1}{2}} + m^{\frac{1}{2}} + n^{\frac{1}{2}} + p^{\frac{1}{2}} = 0$, and the equation of the quartic surface, dual to the cubic surface, is $x^{\frac{1}{2}} + y^{\frac{1}{2}} + z^{\frac{1}{2}} + t^{\frac{1}{2}} = 0$. This meets each of the planes $x = 0$, $y = 0$, etc., in a conic, at every point of which it touches the plane, any two of these four conics having a point of contact, on the line of intersection of their planes. The surface has also three double lines, such as that given by $y - z = 0$, $t - x = 0$; these meet in the point $(1, 1, 1, 1)$, which is a triple point of the surface. Every tangent plane of the surface meets it in a curve breaking up into two conics; the four intersections of these consist of the point of contact of the plane, and the three points where the plane meets the double lines of the surface. The surface can be represented, on a plane (ξ, η, ζ), by means of the formulae

$$x = (\xi - \eta - \zeta)^2, \quad y = (\eta - \zeta - \xi)^2, \quad z = (\zeta - \xi - \eta)^2, \quad t = (\xi + \eta + \zeta)^2,$$

which are equivalent to

$$\xi\,(t + x - y - z) = \eta\,(t + y - z - x) = \zeta\,(t + z - x - y).$$

Conversely, let $U = 0$, $V = 0$, $W = 0$, $P = 0$, be any four general conics in a plane, expressed in any variables. Then the surface expressed by $X : Y : Z : T = U : V : W : P$ is essentially the same as the above; namely, we can find four linearly independent linear functions of U, V, W, P which, in terms of suitable coordinates in the plane, have the forms $(\xi - \eta - \zeta)^2, \ldots, (\xi + \eta + \zeta)^2$. For, there are two tangential conics which are inpolar to all of $U = 0, \ldots, P = 0$; let coordinates be taken so that the four common tangents of these two tangential conics are $\xi - \eta - \zeta = 0, \ldots, \xi + \eta + \zeta = 0$; the four original conics are then outpolar to the three point-pairs expressed tangentially by $v^2 - w^2 = 0$, $w^2 - u^2 = 0$, $u^2 - v^2 = 0$, these being the opposite pairs of intersections of the four lines. The general conic, $a\xi^2 + 2f\eta\zeta + \ldots = 0$, outpolar to these point-pairs, is $\xi^2 + \eta^2 + \zeta^2 + 2f\eta\zeta + 2g\zeta\xi + 2h\xi\eta = 0$; as each of $\xi^2 + \eta^2 + \zeta^2$, $\eta\zeta$, $\zeta\xi$, $\xi\eta$ is expressible as a linear function of the four squares in question, the result stated is proved. Incidentally, we remark, that, taking X, Y, Z, T proportional to $\eta\zeta$, $\zeta\xi$, $\xi\eta$, $\xi^2 + \eta^2 + \zeta^2$, the equation of the surface is capable of the form $Y^2Z^2 + Z^2X^2 + X^2Y^2 - XYZT = 0$, which puts in evidence the double lines of the surface.

Thus, if U, V, W, P be any four linearly independent homogeneous quadratic functions of three variables, ξ, η, ζ, the envelope of the plane $Ux + Vy + Wz + Pt = 0$ is a cubic surface with four double points. If U_1, U_2, U_3, respectively, denote $\partial U/\partial\xi$, $\partial U/\partial\eta$, $\partial U/\partial\zeta$, and U_{11}, U_{12}, ... denote $\partial^2 U/\partial\xi^2$, $\partial^2 U/\partial\xi\partial\eta$, ..., and so on, and u_{rs} denote $U_{rs}x + V_{rs}y + W_{rs}z + P_{rs}t$, the point of contact of the plane corresponding to a particular set of values of ξ, η, ζ is given by the three equations $U_r x + V_r y + W_r z + P_r t = 0$, and the locus of this point of contact, that is, the surface enveloped by the plane, is given by the equation, obtained by eliminating ξ, η, ζ from these three equations,

$$\begin{vmatrix} u_{11}, & u_{12}, & u_{13} \\ u_{21}, & u_{22}, & u_{23} \\ u_{31}, & u_{32}, & u_{33} \end{vmatrix} = 0,$$

where $u_{rs} = u_{sr}$. The quadrics obtained by equating to zero the first minors of this determinant have four points in common; these are the double points of the cubic surface.

Ex. 1. For the general cubic surface, expressed, in Sylvester's way, by $\Sigma ax^3 = 0$, with $\Sigma ax = 0$, the envelope of the polar planes of the points of the plane which passes through the three points $(x_1, y_1, \ldots)$, $(x_2, y_2, \ldots)$, $(x_3, y_3, \ldots)$, (cf. p. 209), is expressible in the form above, with

$$u_{11} = axx_1^2 + \ldots + euu_1^2, \text{ and } u_{12} = axx_1x_2 + \ldots + euu_1u_2, \text{ etc.}$$

Ex. 2. It follows from the dual relation of the cubic surface with four double points, and the Steiner quartic surface, or may be proved directly, that, by the representation upon the plane, the inflexional curves of the Steiner surface are made to correspond to the conics, expressed by $a^{-1}\xi^2 + \text{etc.} = 0$ $(a + b + c = 0)$, which are inpolar to the conics to which the coordinates on the surface are proportional.

Ex. 3. The inflexional curves of the Steiner surface are rational quartic curves, having the three double lines of the surface as chords. Of the four points in which any such curve is met by a tangent plane of the surface, regarded as represented by the values of the parameter by which any point of the curve may be rationally expressed, two are harmonic conjugates in regard to the other two.

Ex. 4. The inflexional curves of the surface expressed by the equation $x^m + y^m + z^m + t^m = 0$ satisfy the equation

$$(ax^m)^{\frac{1}{2}} + (by^m)^{\frac{1}{2}} + (cz^m)^{\frac{1}{2}} = 0,$$

where a, b, c are any constants whose sum is zero. Verify this in the case of the cubic surface with four nodes and in the case of the Steiner surface.

Ex. 5. If $\phi_1 = 0, \ldots, \phi_6 = 0$ be any six conics in a plane, the equations $x_1/\phi_1 = x_2/\phi_2 = \ldots = x_6/\phi_6$ represent, in space of five dimensions, a surface (containing ∞^2 points), known as Veronese's surface. Evidently the Steiner surface may be regarded as arising by projection of this surface, *from a line.*

Ex. 6. The lines joining a point, O, of coordinates x, y, z, t, to the points $(a, 1, 1, 1)$, $(1, b, 1, 1)$, etc., meet the planes $x=0$, $y=0$, etc., respectively, in coplanar points. Prove that the locus of O is the Hessian of the cubic surface

$$\Sigma \frac{x^3}{a(a-1)} + \frac{u^3}{(e-1)(3-2e)} = 0,$$

where e and u are defined by

$$1 + \Sigma (a-1)^{-1} + (e-1)^{-1} = 0, \quad \Sigma x (a-1)^{-1} + u (e-1)^{-1} = 0.$$

When $a=b=c=d=-3$, taking for Absolute Conic the intersection of the plane $x+y+z+t=0$ with the quadric $x^2+y^2+z^2+t^2=0$, shew (after Steiner, 1845) that the cubic surface with four double points is the locus of a point such that the feet of the four perpendiculars drawn from it to the four planes $x=0$, $y=0$, etc. are coplanar. See Jessop, *Quartic Surfaces*, p. 190; also p. 36 above. And *Archiv d. Math. u. Phys.* IV, 1903, p. 275 (a reference for which the writer is indebted to Mr J. P. Gabbatt).

For the Steiner surface, the reader may consult Jessop, *Quartic Surfaces* (Cambridge, 1916), Chapter VII. For Veronese's surface, see Cayley, *Papers*, VI, p. 198 (1868), and Bertini, *Geometria projettiva d. iperspazi*, 1907, Chapters XIV, XV. See also Castelnuovo, *Atti d. r. Acc. d. Lincei*, III, 1894, p. 22, who proves, after Kronecker, that an irreducible algebraic surface which is met by ∞^2 planes in reducible curves, if not a ruled surface, is a Steiner quartic surface.

Self-polar tetrad in regard to a quadric, 33, 50, 52
Serret, P., 49
Servais, 221
Sextic curve in space, 154, 198
Similitude, centres of, for two spheres, 78
Spheres, 72; cutting at right angles, 76
Squares, quadric polynomial reduced to, 16; expression of a quadric by five, 38, 39; by six, 49
Star-systems, related, 11, 184
Staudt, von, 158, 168
Steiner points, for Pascal figure, 44
Steiner, trihedral pairs, 164, 174, 203; also 208; Steiner system of bitangents of a plane quartic curve, 200; Steiner's quartic surface, 221
Stenfors, 168
Striction, line of, on a quadric, 84
Sturm, 208
Sylvester, 64, 66, 206, 208, 210

Tangent cone, or enveloping cone, of a quadric, 26
Tangent of a cubic curve, 127, 132; tangent plane of a cubic surface, 197
Tangent plane of a quadric, 23, 27
Tangential equation of a quadric, 25
Telling, 148

Tetrad, self-polar, 33, 50, 52, 145; of points whose opposite joins are conjugate points in regard to a quadric, 35; of which opposite joins are at right angles, 78; two tetrads in perspective, 37; two related by reciprocation, 41, 53
Tetrahedral complex, 99, 134
Thomson and Tait, 132
Transformation, cubo-cubic, in space, 141
Trihedral, 164, 174, 203

Umbilicus of a quadric, 80; of a paraboloid, 83; umbilicar generators of a quadric lie on a quartic surface, 93

Veronese, 223

Wakeford, 148
Weddle's surface, 154
Wilton, 224

Zeuthen, 158

The Figure of fifteen lines and fifteen points, in space of four dimensions.
(See Ch. V.)

PRINCIPLES OF GEOMETRY

BY

H. F. BAKER, Sc.D., LL.D., F.R.S.,
LOWNDEAN PROFESSOR OF ASTRONOMY AND GEOMETRY, AND FELLOW OF
ST JOHN'S COLLEGE, IN THE UNIVERSITY OF CAMBRIDGE

VOLUME IV

HIGHER GEOMETRY

BEING ILLUSTRATIONS OF THE UTILITY OF THE
CONSIDERATION OF HIGHER SPACE, ESPECIALLY
OF FOUR AND FIVE DIMENSIONS

CAMBRIDGE
AT THE UNIVERSITY PRESS
1925

PRINTED IN GREAT BRITAIN

PREFACE

THE present volume, the first written and the most revised, of the book, for which indeed, mostly, the earlier volumes were undertaken, still bears many marks of the difficulty of compressing the matter into brief compass. But the writer hopes that it may seem to the reader as remarkable as it does to him, that it should be possible to comprehend under one point of view, and that so simple, the introduction to nearly all the surfaces ordinarily studied in the geometry of three dimensions, as well as the usual line geometry. Chapters v, vi, vii seek to make clear that this is so. To these the earlier chapters are auxiliary. But Chapters ii and iv have been introduced as much for their own interest as for their illustrative value; the results obtained in these two chapters are not required in the subsequent pages. It is hoped that the Table of Contents, and the Index, may make it easy to use the volume. It will of course be understood that the volume is throughout intended to be introductory and illustrative; hardly anywhere is it complete.

To the Staff of the University Press grateful acknowledgments are due for their continued courtesy and care.

TABLE OF CONTENTS

CHAPTER I. INTRODUCTORY. RELATIONS OF THE GEOMETRY OF TWO, THREE, FOUR AND FIVE DIMENSIONS

PAGES

SECTION I. THEOREMS OF TWO AND THREE DIMENSIONS . . . 1—32

The conics touching the fives from six arbitrary lines of a plane . 1—4

Exx. 1—4. *Particular algebraic results; equation of triangularly circumscribed conic.* . . . . 4—6

Representation of a plane upon a quadric . . . . . 6—8

The generalised Miquel theorem . . . . 8—10

Ex. 1. *The conic of an arbitrary plane determined by joins of five points* 10, 11

Ex. 2. *Cubic curve through the five points gives a self-polar triad* . 11

Ex. 3. *Dual of theorem of Ex.* 1; *consequence* 11

Ex. 4. *Aggregate of conics thus arising for sets of five points of a cubic curve* 11, 12

Ex. 5. *Alternative proof of generalised Miquel theorem* . . 12

Ex. 6. *A plane theorem arising from Ex.* 5 12

The theory of inversion in a plane . . . . 12—14

Ex. 1. *Equations for inversion in a plane* 14

Ex. 2. *Relations between centres of inverse circles* . . . 14, 15

Ex. 3. *Inversion of one given circle into another* 15

Ex. 4. *Centres of similitude and circle of similitude of two circles* . 15

Ex. 5. *Circles through threes of four points; property of circles of similitude* 15, 16

Ex. 6. *Quadric touching four planes having double contact with another* 16

Ex. 7. *Relation of two points of contact in Ex.* 6 . . . 16

Ex. 8. *Relation expressed by means of a cubic curve* . . . 16, 17

Ex. 9. *Employment of cross-ratios* 17

Ex. 10. *A line, and its polar line, intersecting a quadric* . . 17

Ex. 11. *Five circles constructed from five given circles* . . 17, 18

Wallace's theorem for four circles and Moebius's figure of two tetrads . . . . 18—20

Ex. 1. *Dual of Moebius's figure* 20

Ex. 2. *A quartic surface considered by Bauer* 20, 21

Ex. 3. *A theorem of Steiner's for two triads of points* . . . 21

Additions to Wallace's theorem in a plane 21, 22

Ex. 1. *Pedal circles orthogonal to one circle* . . . . 22—24

Ex. 2. *Alternative to use of associated points* 24

Ex. 3. *Pedal properties in threefold space* 24, 25

Ex. 4. *Theorem of symmetry of five points, for pedal property* . 25

PAGES

Ex. 5. *Pedal property of circle generalised to rational curve of higher space* 25, 26
Ex. 6. *Generalised form of pedal property* 26
Ex. 7. *Algebraic proof of preceding results* 26, 27
Ex. 8. *A generalised orthocentre of four arbitrary points* . . 28
Ex. 9. *Theorem for two systems of conics* 28
Ex. 10. *A property of the cubic surface with four double points* . 28
Ex. 11. *Cubic curve in threefold space, three tetrads upon* . . 28, 29
Ex. 12. *Algebraic form of result of Ex.* 11 29
Theorems for circumscribed circles for any number of lines in a plane . . . . 29—31
Ex. 1. *Representation of points of quadric by transversals of two lines* 31, 32
Ex. 2. *Six conics triangularly inscribed to another* . . . 32
SECTION II. THEOREMS OF THREE AND FOUR DIMENSIONS . . . 32—40
Tetrahedral complex, determined by planes meeting three lines in fourfold space . . . . 32—34
Ex. *Algebraic formulation* 34
Analogous generation of a linear complex 34, 35
Ex. *Algebraic formulation*. 35, 36
Spheres as determined from sections of a quadric in fourfold space 36—38
Exx. 1, 2. *Two conjugate points of quadric in fourfold space* . 38
Ex. 3. *Representation of a circle by a line in fourfold space* . 38, 39
Ex. 4. *Two spheres cut everywhere at the same angle* . . . 39, 40
SECTION III. USE OF SPACE OF FIVE DIMENSIONS . . . . 40—64
The representation of lines of threefold space by points of fivefold space . . . . 40—42
Ex. 1. *Representation of two conjugate or apolar linear complexes* 42
Ex. 2. *Six linear complexes mutually conjugate* 42
Ex. 3. *General form of theorem of Ex.* 2 . . . . . 42, 43
The lines common to three, and to four, linear complexes . . 43, 44
Planes lying entirely on the quadric fourfold in the space of five dimensions 44, 45
The planes of the quadric fourfold treated with the symbols . . 45—47
The aggregate of the planes lying on a quadric in fivefold space . 47, 48
Ex. 1. *Representation of point and polar plane in regard to a focal system* 48
Ex. 2. *Representation of a pair of lines, polars in regard to a quadric* 48, 49
The representation of congruences of lines of the original space . 49, 50
Number of lines common to two congruences in threefold space . 50, 51
Ex. *Number of chords common to two curves* 51
The chords of a cubic curve in the threefold space. Veronese's surface . . . . 52—54

PAGES
Ex. 1. *The section of Veronese's surface by a fourfold space.* . 54
Ex. 2. *The representation in fivefold space of the conics of a plane* 54
Ex. 3. *Statement of some properties of Veronese's surface* . . 54, 55
Lie's correspondence between lines and spheres in space of three dimensions 55, 56
Ex. 1. *Algebraic formulation of the correspondence* . . . 56, 57
Ex. 2. *Comparison with deduction of sphere from fourfold space* . 57
Ex. 3. *The eight pairs of spheres which touch four spheres* . . 57, 58
Ex. 4. *The eight spheres touching four planes* 58
Ex. 5. *The double-six theorem expressed in terms of spheres* . 58
Generalisation of Wallace's theorem. The theorem of the double-six. A theorem for six lines with a common transversal . 58—60
Exx. 1—5. *Proofs of the theorems* . . . . 60—64
Note. Another proof of Wallace's theorem, and extensions . 64

CHAPTER II. HART'S THEOREM, FOR CIRCLES IN A PLANE, OR FOR SECTIONS OF A QUADRIC

The sections of a quadric which touch three given sections . . 65, 66
Ex. 1. *A pair of variable sections of a quadric touching one another and two fixed sections* 66
Ex. 2. *Construction of the circles touching three given circles* . 66
Ex. 3. *A theorem for circles through threes of four special points*. 66, 67
Ex. 4. *Circles cutting three given circles at equal angles* . . 67
Ex. 5. *Circles cutting four given circles at equal angles* . . 67
Ex. 6. *Circles cutting three given circles at given angles* . . 67
Ex. 7. *Common tangents, of three circles, which meet in a point* . 67, 68
Ex. 8. *Solution of generalised Malfatti's problem*. . . . 68, 69
Ex. 9. *Equations of sections touching three sections of a quadric* . 69, 70
Exx. 10—15. *Various algebraic results* 70, 71
The Hart circles of three circles when the four have a common orthogonal circle 71, 72
The Hart circles of three circles in general . . . . . 72—75
Ex. 1. *The various cases* 75
Ex. 2. *The point of contact of the Hart section* 75, 76
Ex. 3. *The bipolar character of the figure obtained* . . . 76, 77
Ex. 4. *Eight sections divided into four pairs* 77
Ex. 5. *Relations with metrical geometry* 78
Ex. 6. *The particular case of the Feuerbach circle* . . . 78—80
Ex. 7. *The same Hart section arises in different ways* . . . 80
Ex. 8. *The radius of the Hart section*. 80, 81
Ex. 9. *Four circles arising from the intersections of three circles* . 82
The bifocal property is necessary as well as sufficient . . . 82—85
Ex. 1. *A particular form of the equation of the quadric* . . 85, 86

PAGES
Exx. 2, 3. *Two algebraic results* 86
Ex. 4. *Relations between four sections and four tangent sections* . 86—88
Ex. 5. *The harmonically conjugate quadric in regard to tangent sections* 88
Ex. 6. *The Hart circle defined by angles of intersection* . . 88

CHAPTER III. THE PLANE QUARTIC CURVE WITH TWO DOUBLE POINTS

The generation of the curve. The four principal circles . . 89, 90
The curve as an envelope of circles. The director conic . . 90
Ex. 1. *Algebraic formulation* 90, 91
Ex. 2. *Two tangent circles have their points of contact on a circle*. 91
The four director conics are confocal 91, 92
The sixteen foci of the quartic curve. Are intersections of a principal circle and a director conic . . . . . . 92—94
Relation of distances of point of curve from three foci . . . 94
Construction of the plane quartic curve given four foci lying on a circle . . . . 94—96
Inversion of the curve into itself 96, 97
Ex. 1. *Cubic curves with two fixed points, arising by inversion* . 97
Ex. 2. *Equations for the case of the cubic curve* 97, 98
Ex. 3. *Case of quartic with four foci on a line* 98
Ex. 4. *The Cartesian, Limaçon and Cardioid* 98, 99
Angles of intersection of enveloping circles of the plane quartic which belong to different families . . . . 99—101
Exx. 1, 2. *Theorem for eight intersections of four circles taken in order* 101
Ex. 3. *Condition by angles of intersection for three circles to meet in a point* 101
Exx. 4, 5. *Angles between six planes, in regard to a quadric* . 102, 103
Ex. 6. *Theorem of intervals, for quadrics with ring contact* . . 103
Ex. 7. *Descriptive form of distance theorem for focal conics*. . 103
Ex. 8. *A theorem for the foci of an anallagmatic curve* . . 103

CHAPTER IV. A PARTICULAR FIGURE IN SPACE OF FOUR DIMENSIONS

The structure of the figure. Identity of numbers with those for lines of cubic surface 104, 105
Geometrical bearings of the figure. The group 105
The establishment of the figure . . . . 105—111
Exx. 1—4. *Some particular results. Connexion with theory of spheres* 111, 112

CHAPTER V. A FIGURE OF FIFTEEN LINES AND POINTS, IN SPACE OF FOUR DIMENSIONS; AND ASSOCIATED LOCI

PAGES

The figure of fifteen lines and points . . . . 113—115

Proof of the incidences with the help of the symbols . . . 115, 116

Ex. 1. *A property of five associated lines* 117

Ex. 2. *A generation of five associated lines* 117

Ex. 3. *A quadric surface obtained from six points in fourfold space* 117

Ex. 4. *Harmonic inversion of figure, with point and solid fundamental* 117

Ex. 5. *Dual of the figure. Harmonic inversion with two fundamental planes* . . . . 117—119

Ex. 6. *Harmonic inversion with line and plane fundamental* . 119

Ex. 7. *Separation of the figure into two parts, in ten ways* . . 119, 120

Ex. 8. *Application of inversion of Ex. 6 to quartic curve in fourfold space* 120

The associated line of a set of five is met by all planes meeting the first four lines . . . . 120—123

Interpolation in regard to quadric point-cone and line-cone . . 120—122

The six systems of planes 123, 124

The planes of the figure deduced with the help of the symbols . 124, 125

The equation of an associated quartic locus 125, 126

Ex. *The six sets of associated lines give related ranges on certain conics* 127, 128

The tangent solid of the quartic locus Σ 128, 129

The equations of the singular solids 129, 130

The intersections of a tangent solid of Σ with the fifteen fundamental lines . . . . 130—133

The intersections of a tangent solid of Σ with the planes of the six systems . . . . 134—136

Ex. 1. *Planes of a system meeting a line. Algebraic expression* . 136, 137

Ex. 2. *Equations for congruence of lines on tangent solid, by planes of a system* 137, 138

Ex. 3. *Particular algebraic results* 138

Ex. 4. *Intersection of locus Σ with tangent solid is a Kummer surface* 138, 139

Ex. 5. *Six conjugate linear complexes determined by six points* . 139, 140

Ex. 6. *Algebraic formulation of theorem of Ex. 5* 140

Ex. 7. *Number of non-intersecting pairs and threes of lines in the figure* 140

Ex. 8. *Other forms of congruence of lines in tangent solid, by planes of a system* 140, 141

Ex. 9. *Theorem for relation of a line to four mutually inscribed tetrads* 141, 142

PAGES

Ex. 10. *The locus Σ giving rise to Kummer surface, or to Plücker's Meridian Surface* 142, 143
Ex. 11. *Six arbitrary lines in fourfold space are met by five associated planes* 143
Ex. 12. *Solid through associated plane meets four planes in lines of a quadric* 143, 144
Ex. 13. *Joins of two triads met by solid in six planes touching a quadric cone* 144, 145
Ex. 14. *A plane in a singular solid determines a quadric cone* . 145
Ex. 15. *Aggregate of planes each joining corresponding points in three related planes* 145, 146
Exx. 16, 17. *Various algebraic results* 146, 147
Ex. 18. *Enveloping cone of Segre's locus from point of a particular line* 147
Ex. 19. *Trisecant planes of a quartic curve in fourfold space* . 147
Ex. 20. *Symmetrical tangential equation of Segre's quartic locus* . 147, 148
Ex. 21. *Quadric in regard to which Segre's figure is self-polar* . 148
Ex. 22. *Derivation of Segre's figure from fivefold space* . . 149
Ex. 23. *The projection of Segre's figure on to a threefold space* . 149—151

The dual of the figure which has been considered. The cubic locus *S* 151—158
Ex. 1. *Equations for the six lines of the locus S through an arbitrary point* 158
Ex. 2. *The equation of the Weddle surface*. 158, 159
Ex. 3. *Quadratic congruence obtained by projection of lines of S* . 159
Ex. 4. *Dual derivation of Weddle's surface* 159
Ex. 5. *The locus Σ, and its tangent solid, in terms of parameters* . 159, 160
Ex. 6. *Quartic surface with fifteen double points, changed to surface with five double points* 160
Ex. 7. *The locus S by projection from fivefold space* . . . 160
Ex. 8. *Theory of system of any four quadrics in threefold space* . 160

CHAPTER VI. A QUARTIC SURFACE IN SPACE OF FOUR DIMENSIONS. THE CYCLIDE

A quartic surface in space of four dimensions 161, 162
Preliminary algebraic consideration of the surface . . . 162—165
Ex. 1. *Surface projected on to plane by planes through a line of the surface* 165
Ex. 2. *Reduction of equations of two quadric point-cones* . . 165
Ex. 3. *Combination of harmonic inversions from points of a simplex* 165
Ex. 4. *Algebraic proof surface contains only sixteen lines* . . 166
Ex. 5. *Algebraic arrangement of lines* 166

Resumption of the descriptive theory of the quartic surface. The sixteen lines . . . . 166—168

PAGES

The self-polar pentad for the quartic surface . . . . . 168—170

Ex. 1. *Harmonic inversion of the lines of the figure* . . . 170

Ex. 2. *The lines meet in pairs in eight points of a face of the pentad* 170

Ex. 3. *A notation for the sixteen lines. Double-fours of lines* . 170, 171

The conics lying on the quartic surface 171, 172

The cubic surface in space of three dimensions; and the theory of inversion 172, 173

Ex. 1. *Equation for a cubic surface derived from fourfold space* . 173

Ex. 2. *The twenty-seven lines of the cubic surface obtained by projection* 174

Ex. 3. *A line meeting the Absolute conic inverts into an intersecting line meeting this conic* 174

The Cyclide, or quartic surface with a double conic, in threefold space 174, 175

Ex. 1. *Equation of Cyclide, and of enveloping spheres* . . . 175, 176

Ex. 2. *Cyclide as locus of circle, intersection of corresponding spheres of two systems* 176

Ex. 3. *Cyclide as locus of limiting points of fixed sphere and varying tangent plane of quadric* 176, 177

Ex. 4. *Enveloping spheres meet Cyclide on tangent planes of a quadric cone* 177

The five generations of the Cyclide, with confocal quadric surfaces 177, 178

Ex. 1. *The focal conics of the confocal principal quadrics* . . 178, 179

Ex. 2. *The angle between two enveloping spheres of different systems* 179

Ex. 3. *The five inversions of a Cyclide into itself.* . . . 179

Ex. 4. *Four points of double conic of Cyclide at which tangent planes coincide* 179, 180

Confocal Cyclides. Three through arbitrary point with given focal curve, cutting orthogonally . . . . 180—183

Ex. 1. *Algebraic formulation* 183

Ex. 2. *Lines in fourfold space which become normals of Cyclide* . 183—186

Ex. 3. *The lines of curvature of a Cyclide* . . . . . 186—188

Ex. 4. *The normals of Cyclide along line of curvature generate a developable surface* 188, 189

Ex. 5. *Sixteen lines of Cyclide are complete intersection with a quartic surface* 189

Ex. 6. *A line of curvature is inverted into a line of curvature* . 189

Ex. 7. *A criterion for a line of curvature* 189

Ex. 8. *Two orthogonal surfaces intersecting in a line of curvature on one* 189

Ex. 9. *Plane lines of curvature* 189, 190

Ex. 10. *Differential equation for inflexional curve, and for line of curvature* 190

In regard to some particular cases. The Dupin Cyclide . . 190—194

PAGES
Ex. 1. *An irrational form of the equation of a general Cyclide* . 194, 195
Ex. 2. *Equations for a Cyclide with two double points* . . . 195, 196
Ex. 3. *Equations for a Cyclide with four double points* . . 196—198
Ex. 4. *Maxwell's generation of Dupin's Cyclide generalised* . . 198
Ex. 5. *Inversion of Dupin's Cyclide into an Anchor Ring* . . 198—200
Ex. 6. *Two theorems for inversion of spheres* 200
Ex. 7. *The envelope of a sphere touching three spheres* . . . 200, 201
Ex. 8. *The inversion of Dupin's Cyclide into a Quadric cone of revolution* 201
Ex. 9. *Dupin's Cyclide given by its tangent planes* . . . 201, 202
Ex. 10. *Further equations for Dupin's Cyclide* 202

CHAPTER VII. RELATIONS IN SPACE OF FIVE DIMENSIONS. KUMMER'S SURFACE

Klein's figure in three dimensions, related to a figure in five dimensions . . . . 203—205
Exx. 1—4. *Various particular formulae* 205, 206
Ex. 5. *Origin and scheme for ten important quadric surfaces* . 206—208
A transformation of Segre's figure, in space of four dimensions, to a figure in five dimensions . . . . 208—211
Relation of the transformation to the theory of Kummer's surface 211, 212
Kummer's quartic surface as the locus of singular points of a quadratic complex of lines . . . . 212—217
Ex. 1. *The question of the covariance of the transformation* . 217
Ex. 2. *The tetrahedroid, and Wave Surface, of Fresnel* . . 217, 218
Kummer's surface in the geometry of space of five dimensions . 218—221
The tangent lines of a Kummer surface at a point . . . 221, 222
The inflexional directions at a point of the Kummer surface. . 222, 223
The associated quadratic congruences . . . . . . 223—225
The common singular points and planes of the six congruences . 225—227
The confocal quadrics . . . . 227—229
Singular planes through a more particular point 229, 230
The Inflexional (or Asymptotic) curves of the Kummer Surface . 230—234
The rationality of the Quadratic Complex, and of the Quadratic Congruence . . . . 234—237
The generation of a quadric in fivefold space. The tetrahedral complex in threefold space . . . . 237—240
The singular points and planes of a Quadratic Congruence. Caporali's theorem . . . . 240—243
Exx. 1—3. *Various algebraic results* 243, 244

CORRECTIONS TO VOLUME III 244

INDEX . . . . 245—250

CHAPTER I

INTRODUCTORY. RELATIONS OF THE GEOMETRY OF TWO, THREE, FOUR AND FIVE DIMENSIONS

THE present chapter consists of various examples of the interest and importance of the comparison of the geometry of spaces of different dimensions. The first section (pp. 1—32) is concerned with relations between theorems in two and in three dimensions. The second section (pp. 32—40) deals with the representation in four dimensions of some results belonging to ordinary space of three dimensions. The last section (pp. 40—64) deals with the employment of space of five dimensions for the consideration of properties arising both in three and in two dimensions. Some few references occur to space of any number of dimensions.

SECTION I. THEOREMS OF TWO AND THREE DIMENSIONS

The conics touching the fives from six arbitrary lines of a plane. Let three lines, p, q, r, be given in a plane, as well as a fourth line containing two points, I, J; let any conic be drawn touching the four lines; let σ be the conic, through the points I, J, which contains the three intersections of the lines p, q, r; then this conic σ passes through the point, S, in which intersect the tangents from I, J to the former conic. Or, in other words (Vol. II, p. 81), the circle through the intersections of three tangents of a parabola contains the focus of this parabola. Thus if four lines be given, beside the line which contains the points I, J, the conic touching the five lines being then definite, the four conics, all through I, J, each containing the intersections of three of the four given lines, meet in a point, namely, the point, S, in which the tangents from I, J to the former conic intersect (Vol. II, p. 82); namely, these are four circles meeting in the focus of the parabola. If now, finally, five lines be given, beside the line containing the points I, J, there will be five parabolas, each a conic touching the last line and four of the others, and five foci, S_1, S_2, ..., S_5. It is the case that the circle containing any three of these foci passes through the other two, that is, that the seven points S_1, ..., S_5, I, J lie on a conic. Of this theorem a proof was given by Clifford ("A synthetic proof of Miquel's theorem," *Math. Papers*, 1882, p. 38), with the help of certain particular cubic curves.

A circle through the focus, S, of a parabola is a conic containing the intersections of three tangents of the parabola, namely IJ, IS, JS, and may be said to be triangularly circumscribed to the parabola. Conversely, any conic triangularly circumscribed to a conic and meeting a tangent of this in points I, J, contains the intersection, S, of the tangents to this from I and J; it may, therefore, be regarded as a circle through the focus of a parabola, when I and J are taken as the Absolute points. Thus the theorem above referred to may be stated by saying that, if a, b, c, d, l' and l be six arbitrary lines given in a plane, and I, J be two arbitrary given points of the line l, and five conics be defined each as touching l and four of the lines a, b, c, d, l', then there exists a conic passing through I and J which is triangularly circumscribed to these five conics. The symmetry may suggest that this latter is also triangularly circumscribed to the conic which is defined by touching the five lines a, b, c, d, l'; this is in fact the case. We thus have six conics, each touching five of the six given lines; and each of the six lines touches five of the conics. There cannot be two conics through the points, I, J, of l, both triangularly circumscribed to the six conics; such a conic, if existent, is defined by the points I, J and three of the conics touching the line IJ, namely as containing the intersections, S_1, S_2, S_3, of the tangents from I, J to these three conics, respectively.

To prove this symmetrical result we may proceed as follows: Denote the plane of the six given lines, a, b, c, d, l, l' by ϖ. Draw through each of the lines a, b, c, d an arbitrary plane, denoting the intersections of these in threes by A, B, C, D, of which D is the intersection of the planes through a, b, c, and so on. It is assumed that A, B, C, D are not in a plane. Through the six points consisting of A, B, C, D and the two arbitrary points I, J, of the line l, there can be put a definite cubic curve, which we denote by γ. This will meet the plane ϖ in another point beside I and J; say, in E. Then, through the five points A, B, C, D, E there can be drawn another cubic curve, γ', to have the line l' for chord, meeting this, suppose, in the points I', J' (Vol. III, p. 139). We prove that the conic, ω, containing the five points I, J, E, I', J', is triangularly circumscribed to the six conics touching the fives of the six given lines a, b, c, d, l, l'. It is thus independent of the planes drawn through a, b, c, d.

The conic ω is the intersection with the plane ϖ of the quadric, Ω, defined by the nine points A, B, C, D, E, I, J, I', J'; the cubic curves, γ, γ', each meeting Ω in seven points, lie on this quadric. Cubic curves lying on a quadric are of two families, since such a curve meets all generators of the surface, of one system of generators, in one point, and all generators of the other system in two points;

two cubics of the same family have four common points, but two cubics of different families have five common points (Vol. III, p. 139). Thus the curves γ, γ' are of different families on Ω.

We prove now, first, that the conic ω is triangularly circumscribed to the conic touching the lines a, b, c, d, l; namely by obtaining triads of points of ω whose joins touch this conic (a, b, c, d, l). Let P be any point of ω; through this, and the other four points, A, B, C, D, of Ω, there can be drawn, lying on Ω, a cubic curve of the same family as γ (Vol. III, p. 129). This curve will meet ω in two further points, say Q and R. Either of these, with A, B, C, D, determines the cubic curve, and so determines the other two of the three points, P, Q, R, of ω. Thus, as P varies on ω, the triads P, Q, R form an involution of sets of three points thereon, and the lines QR, RP, PQ all touch a conic (Vol. II, p. 135); this conic, which we may denote by λ, is evidently triangularly inscribed in ω. We prove that λ is the conic touching a, b, c, d, l, by considering different positions of P. When P is at E, the line QR is the line l; thus λ touches l. In general the cubic curve through A, B, C, D, P, Q, R is projected from P by a quadric cone, which may be defined as that containing PA, PB, PC, PD and a particular one of the two generators of Ω at that point P. But when P is at one of the two intersections of the line d with ω, this cone degenerates, becoming the aggregate of the plane ABC, which contains d, and the plane joining PD to the particular generator at P spoken of; one of the two lines PQ, PR, in which the cone meets the plane ϖ, is thus the line d. Therefore the conic λ touches d. By a similar argument it touches a, b, c.

To prove that the conic ω is triangularly circumscribed to the conic touching a, b, c, d and l', we describe a cubic curve through a varying point, P, of ω and through A, B, C, D, lying on Ω, but of the same family as the curve γ'.

That the conic touching a, b, c, and both of l and l', is triangularly inscribed to ω, we likewise prove by obtaining an involution of sets of three points lying on ω. For this, let the points in which the lines DA, DB, DC meet the plane ϖ be denoted, respectively, by A_1, B_1 and C_1, and consider the conics drawn through the four points A_1, B_1, C_1 and E. The sets of three points other than E in which these conics meet ω are then sets of such an involution (Vol. II, p. 138), and the three joins of the points of such a set are tangents of a conic, which we denote by δ. One conic through A_1, B_1, C_1 and E consists of the two lines B_1C_1 and A_1E; thus δ touches B_1C_1, which is the line a. Similarly δ touches b and c. Again, the conics through A_1, B_1, C_1 and E may be defined by quadric cones, of vertex D, containing DA, DB, DC and DE; one such cone, however, is the cone which contains the cubic curve γ, and this meets the conic ω in the points I, J. Thus the conic δ touches the line l. Another such cone is that containing the curve γ', which meets ω in I' and J'. Thus δ also touches l'. It is thus shewn that the conic touching a, b, c and l, l' is triangularly inscribed in ω. An analogous argument proves ω to be triangularly circumscribed to the *three* conics touching l, l' and, respectively, b, c, d; c, a, d; a, b, d.

The theorem stated is thus completely established. It has been remarked that the conic obtained, triangularly circumscribed to the six primary conics, is uniquely determined by its intersections, I, J, with one of the six given lines, l. It is clear, however, from the reasoning given that the conic is also determinate when E is given; its intersections with l being on the tangents from E to the conic touching a, b, c, d, l, and its intersections with l' being on the tangents from E to the conic touching a, b, c, d, l', while the conic passes through E. Thus, whatever be the planes, drawn through a, b, c, d, by which A, B, C, D are determined, the cubic curve drawn through E, A, B, C, D, to have l for chord, meets l in the same two points, I, J; and similarly for l'.

Ex. 1. If E, I, J be three points of a cubic curve in space, of which A, B, C, D are four other points, the two axial pencils of planes joining EI and IJ to A, B, C, D are related to one another; and the former is related to the range on EI determined by the four planes containing A, B, C, D, the latter being similarly related to the range which these four planes determine on IJ. Wherefore, there is a conic, in the plane EIJ, touching the four lines in which this plane is met by the four planes containing A, B, C, D, and also touching EI, IJ. By parity of reasoning this same conic touches also the line EJ.

Ex. 2. If, in the construction above, the lines a, b, c, d, l, lying in the plane $t=0$, be taken to be

$$x=0,\ y=0,\ z=0,\ ax+by+cz=0,\ lx+my+nz=0,$$

the planes DBC, DCA, DAB, ABC being

$$x=0,\ y=0,\ z=0,\ ax+by+cz-t=0,$$

and the point E be $(\xi, \eta, \zeta, 0)$, prove that the points I, J lie on the conic in the plane $t=0$ given by

$$x^{-1}\xi(mb^{-1}-nc^{-1})+y^{-1}\eta(nc^{-1}-la^{-1})+z^{-1}\zeta(la^{-1}-mb^{-1})=0;$$

this lies on the cone, of vertex D, containing the cubic curve through A, B, C, D, E which has the line l for chord.

Ex. 3. Hence infer that if the six given lines of the original plane be of equations

$$x=0,\ y=0,\ z=0,\ a_r x+b_r y+c_r z=0,\ (r=1, 2, 3),$$

then the general conic which is triangularly circumscribed to the six conics touching the fives of these lines has for equation

$$\begin{aligned}&\Delta(a_1x+b_1y+c_1z)(a_2a_3xYZ+b_2b_3yZX+c_2c_3zXY)\\&\quad+(A_1X+B_1Y+C_1Z)(A_2A_3Xyz+B_2B_3Yzx+C_2C_3Zxy)=0,\end{aligned}$$

where Δ is the determinant (a_1, b_2, c_3), and $A_1, B_2, \ldots$ are the minors of $a_1, b_2, \ldots$ therein, while (X, Y, Z) is an arbitrary point, such that $(a_1^{-1}A_1X, b_1^{-1}B_1Y, c_1^{-1}C_1Z)$ is the point E, or (ξ, η, ζ), of the foregoing theory. This equation, it may easily be seen, is unaltered by cyclical change of the suffixes, X, Y, Z being unaltered; it is derived from a form obtained algebraically by Mr F. P. White (*Camb. Phil. Proc.* XXII, 1924, p. 11). If we take

$$X'=A_1X+B_1Y+C_1Z,\quad Y'=A_2X+B_2Y+C_2Z,\quad Z'=A_3X+\ldots,$$

and also

$$x'=a_1x+b_1y+c_1z,\quad y'=a_2x+\ldots,\quad z'=a_3x+\ldots,$$

the equation is also capable of the form

$$\begin{aligned}&x'(B_1C_1x'Y'Z'+B_2C_2y'Z'X'+B_3C_3z'X'Y')\\&\qquad+\Delta X(b_1c_1X'y'z'+b_2c_2Y'z'x'+b_3c_3Z'x'y')=0,\end{aligned}$$

and of two other forms, obtained from this by cyclical interchange of a, b, c, without change of X', Y', Z'.

Further, if we take the three points P_1, P_2, P_3, where P_r is of coordinates $(a_r^{-1}A_rX, b_r^{-1}B_rY, c_r^{-1}C_rZ)$, and denote the line $a_rx+b_ry+c_rz=0$ by l_r, and the points $(1, 0, 0)$, $(0, 1, 0)$, $(0, 0, 1)$ by A_1, B_1, C_1, and then define a conic, S_1, as that through $(A_1, B_1, C_1, P_2, P_3)$, a conic, S_2, as that through $(A_1, B_1, C_1, P_3, P_1)$ and a conic, S_3, similarly, it will be found that the three pairs of intersections (S_1, l_1), (S_2, l_2), (S_3, l_3) lie on a conic through P_1, P_2, P_3, this conic, through these nine points, being the conic triangularly circumscribed to the six primary conics.

The reader may also be reminded of Taylor's theorem (Vol. II, p. 61), that the poles of an arbitrary line in regard to the six primary conics lie on another conic.

Ex. 4. Any six lines of a plane can in fact be regarded as the projections of six chords of a cubic curve, from a point of this curve, these chords having the property that every five of them have a common transversal. For, taking the six conics touching the fives of the given lines, let the conic which is triangularly circumscribed to these have its equation put in the form $xz-y^2=0$, as is possible in an infinite number of ways. Then with an arbitrary point for the intersection of planes $x=0$, $y=0$, $z=0$, this conic is on the cone projecting from this point the cubic curve whose points are given by $(\theta^3, \theta^2, \theta, 1)$. The tangent line of any conic given in the original plane, $t = 0$, may then be defined by a plane,

$$ux + vy + wz = 0,$$

through the point $(0, 0, 0, 1)$, and the tangential equation of the conic may be taken in the form

$$c'u^2 + a'v^2 - cw^2 - bvw - (a + a')\,wu - b'uv = 0,$$

in which u, v, w are tangential coordinates. The chord of the cubic curve joining the points, other than $(0, 0, 0, 1)$, in which the plane meets the curve, has for coordinates the six

$$wu - v^2,\ uv,\ -u^2,\ wu,\ vw,\ w^2;$$

thus the equation of the conic expresses that the tangent line of this is the projection of a chord of the cubic curve which belongs to the linear complex (a, b, c, a', b', c'). In particular, if

$$aa' + bb' + cc' = 0,$$

the conic is triangularly inscribed to the conic $xz - y^2 = 0$, as we easily verify (Cremona, *Giorn. d. Mat.*, x, 1872, p. 47). Whence, six conics triangularly inscribed to $xz - y^2 = 0$ can be regarded as having the equations $(r = 1, \ldots, 6)$

$$n_r'u^2 + l_r'v^2 - n_r w^2 - m_r vw - (l_r + l_r')\,wu - m_r'uv = 0,$$

each being obtained by projecting the chords of the cubic curve which meet a line of coordinates $(l_r, m_r, n_r, l_r', m_r', n_r')$. When the six conics touch the fives of six lines, so that every five of them have a common tangent, these lines are obtained by projection from six chords of the cubic, forming with the lines $(l_r, m_r, \ldots)$ a double six of lines. (Cf. Wakeford, *Proc. Lond. Math. Soc.*, xv, 1916, p. 340.)

It may be remarked, too, that the conic, $(l_r, m_r, \ldots)$, touching the projections of the chords of the cubic which meet the line $(l_r, m_r, \ldots)$, has, beside five of the originally given six lines, as a sixth tangent, the line $l_r'x + m_r'y + n_r'z = 0$. If we take the intersection of this with the remaining one of the six original lines, we obtain one of six points which lie on a conic. (Cf. Vol. III, p. 136, Ex. 8, and p. 201.)

Representation of a plane upon a quadric. Consider a quadric surface, Ω; and, upon this, a point, U, which is to be taken as centre of projection. Consider also a plane, ϖ. Let the generators at U, of the quadric Ω, meet the plane ϖ in the points I and J. Any plane meets the generators; and, thus, the conic, in which Ω is met by any plane which does not pass through U, is projected from U into a conic of the plane ϖ which passes through I and J. Regarding I and J as Absolute points, we may then speak of this conic as a circle. Conversely, any conic, in the plane ϖ, which passes through I and J, lies on a quadric cone of vertex U; this cone contains the generators UI, UJ; its remaining intersection with Ω is thus a curve of the second order, namely a plane section. Thus plane sections of the quadric Ω, not containing U, and circles of the plane ϖ, are transformable into one another by projection from U. Sections of Ω by planes through U project into lines of ϖ, and conversely.

Let α be any conic section of Ω not passing through U; and let A be the pole of the plane of α, in regard to Ω. Let α' be the circle of the plane ϖ which arises by projection of α from U. We prove that the line UA meets the plane ϖ in the pole, in regard to α', of the line IJ; that is, that the projection of A is the *centre* of the circle α'. Let the line in which the tangent plane at U, of the quadric Ω, is met by the plane of α, be denoted by u; and the point in which the line UA meets the plane of α be denoted by A_0. The line UA is the polar line of u, in regard to Ω; thus the polar plane of A_0 contains u, and A_0 is the pole of u in regard to the conic α; so that any line in the plane of α, through A_0, meets u in the harmonic conjugate of A_0, in regard to the two points in which this line meets the conic α. This relation persists after projection from U; and this proves the statement made. Conversely, however, in the correspondence between the points of the plane ϖ, and the points of the quadric Ω, the centre of the circle corresponds to the point, other than U, in which the line UA meets Ω.

We have explained (Vol. II, p. 166) how to measure the angle between two lines of a plane, say of equations $P+\lambda Q=0, P+\mu Q=0$, with respect to two other lines $P=0$, $Q=0$, by means of the ratio λ/μ. In particular, the angle between two lines lying in the tangent plane of the quadric Ω, at a point O, and meeting at this point, may be measured with respect to the generators of the quadric at this point. As each of these generators meets one of the generators at U, if O project from U into O' on the plane ϖ, the generators at O project into the lines $O'I$, $O'J$. Thus the angle in question is that between the lines in the plane ϖ, into which the two original tangents of Ω at O project, when measured with respect to the two Absolute points I, J of the plane ϖ. If O be one of the intersections of two plane sections of the quadric Ω, the other being Q, and the lines taken at O be the two tangents of these sections at O, the flat pencil in the tangent plane at O, consisting of these lines and the generators at O, is the section by the tangent plane at O of the axial pencil consisting of the two planes, which meet in OQ, and the two tangent planes of Ω drawn from the line OQ; for each of these tangent planes contains a generator at O and a generator at Q. Thus the angle in question is that of the planes of the two sections measured in regard to the two tangent planes of Ω drawn from OQ. If, in particular, the planes of the two sections are conjugate to one another, each containing the pole of the other, then they are harmonic in regard to the two tangent planes of Ω drawn through their line of intersection. Thus we reach the results that two circles in the plane ϖ intersect at the same angle at both their common points, this being the angle between the corresponding planes of the quadric Ω when suitably measured, and that the circles cut at right angles when these planes are conjugate to one another (cf. Vol. II, p. 193). By considering sections of Ω through U, all conjugate to a chosen plane section, we obtain the result that all lines through the centre of a circle cut this at right angles; by considering plane sections all passing through a point not on Ω, this being the pole of a certain section, we obtain the aggregate of all circles in the plane ϖ which cut a certain circle at right angles; by considering sections of Ω by planes through a line, we obtain a system of coaxial circles, whose limiting points are the projections of the two points in which Ω is met by the polar line of the given line, while sections by planes through this polar line give circles cutting at right angles those of the original system; thence, two points of Ω, lying on a line through the pole of a chosen section of Ω, project into two points which are conjugate in regard to the circle into which the chosen section projects; and so on, all the familiar properties of circles being easily interpretable. It may be remarked that the angle between two plane sections of Ω, which we have identified with the angle between two circles, is also the same as the interval between the points which are the poles of these plane sections, measured with respect to the intersections with Ω of the join of these poles.

The generalised Miquel theorem. We have given (Vol. II, p. 70) the theorem that if D, E, F be any points respectively on the joins, BC, CA, AB, of three points of a plane, then the three circles AEF, BFD, CDE meet in a point. We consider this result in particular from our present point of view. There is a corresponding theorem for any number of dimensions, capable of similar proof.

(Roberts, *Proc. Lond. Math. Soc.*, XII (1881), p. 117; *ibid.*, XXV (1893), p. 306; Grace, *Trans. Camb. Phil. Soc.*, XVI (1897), p. 168; Haskell, *Arch. d. Math. u. Phys.*, V (1903), p. 278.)

Suppose we have, in space of three dimensions, any three planes passing through a point, O, say $x = 0$, $y = 0$, $z = 0$, and take three arbitrary points: A on the line of intersection of $y = 0, z = 0$; B on the line of intersection of $z=0, x=0$, and C on the line $x=0, y=0$; and then take, on the plane OBC, the point D; on the plane OCA, the point E, and on the plane OAB, the point F; the planes AEF, BFD, CDE will meet in a point, say Q. If O is taken on an arbitrary given quadric, and A, B, C are the intersections with this quadric of the lines $y = 0$, $z = 0$, etc., while D, E, F are on the sections of this quadric by the planes $x = 0$, $y = 0$, $z = 0$, respectively, then the point Q also lies on this quadric. For, all quadrics through the seven points O, A, B, C, D, E, F have in common a further point; of such quadrics a degenerate one consists of the two planes $OBCD$, AEF; another of the planes $OCAE$, BFD, and a third of the planes $OABF$, CDE. As these degenerate quadrics all contain the point Q, so does the original. When, now, we project the points of the given quadric from O, on to an arbitrary plane, the plane $x = 0$ gives a line containing the projections of the points B, C, D, and so on, and the section of the quadric by the plane AEF gives a circle; the three such circles meet in the point which is the projection of Q. This proves the theorem of Miquel.

It is equally the case that, in space of three dimensions, if A, B, C, D be any four points, and points, P, Q, R, P', Q', R' be taken arbitrarily, respectively on the lines DA, DB, DC, BC, CA, AB, then the four spheres, each containing one of the four points A, B, C, D and also the three points on the joins of this to the other points, meet in a point. These are the spheres $APQ'R'$, $BQR'P'$, $CRP'Q'$, $DPQR$. A proof is as follows. In space of four dimensions, consider four threefolds, $x=0$, $y=0$, $z=0$, $t=0$, meeting in a point O; any three of these threefolds will meet in a line through O, and upon each of the four lines so obtained a point may be taken; let the point on the line $y = 0$, $z = 0$, $t = 0$ be A, the others being B, C, D, of which, for example, D is on $x = 0$, $y = 0$, $z = 0$. Upon the plane $y = 0$, $z = 0$, which contains the lines OA, OD, let the point P be taken, arbitrarily; and, similarly, the points Q and R be taken on the planes OBD, OCD, respectively, as also P', Q', R' on the respective planes OBC, OCA, OAB. Then consider the threefolds $APQ'R'$, $BQR'P'$, $CRP'Q'$, $DPQR$, which we denote, respectively, by $\xi = 0$, $\eta = 0$, $\zeta = 0$, $\tau = 0$; and let T be their point of intersection. It can then be shewn that T lies on any quadric threefold constructed to contain the points $O, A, B, C, D, P, Q, R, P', Q', R'$. In fact the equation of a quadric threefold, in fourfold space, contains fifteen terms; thus a quadric through the eleven specified points will be of the form $\lambda_1 U_1 + \ldots + \lambda_4 U_4 = 0$, where $\lambda_1, \ldots, \lambda_4$ are arbitrary, and $U_1 = 0, \ldots, U_4 = 0$ are four such quadrics, which we suppose to be linearly independent. It follows that any quadric through the eleven specified points will also pass through the remaining $2^4 - 11$, or five, common points of these four quadrics. This assumes that these four quadrics have no common curve, or surface, and intersect in sixteen points. We can, however, at once specify four degenerate quadrics through the eleven points, namely $x\xi = 0$, $y\eta = 0$, $z\zeta = 0$, $t\tau = 0$; for instance $x = 0$ contains O, B, C, D, P', Q, R, and $\xi = 0$ contains A, P, Q', R'. Thus, every quadric through the eleven points contains the point, T, common to $\xi = 0$, $\eta = 0$, $\zeta = 0$, $\tau = 0$. This is the result desired. The four other common points of these four quadrics, which equally lie on any quadric through the eleven points, are the points such as $\eta = 0$, $\zeta = 0$, $\tau = 0$, $x = 0$. It can be shewn now that, by projection from O upon any threefold space, the theorem enunciated in regard to the four spheres is obtained. But, for convenience, the discussion of the derivation of a sphere by projection from space of four dimensions is deferred to a later section of this chapter (p. 36). A similar proof holds in higher space; this depends on a theorem that, in space of n dimensions, all quadric $(n-1)$-folds through $\frac{1}{2}n(n+1)+1$ general points are expressible by n such quadrics, and pass through $2^n - 1 - \frac{1}{2}n(n+1)$ other points.

From the Miquel theorem in a plane we were able to infer (Vol. II, p. 71) that, if four arbitrary lines be given, the circles each containing the intersections of three of these lines, four in all, would meet in a point; namely, by supposing the points D, E, F, in the enunciation given above, to be in line. This theorem, ascribed to Wallace (Scoticus, *Leybourn's Math. Repos.*, I, 1806, p. 170), will be considered below (p. 18). If, in the corresponding theorem above considered, for four spheres in space of three dimensions, we suppose the six points P, Q, R, P', Q', R' to be in a plane, the four spheres there taken will still meet in a point, but this point will be on the plane containing the six points. This is obvious by considering the Wallace theorem for the four lines in this plane which are obtained by the intersections of this plane with the four planes BCD, CAD, ABD, ABC; the four spheres of the theorem meet this plane in circles. We cannot, therefore, go on to infer that the sphere through A, B, C, D passes through the point of intersection of the first four spheres, as in the plane case; the five spheres meet in fours in points lying one on each of the five planes involved. It will be seen below (p. 59) that the generalisation of the Wallace theorem, which thus does not hold in space of three dimensions, holds nevertheless in space of four dimensions, and in space of any even number of dimensions (see Grace, *as above*, p. 163).

Ex. 1. Through five points, A, B, C, D, E, in three dimensions, can be drawn five linearly independent quadrics. The conics in which these meet an arbitrary plane, ϖ, are also linearly independent, and determine a definite conic, σ, inpolar to all of these. Thus every quadric through A, B, C, D, E meets the plane ϖ in a conic which is outpolar to σ. Such a quadric is formed by the plane ABC taken with any plane through the line DE; hence the point in which ϖ is met by DE is the pole, in regard to σ, of the line in which ϖ is met by the plane ABC. Thus the system of ten points and lines, in which the joining lines and planes of A, B, C,

D, E meet the plane ϖ, is self-polar in regard to the conic σ A similar proof holds for the theorem obtained similarly by taking $(n+2)$ points in space of n dimensions (cf. Vol. II, p. 218), the number of linearly independent quadric $(n-1)$-folds which pass through $(n+2)$ general points, namely $\frac{1}{2}n(n+1)-1$, being one less than the number of terms in the equation of a quadric $(n-2)$-fold in a space of $(n-1)$ dimensions.

Ex. 2. A cubic curve through five points, A, B, C, D, E, meets an arbitrary plane, ϖ, in a triad which is self-polar in regard to the conic, σ, determined in ϖ by these five points, as in Ex. 1. For the three linearly independent quadrics, through the curve, meet ϖ in conics, outpolar to σ, all passing through the points of this triad. The corresponding theorem for a rational curve of order n, through $(n+2)$ points of space of n dimensions, can be similarly proved.

Ex. 3. The dual of the theorem referred to in Ex. 1 is that, if we have five planes, α, β, γ, δ, ϵ, and consider the ∞^4 quadrics touching these planes, then the enveloping cones to these quadrics, drawn from any point, E, are all inpolar to a particular quadric cone, say Σ, of vertex E, determined by the five given planes and the point E. Let the intersections of the four planes α, β, γ, δ be denoted by A, B, C, D, the point D being the intersection (α, β, γ), and so on. Then the line ED is the polar line of the plane joining E to the line (δ, ϵ), in regard to the cone Σ; and the line joining E to the point $(\beta, \gamma, \epsilon)$ is the polar line of the plane joining E to the line (α, δ); that is, the line joining E to the point where AD meets ϵ is the polar line of the plane EBC, in regard to Σ. Thus, considering the conic where the plane ϵ is met by the cone Σ, this conic, σ, is that before described, in regard to which the joining lines and planes of the five points A, B, C, D, E determine a polar system in the plane ϵ in which σ lies.

Regarding σ as an Absolute conic, the point E is the intersection of perpendiculars drawn from the points A, B, C, D, respectively to the planes α, β, γ, δ; and each pair of opposite joins of A, B, C, D, such as BC and AD, are at right angles to one another (cf. Vol. III, p. 78, Ex. 7). In regard to σ, the relation of the five points A, B, C, D, E is symmetrical.

Ex. 4. Five points of a given cubic curve, A, B, C, D, E, determine as above a conic, σ, in a given arbitrary plane. Consider what is the aggregate of all such conics when the five points of the cubic curve have all possible positions thereon. If the curve meet the plane in the points P, Q, R, any such conic, σ, must be such that P, Q, R are a self-polar triad in regard to σ, as we have seen. The five quadrics through A, B, C, D, E may be regarded as consisting of three quadrics containing the curve, together with two degenerate quadrics each consisting of the plane ABC taken with a plane through the line DE. Thus the point F, in which the line DE meets the plane PQR, must be the pole, in regard to σ, of the line in which the plane ABC meets the plane PQR. Conversely, then, taking any conic, σ, in regard to which P, Q, R are a self-polar triad, we can find five points A, B, C, D, E of the cubic curve, for which this is the appropriate conic. Namely, by taking A, B, C arbitrarily upon the curve, then finding the pole, F, of the plane ABC in regard to σ, and then drawing the chord, DE, of the curve which passes through F. The aggregate of the conics, σ, for all possible sets of five points of the curve, is thus the same as the aggregate of the conics of the plane PQR in regard to which P, Q, R are a self-polar triad.

Ex. 5. The proof of Miquel's theorem in a plane which was given in Vol. II, p. 70, was in effect by the polar system determined on the Absolute line by the conics through four points of the plane. This proof can be used also for the Miquel theorem for the four spheres through $APQ'R'$, $BQR'P'$, $CRP'Q'$, $DPQR$, in the notation used above. For it can be shewn that, if O be any further independent point, in the space of three dimensions, and we consider the four conics, in any plane ϖ, such as the conic σ in Ex. 1 above, arising, respectively, from the four sets of five points $OAPQ'R'$, $OBQR'P'$, $OCRP'Q'$, $ODPQR$, then these conics are linearly connected. Denote these conics by σ_1, σ_2, σ_3, σ_4. Thus, if three quadrics drawn, respectively, through $APQ'R'$, $BQR'P'$, $CRP'Q'$ have in common a conic, S, on the plane ϖ, then S, being outpolar to each of σ_1, σ_2, σ_3, is outpolar to σ_4; from this the proof can be completed.

Ex. 6. The theorem referred to in Ex. 5 is equivalent to the following: Let x, y, z, t be four lines in a plane, and A, B, C, D be four points of the plane, such that the line AD contains the point (y, z), the line BC contains the point (x, t), and so on, the six joins of the four points containing the six intersections, properly chosen, of the four lines. Further, let P, Q, R, P', Q', R' be arbitrary points respectively on the lines AD, BD, CD, BC, CA, AB. Then the triads P, Q, R and x, y, z, being in perspective from D, are polars of one another in regard to a conic, say σ_4; similarly, the triads P, Q', R' and y, z, t are polars of one another in regard to a conic, σ_1; and there are two other conics, σ_2, σ_3, determined similarly. These four conics are linearly connected.

The theory of inversion in a plane. Consider a particular correspondence of two points of space in three dimensions, which is of importance. Let L be a fixed point, and λ a fixed plane. To any point, P, we can then make correspond the point, P', of the line LP, which is harmonically conjugate to P, with respect to L and the point of LP which lies on λ; then, conversely, the point corresponding to P' is the point P itself. By this correspondence, to the points of a line, PQ, correspond the points of another line, $P'Q'$, and these two lines meet on the plane λ; also, to the points of a plane, PQR, correspond the points of another plane, $P'Q'R'$, these two planes meeting in a line of the plane λ. Hence, also, as a particular result, to the points of a quadric cone, of vertex O, correspond the points of another quadric cone, of vertex, say, O', these two cones having in common the points of a conic in the plane λ. The two cones have then in common, also, the points of another conic; the points of this second conic must then correspond to one another in pairs, since the cones have no points in common other than those of these two conics, and the points of the conic in the plane λ correspond each to itself. The plane of the second conic common to the two cones must, therefore, pass through L; and, hence, the tangent planes of the two cones at the points where the second conic meets the plane λ, which are points of contact of the cones, must pass through L, as well as through the vertices of both cones.

Now suppose that the plane λ is the polar plane of L in regard to a certain quadric, Ω. Then the point, P', which corresponds to a point, P, lying on the quadric, is the second intersection of LP with Ω; and, to a plane section of Ω, corresponds another plane section, lying on the quadric cone joining L to the first section, the two sections meeting in two points of the polar section, λ. Unless, indeed, the first section is in a plane passing through L, in which case the second section coincides with it. Let, now, U be a definite point of the quadric Ω, and ϖ a definite plane, and let us project the points of Ω from U upon ϖ, as before. Then the polar section, λ, of L, projects into a definite circle of ϖ, say $[\lambda]$, with centre at the projection of L, as we have seen; two points, P, P', of Ω, on a line through L, project into two points of ϖ, say $[P]$ and $[P']$; as every plane through the line LPP' gives a section of Ω which is conjugate to the polar section λ, the points $[P]$, $[P']$ lie on an infinite number of circles cutting the circle $[\lambda]$ at right angles; thus the points $[P]$, $[P']$ lie on a line through the centre of $[\lambda]$, and are inverse points in regard to this circle, being harmonic conjugates in regard to the points where the line $[PP']$ meets $[\lambda]$. This *inversion* is the same as that defined in Vol. II, p. 67. A line, or a circle, of the plane ϖ, is clearly changed by this process into a circle, or, in particular, into a line, the circles inverse to one another in regard to $[\lambda]$ being those corresponding to two plane sections of Ω which lie on a quadric cone of vertex L. If, on Ω, P and P' be two points of a line through L, either generator at P meets one of the generators at P', the point of meeting being the point of contact, of a tangent plane of Ω drawn through the line PP', and, therefore, on the polar section

λ; thus these generators correspond to one another in regard to L; from this it is easily seen that two circles in the plane ϖ intersect at the same angle as their inverse circles in regard to $[\lambda]$, the angle being measured as explained above. Again, any plane section, μ, of Ω, its pole M, and the enveloping cone of Ω along μ, whose vertex is M, are changed by the correspondence in regard to L, respectively, into a section μ', its pole M', and the enveloping cone of Ω along μ'; thus, in the plane ϖ, any circle and two points which are inverses to one another in regard to this circle, are changed, by inversion in regard to $[\lambda]$, into a circle and two points inverse to one another in regard thereto. It may also be remarked that if, instead of L, we take another point, L_1, lying on the line UL, and its corresponding polar section, λ_1, as base for the correspondence, the difference in the plane ϖ is that inversion takes place in regard to another circle, $[\lambda_1]$, having the same centre as $[\lambda]$.

Ex. 1. Taking coordinates in which the plane ϖ is $t=0$, the point of projection, U, is $x=0$, $y=0$, $z=0$, with $z=0$ for the tangent plane of Ω at this point, the generators being $x \pm iy = 0$, $z=0$, the equation of Ω is of the form $F=0$, where

$$F = x^2 + y^2 + 2gzx + 2fyz + cz^2 - 2zt.$$

If, then, L be (x_0, y_0, z_0, t_0), the point, P, of Ω, be (ξ, η, ζ, τ), and P' be $(\xi', \eta', \zeta', \tau')$, such that $\xi' = \xi + \lambda x_0, \ldots, \tau' = \tau + \lambda t_0$, these satisfying the equation of Ω, we find

$$\lambda = -2\left[\xi x_0 + \eta y_0 + g(\zeta x_0 + \xi z_0) + f(\eta z_0 + \zeta y_0) + c\zeta z_0 - \zeta t_0 - \tau z_0\right] F_0^{-1},$$

where F_0 is the value of F for (x_0, y_0, z_0, t_0). Thus $\xi', \eta', \zeta', \tau'$ are expressible as homogeneous linear functions of ξ, η, ζ, τ. Taking

$$R^2 = \left[(\xi z_0 - \zeta x_0)^2 + (\eta z_0 - \zeta y_0)^2\right] z_0^{-2} \zeta^{-2}, \quad k^2 = F_0 z_0^{-2}$$

we easily compute $\zeta'/\zeta = R^2 k^{-2}$ and

$$\frac{\xi' z_0 - \zeta' x_0}{\zeta'} = \frac{k^2}{R^2} \frac{\xi z_0 - \zeta x_0}{\zeta},$$

$$\frac{\eta' z_0 - \zeta' y_0}{\zeta'} = \frac{k^2}{R^2} \frac{\eta z_0 - \zeta y_0}{\zeta};$$

these are the formulae of inversion in the plane ϖ, in which (ξ, η, ζ) are the coordinates of a point, and (ξ', η', ζ') those of the inverse point, the circle, $[\lambda]$, of inversion having the equation

$$(xz_0 - x_0 z)^2 + (yz_0 - y_0 z)^2 - k^2 z^2 z_0^2 = 0.$$

Ex. 2. We can (Vol. II, p. 69, Ex. 4) state a relation between the centres of two circles of the plane ϖ which are inverses of one another in regard to the circle $[\lambda]$. But the relation in the space of three dimensions is simpler, these centres being the projections, from U, of the poles of two plane sections of Ω which lie on a quadric cone of vertex L.

Ex. 3. Two plane sections of a quadric, having two points in common, lie on two quadric cones (Vol. III, p. 10). Projecting these sections upon a plane from any point of the quadric, and at the same time the section by the polar plane of the vertex of one of the containing cones, we see that, if two circles be given in a plane, there are two circles of inversion by means of which one of the given circles is changed into the other.

Ex. 4. The *circle of similitude* of two given circles $[\alpha]$, $[\beta]$, of the plane ϖ (Vol. II, p. 132), may be considered from the present point of view. With a pair of plane sections, α, β, of Ω, intersecting in a line l, and the pair of tangent planes of Ω through the line l, an axial pencil of pairs of planes in involution, can be defined. Thereby, to the plane lU, joining l to the point U of Ω, there is defined a section, γ, passing through l, the two planes, lU, γ, being a pair of the involution. Prove that, if the quadric be projected from U, on to a plane ϖ, whereby the sections α, β become the circles $[\alpha]$, $[\beta]$, then the section γ becomes the circle, coaxial with $[\alpha]$ and $[\beta]$, passing through the centres of similitude of these, that is, the circle of similitude. The centres of similitude are the two intersections of common tangents of $[\alpha]$, $[\beta]$ which lie on the line joining the centres of these circles. The circles are supposed unequal.

Ex. 5. If we have four circles in a plane meeting, in threes, in four points, there are six circles of similitude, one for each pair. It can be shewn that these meet in a point. This follows easily if we assume (see below, Ex. 6) that, if A, B, C, D, U be points of a quadric, Ω, then the quadric, Σ, described to touch the planes BCD, CAD, ABD, ABC and to contain the generators of Ω at U, contains two other generators of Ω, say those at U'. For then, regarding Ω and Σ as defined by their tangent planes, and considering the degenerate tangential quadric which consists of all the planes through the points U and U', we have three quadrics such that all the tangent planes common to any two of them are equally tangent planes of the third, these consisting of all the planes through the generators of Ω (and Σ) at U and U'. The three pairs of tangent planes of these three quadrics which pass through any line are, therefore, three pairs of an axial involution. In particular, taking AB for the line, the pair of planes ABU, ABU' belong to the involution determined by two pairs, namely the pair ABC, ABD, and the pair which consists of the tangent planes to Ω drawn from AB. From this it follows that the sections of Ω by the planes ABC, ABD project from U, on to any plane, into two circles whose circle of similitude passes through the projection of U'. Thus, by a similar argument, the sections of Ω by the four planes BCD, ..., ABC

become, projected from U, four circles whose six circles of similitude all pass through the projection of U'.

Ex. 6. To prove that the quadric, Σ, containing the generators of a quadric Ω at a point U of this, and also touching four planes, α, β, γ, δ, whose four points of intersection lie on Ω, also contains two other generators of Ω, say at U', we use the fact that a quadric which touches the tangent planes of Ω drawn from one point, P, also touches the tangent planes of Ω drawn from another point, P'. If we denote the tangential equation of Ω, referred to the planes α, β, γ, δ, by $\Omega = 0$, and (ξ, η, ζ, τ), $(\xi', \eta', \zeta', \tau')$ be the coordinates of P, P', the equation of the quadric in question is then $\Omega - kPP' = 0$, where $P = l\xi + m\eta + n\zeta + p\tau$, $P' = l\xi' + \ldots + p\tau'$. If this quadric touch the planes α, β, γ, δ, its equation must contain no terms in l^2, m^2, n^2, p^2. Thus, if the coefficients of these terms in Ω be A, B, C, D, the quadric touching α, β, γ, δ and also the tangent cone of Ω drawn from the point (ξ, η, ζ, τ), touches also the tangent cone of Ω drawn from $(A\xi^{-1}, B\eta^{-1}, C\zeta^{-1}, D\tau^{-1})$. Now, in particular, let (ξ, η, ζ, τ) be on Ω; then we know, or it is easily verified, that, as Ω contains the four intersections of the planes α, β, γ, δ, the point $(A\xi^{-1}, \ldots, D\tau^{-1})$ is likewise on Ω (Vol. III, p. 55). Thence, the quadric in question, containing the tangent planes of Ω from a point of itself, contains the generators of Ω at this point; and it is proved that it then contains the generators at another point.

Ex. 7. At the point (ξ, η, ζ, τ) of the quadric

$$fyz + \ldots + uxt + \ldots = 0,$$

let the equation of the tangent plane be written

$$\lambda x + \mu y + \nu z + \varpi t = 0.$$

Using A, B, C, D, respectively, for fvw, gwu, huv, fgh, prove that the polar reciprocal of the quadric, in regard to the quadric

$$A^{-1}\xi\lambda x^2 + B^{-1}\eta\mu y^2 + C^{-1}\zeta\nu z^2 + D^{-1}\tau\varpi t^2 = 0,$$

is a quadric containing the generating lines of the original both at (ξ, η, ζ, τ) and at $(A\xi^{-1}, B\eta^{-1}, C\zeta^{-1}, D\tau^{-1})$.

Ex. 8. Prove that the quadrics $xy + hzt = 0$, $xy + kzt = 0$ are polar reciprocals of one another in regard to any quadric whose equation is of the form $ax^2 + by^2 + hkz^2 + abt^2 = 0$, and that tetrads of points of the first quadric exist which are self-polar in regard to the last, two points of the tetrad, which are conjugate in regard to the last quadric, being arbitrary. Prove, also, that the four points of such a tetrad, taken with the points to which the coordinates are referred, are eight associated points; and that the cubic curve containing the points of the tetrad and two of the reference points whose join is a generator, lies on the first quadric. Hence, also, if AC, AD be two intersecting generators of a quadric, and P, Q, R be any three points of the quadric, the cubic curves on the quadric defined, respectively, by P, Q, R, A, C and by P, Q, R, A, D, have, as their fifth intersection, a point S, such that another quadric can be constructed, touching the four planes QRS, ..., PQR, to contain the generators of the original quadric at C and at D (cf. Vol. III, p. 55).

Ex. 9. If we employ the *cross-ratio* of four lines (cf. Vol. II, p. 166), it is a fundamental property that, if A, B, C, D be four fixed points of a conic, the lines joining these to any point of the conic have an invariable cross-ratio, say $(A, B; C, D)$. It can be shewn that if two circles meet in points A, B, beside the Absolute points I, J, the circle of similitude of these circles has, for its value of $(A, B; I, J)$, the product of the values belonging to this on the two circles. From this it can be shewn at once that, if the circles defined by the triads of coplanar points (B, C, D), (C, A, D), (A, B, D), (A, B, C) be denoted, respectively, by S_1, S_2, S_3, S, then the circles of similitude of the pairs (S, S_1), (S, S_2), (S, S_3), supposed undegenerate, meet in a point. And the theorem of Ex. 5 is deducible.

It can be shewn that the two tangents drawn to one circle of a pair from any point of their circle of similitude are at the same angle as the tangents from this point to the other circle. Hence, from what is proved above, there is a point at which the four circles, drawn through the triads of four points of a plane, subtend equal angles. This result was given by Dr G. T. Bennett.

If V be the vertex of one of the two quadric cones which contain the sections of a quadric by two planes α, β, whose line of intersection is l, and the line joining V to a point, U, of the quadric, meet the quadric again in U_1, the plane lU_1 meets the quadric in a section projecting into the circle of similitude of the two circles into which the sections α, β project, the centre of projection being U.

If W be the vertex of the other quadric cone containing the sections α, β, the planes lU, lU_1 are harmonic conjugates in regard to the planes lV, lW.

If a conic meet the joins BC, CA, AB, of three points A, B, C, respectively in P, P'; Q, Q'; R, R': if QR, $Q'R'$ meet in X; RP, $R'P'$ meet in Y, and PQ, $P'Q'$ meet in Z: if H be any point of the conic, and the lines HX, HY, HZ, meet the conic again in X_1, Y_1, Z_1, respectively: then the lines AX_1, BY_1, CZ_1 meet in a point. We can deduce from this that the three circles of similitude of the three pairs of three arbitrary circles, in a plane, are coaxial.

Ex. 10. For any quadric, given in point coordinates $ax^2+\ldots=0$, let (ξ, η, ζ, τ), $(\xi', \eta', \zeta', \tau')$ be two points of the quadric, let $\phi=a\xi\xi'+\ldots$ be the polar form, linear and symmetrical in (ξ, η, ζ, τ) and $(\xi', \eta', \zeta', \tau')$, let Δ be the discriminantal determinant, and $\sigma=\phi/2\Delta$. If the tangent planes at (ξ, η, ζ, τ), $(\xi', \eta', \zeta', \tau')$ meet in a line which cuts the quadric in (x, y, z, t) and (x', y', z', t'), prove that $(xx'/A)^{-1}(\sigma-\xi\xi'/A)=(yy'/B)^{-1}(\sigma-\eta\eta'/B)=$ etc., where A, B, ... are the minors of the diagonal elements of Δ.

Ex. 11. Given a quadric, Ω, and five planes, α, β, γ, δ, ϵ, let a quadric be drawn through the four intersections of α, β, γ, δ to contain the section $\Omega\epsilon$; this quadric will have with Ω another plane section, say ϵ_1. Similarly a quadric can be drawn through the four intersections of α, β, γ, ϵ to contain the section $\Omega\delta$; this quadric will have with Ω another plane section, say δ_1. Shew that the sections δ_1, ϵ_1 lie on a quadric cone whose vertex is the intersection of the planes α, β, γ.

Projecting on to a plane, we have five given circles, (α), (β), (γ), (δ), (ϵ), and five other circles, (α_1), ..., (ϵ_1), such that (δ_1) and (ϵ_1) are inverses of one another in regard to the circle which cuts all of (α), (β), (γ) at right angles; and so on. There are ten pairs such as (δ_1), (ϵ_1), and each circle such as (ϵ_1) is the inverse of all the other four with appropriate circles of inversion.

Relation between Wallace's theorem for four circles, and Moebius's figure of two inscribed tetrads. We have given (Vol. II, p. 71) the theorem that, if four arbitrary lines be given in a plane, the four circles, each defined by the intersections of three of the lines, meet in a point. This result is ascribed to Wallace (1806; see *Camb. Phil. Proc.*, XXI, 1923, p. 348). We have also (Vol. I, p. 61) given the theorem, due to Moebius (1828; see *Ges. Werke*, I, 1885, p. 443), that it is possible for two tetrads of points in three dimensions to be so situated that every point of either tetrad lies on the plane determined by three points of the other tetrad. We give here some interesting results of which one incidental consequence is the essential identity of the figures arising in these two theorems. The order in which these results are given is chosen, however, with a further aim.

Let P_1, P_2, P_3, P_4 be any four points in a plane; through each of the six joins of these four points let an arbitrary plane be drawn, the plane through the join of P_i and P_j being denoted by α_{ij}. Every three of these planes, by their intersection, determine a point. Let the point of intersection of the planes, α_{23}, α_{31}, α_{12}, drawn through the joins of the three points P_1, P_2, P_3, be denoted by P_4'. There arise four such points, P_1', P_2', P_3', P_4'. We prove that these lie in a plane. This is, in fact, only a restatement of Moebius's theorem, as may be seen by comparison with p. 61 of Vol. I, where a diagram is given: denote the points P_1, P_2, P_3, P_4, respectively, by A, B, C and D'; let the point of intersection of the arbitrary planes drawn through BC, CA, AB be denoted by D, the point of intersection of the planes drawn through BC, BD', CD' be denoted by A', and similarly for B' and C'; consider then the line of intersection of the planes ABC, $A'B'C'$, denoting the points where this line is met, respectively, by BC, AD', CA, BD', AB, CD', by P, P', Q, Q', R, R'; then, the points B', C' are both on the plane which was drawn through AD', so that $B'C'$ meets AD', and, hence, $B'C'$ passes through P'; in the same way, $C'A'$ passes through Q', and $A'B'$ passes through R'; as P, P'; Q, Q'; R, R' are the points of intersection of a line with the pairs of opposite joins of the four points A, B, C, D', these three pairs of points are in involution; whence it follows (Pappus' theorem being assumed) that the three lines PA', QB', RC' meet in a point, say D_1; the point D, of the theorem, lies on the plane BCA', for both A' and D are on the same arbitrary plane drawn through the line BC; thus we infer that D_1 is the same as D; this, however, shews that the four points A', B', C', D are in one plane; this is what was to be proved.

The dual of the preceding theorem is as follows: From the point O, let there be drawn, in space of three dimensions, four arbitrary planes, α_1, α_2, α_3, α_4; upon the line of intersection of any two of these planes, say of α_1 and α_2, let there be taken an arbitrary point, which, for the case of these two planes, may be denoted by P_{12}. The three points so taken upon the lines of intersection of any three of the original planes determine a new plane; for example, the points P_{23}, P_{31}, P_{12} determine a plane which we may denote by α_{123}. There are four such planes; the theorem is that these meet in a point, say O'. The figure contains eight points, $O, P_{23}, \ldots, P_{34}, O'$, and eight planes, $\alpha_1, \ldots, \alpha_4, \alpha_{234}, \ldots, \alpha_{123}$; of these, four planes pass through every point, and four points lie in every plane. Moreover, the points are a system of *associated* points (Vol. III, p. 154), being the intersections of three linearly independent quadrics; for instance, the plane α_1 contains O, P_{12}, P_{13}, P_{14}, and the plane α_{234} contains P_{23}, P_{34}, P_{42}, O'; thus the plane-pair (α_1, α_{234}) is such a quadric, and two others, independent of this, are formed by the plane-pairs (α_2, α_{314}), (α_3, α_{124}). The dual theorem, that the eight planes of two Moebius tetrads touch three independent quadric envelopes, is also easily verified. (Cf. Vol. III, p. 138, Ex. 14.)

Now suppose that we have four lines in a plane, and also two points, I, J, in this plane. We may consider the four conics, all passing through I and J, each determined as also passing through the three intersections of three of the lines. The Wallace theorem is that these four conics have another common point. Take an arbitrary point, O, outside the plane, and describe a non-degenerate quadric containing O and the two lines OI, OJ. Consider the four planes joining O to the four lines of the plane; say, these are α_1, α_2, α_3, α_4; let the line of intersection of α_1 and α_2 meet the quadric, beside O, in the point P_{12}; and so on; the plane, α_{123}, containing the points P_{23}, P_{31}, P_{12}, will meet the quadric in a conic which projects from O, on to the plane, into one of the four conics of the Wallace theorem. The point, O', in which the four planes such as α_{123} intersect, will lie on this quadric, by the property of eight associated points. The Wallace theorem thus follows.

The theorem that the four planes $\alpha_{234}, \ldots, \alpha_{123}$ meet in a point, O', is capable of a suggestive analytical proof, as follows: Denote the equations of the four planes $\alpha_1, \ldots, \alpha_4$, drawn through O, respectively by $x_1 = 0$, $x_2 = 0$, $x_3 = 0$, $x_4 = 0$; these will be connected by a linear identity, say, $ax_1 + bx_2 + cx_3 + dx_4 = 0$. Let $t = 0$ be the equation of any chosen plane not passing through O. The equation of any one of the four planes $\alpha_{234}, \ldots, \alpha_{123}$ may be expressed in terms of t and any three of x_1, x_2, x_3, x_4. We may then suppose the equations of these four planes to be, respectively,

$$k_{12}x_2 + k_{13}x_3 + k_{14}x_4 - at = 0,$$

$$\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots$$

$$k_{41}x_1 + k_{42}x_2 + k_{43}x_3 - dt = 0,$$

where x_1 does not appear in the first equation, ..., and x_4 does not appear in the last. Then the point P_{23}, for example, lying on $x_2 = 0$, $x_3 = 0$, lies on α_{234} and on α_{123}; thus it satisfies both the equations $k_{14}x_4 - at = 0$, $k_{41}x_1 - dt = 0$, as well as the identity $ax_1 + dx_4 = 0$. Thence we infer that $k_{14} + k_{41} = 0$. In general, then, in the same way, we have $k_{rs} + k_{sr} = 0$, and, with these identities, the four planes are adequately given by the equations. The condition that these four planes meet in a point is then given, if we add to the four equations the identity $ax_1 + \ldots + dx_4 = 0$, by the vanishing of a determinant of five rows and columns, in which the elements of the first row are $0, k_{12}, k_{13}, k_{14}, -a$, and so on, and the elements of the fifth row are $a, b, c, d, 0$. As this determinant is skew symmetrical, and of odd order, it vanishes identically. See, below, p. 61; and, for another proof of Wallace's theorem, see p. 64.

Ex. 1. Moebius's theorem, above identified with a figure from which Wallace's theorem follows, can be stated thus (cf. Vol. I, p. 61): If a line meet the joins of three points, A', B', C', respectively, in P', Q', R', and the joins of these to three other points, A, B, C, namely the lines $P'A$, $Q'B$, $R'C$, meet in a point, D', then the intersections of the line with the joins of A, B, C, say the points P, Q, R, when joined to A', B', C', will give three lines PA', QB', RC', which also meet in a point, D.

The dual result is that if the joins of a point, O, to three points A', B', C', meet the joins BC, CA, AB, of three points A, B, C, in three points which are in line, then the joins of O to A, B, C meet $B'C'$, $C'A'$, $A'B'$, respectively, in three points also in line. It may easily be found that O lies on a certain cubic curve, whose equation thus appears as capable of two forms.

Ex. 2. We may similarly, in three dimensions, consider the locus of a point whose joins to four given points meet four given planes in points lying on a plane. This locus is a quartic surface, considered by Bauer (*Sitzber. bayer. Ak.*, München, XVIII, 1888, p. 337). When the four given planes determine a tetrad of points in perspective with the four given points, the locus is the Hessian of a cubic surface. (Cf. Vol. III, p. 223.) In general, the reciprocity which holds for the case of Ex. 1 does not hold in three dimensions. If the four given points are in one plane, and are the poles of the four given planes in regard to a conic in this plane, then, with this conic as Absolute conic, the locus is that of a point such that the perpendiculars from it to the given planes have their feet on a plane; this locus is a cubic surface with four double points. (see below, p. 25).

Ex. 3. The reader may compare the result of Ex. 1 with the theorem given by Steiner (*Ges. Werke*, I, p. 157): If the perpendiculars drawn from three points, A', B', C', to the joins, BC, CA, AB, of three other points, meet in a point, so do the perpendiculars drawn from A, B, C to the joins $B'C'$, $C'A'$, $A'B'$, of the first three points. This will be found to be true in the more general form: Given two triads of points, A', B', C', and A, B, C, and also an arbitrary conic; if A', B', C' be in perspective with the triad formed by the poles of BC, CA, AB, taken in regard to this conic, then A, B, C are in perspective with the poles of $B'C'$, $C'A'$, $A'B'$. And generalisation is possible to two tetrads of points in three dimensions.

Additions to Wallace's theorem in a plane. Wallace's theorem has additions (Vol. II, p. 72), ascribed to Steiner (1828, cf. *Ges. Werke*, I, p. 197), to the effect that the feet of the perpendiculars, drawn from the Wallace point to the four lines, lie in line, and that the centres of the four circles which meet in the Wallace point, lie on a circle containing the Wallace point. We proceed now to obtain these results by projection from the figure in three dimensions. Let O, A, B, C be four points of a quadric; let P be any point of the section of the quadric by the plane ABC; and let I, J be the points in which the generators of the quadric at O meet the generators at P. Thus the planes OPI, OPJ are the tangent planes of the quadric drawn from the line OP, and OP is the polar line of IJ. Next, let U, V, W be the poles, lying in the tangent plane at O, respectively of the planes OBC, OCA, OAB. We can prove that the six points O, I, J, U, V, W are on a conic. For, if OI, OJ meet the section of the quadric by the plane ABC in I', J', the fact that this section contains the six points P, I', J', A, B, C involves (Vol. II, p. 29) that the planes joining O to the six lines $I'J'$, PI', PJ', BC, CA, AB touch a quadric cone; and the poles of these planes, respectively, are the points O, I, J, U, V, W. Conversely, if conics be taken, in the tangent plane at O, through the four points O, U, V, W, and one of these meet the generators at O in the points I, J, the second tangent plane of the quadric, drawn from the line IJ, touches the quadric in a point, P, of the section by the plane ABC. When we project the figure on to a plane, from the point P, the three sections OBC, OCA, OAB become circles, the projections of I, J being the Absolute points, their centres being the projections of U, V, W; and we have the result that, if three circles in a plane have a common point, their three other intersections being in line, then their centres determine a circle passing through their common point. When we project the figure from the point O, the section of the quadric by the plane OUP becomes a line, through the projection of P, which is at right angles to the line into which the conjugate section OBC projects, the Absolute points being again the projections of I and J. Let H be the point in which the sections OBC, OUP meet, other than O; also let O' be the point which, on the conic $OIJUVW$, is the harmonic of O in regard to I and J; it can be shewn that the line OH lies on the polar plane of O'. To prove this it is sufficient to shew that the polar line of OH, which lies in the tangent plane at O, and contains the pole, U, of the plane OBC, passes through O'. For this, consider the pole of the plane OUP. This pole is the intersection of the polar planes of O, U, P; that is, it lies in the tangent plane at O, in the plane OBC, and in the tangent plane at P; it is thus the intersection of the tangent line, at O, of the section OBC, with the line IJ; the tangent line, at O, of the section OBC, is however harmonic to OU in regard to OI, OJ. Thus the pole of the plane OUP is the point, of IJ, where this is met by the line, from U, which is harmonic to UO in regard to UI and UJ. This line contains O'; as it contains U, it is the polar line of OH. Now the point O' is determined by O, I, J and the conic $OIJUVW$ alone. Thus, as we have proved that the polar plane of O' contains the line (OBC, OUP), it follows that this plane also contains the lines (OCA, OVP) and (OAB, OWP); in other words the points, other than O, in which the sections OBC, OCA, OAB are respectively met by the planes OPU, OPV, OPW, lie in a plane through O. Wherefore, projecting from O, on to a plane, we have the result that if the perpendiculars be drawn to the joins of three points (the projections of A, B, C), from any point (the projection of P) on the circle containing these points, then the feet of these perpendiculars are on a line (Vol. II, p. 71). From this result, and the result obtained in regard to the centres of three circles which meet in a point, the additions to Wallace's theorem are obtained at once.

Ex. 1. If, with any two points, I, J, as Absolute points, the perpendiculars be drawn to the joins of three points, A, B, C, of a plane, from any point, P, the feet of these determine in general a circle, the pedal circle of P (Vol. II, p. 87). We have proved (Vol. II, p. 88) that, if P move on a line passing through the centre of the circle which contains A, B, C, the pedal circles have a common point (Bobillier, *Gergonne's Ann.*, XIX, 1828, p. 356; Fontené, *Nouv. Ann.*

de Math., v, 1905, p. 504; vi, 1906, p. 55). This point will then be the intersection of the pedal lines of the two points of intersection of the circle A, B, C with the line on which P moves. It can be shewn that these pedal lines are at right angles, and that their point of intersection is on the nine points circle of A, B, C. More generally, if P move on an arbitrary fixed line, there is a circle to which all the pedal circles are at right angles; this remark the writer owes to Mr J. H. Grace. It will now be shewn further that this remains true when P moves on a certain cubic curve, which in particular may degenerate into the aggregate of a line and a conic.

Let O, A, B, C be fixed points of a quadric, the poles of the planes OBC, OCA, OAB, lying in the tangent plane at O, being denoted by U, V, W. Let P be any other point of the quadric. Let the plane OPU meet the section OBC in H, beside O; similarly let OK, OL, where K, L are on the quadric, be the lines (OPV, OCA) and (OPW, OAB). When we project from O, on to a plane, and take for Absolute points, I, J, the points of the plane lying on the generators of the quadric at O, the pedal circle, in regard to the projections of A, B, C, of the point which is the projection of P, is the circle obtained as the projection of the section HKL of the quadric. To prove that the pedal circles, for certain positions of P, cut a fixed circle at right angles, we prove that the corresponding planes HKL pass through a fixed point of space; when this point is on the quadric the pedal circles meet in a point.

We can suppose the equation of the quadric, referred to O,A,B,C, to be

$$fyz + gzx + hxy + t(x + y + z) = 0,$$

where $t = 0$ is the plane ABC, and $x = 0$ the plane OBC, etc. The point U then has coordinates $(-f, w, v, fu)$, where $2u = g + h - f$, $2v = h + f - g$, $2w = f + g - h$. If the point P, on the quadric, be (ξ, η, ζ, τ), the point H, where the line (OBC, OUP) meets the quadric, beside O, is then found to be

$$\{0,\ w\xi + f\eta,\ v\xi + f\zeta,\ -(w\xi + f\eta)(v\xi + f\zeta)(\xi + \eta + \zeta)^{-1}\},$$

with similar coordinates for K and L; from these the plane HKL is found, expressed without τ, to be

$$x\xi X + y\eta Y + z\zeta Z + t(\xi + \eta + \zeta)(f\eta\zeta + g\zeta\xi + h\xi\eta) = 0,$$

where

$$X = (u\eta + g\zeta)(u\zeta + h\eta),\quad Y = (v\zeta + h\xi)(v\xi + f\zeta),$$
$$Z = (w\xi + f\eta)(w\eta + g\xi).$$

It will be shewn that when P moves on a section of the quadric by a fixed plane containing O and the pole of the plane ABC, the plane HKL passes through a definite point of the quadric; this leads to the theorem above referred to, given in Vol. ii, p. 88. More generally, regarding x, y, z, t, in the above equation of the plane HKL, as fixed, and regarding (ξ, η, ζ) as variable, these being taken as proportional to the coordinates of the projection of P, the equation will represent a locus for P such that the corresponding pedal circles cut a fixed circle at right angles; the Absolute points are given by

$$f\eta\zeta + g\zeta\xi + h\xi\eta = 0, \quad \xi + \eta + \zeta = 0.$$

It can be shewn, in particular, that if l, m, n be arbitrary, and x, y, z, t be given, with $q = vw + wu + uv$, by $ux = mn - t$, $vy = nl - t$, $wz = lm - t$ and

$$u^{-1}v^{-1}w^{-1}q^2t = q\,(mnu^{-1} + nlv^{-1} + lmw^{-1}) \\ - u\,(m-n)^2 - v\,(n-l)^2 - w\,(l-m)^2,$$

then the cubic relation connecting ξ, η, ζ is satisfied either by $l\xi + m\eta + n\zeta = 0$ or by $lf\xi^{-1} + mg\eta^{-1} + nh\zeta^{-1} = 0$. More particularly, if l, m, n be such that $lfu + mgv + nhw = 0$, the values for x, y, z, t, namely, $u^{-1}l\,(m+n)$, $v^{-1}m\,(n+l)$, $w^{-1}n\,(l+m)$, and $-(mn+nl+lm)$, correspond to a point lying on the quadric, and the equation $l\xi + m\eta + n\zeta = 0$ corresponds to a line through the centre of the circle ABC; we then have the result of Vol. II, p. 88.

Ex. 2. If four planes, $\alpha, \beta, \gamma, \delta$, be drawn through a point, O, of a quadric, the lines of intersection (β, γ), (γ, α), (α, β), (α, δ), (β, δ), (γ, δ) meeting the quadric again, respectively, in A, B, C, A', B', C', we have proved that the planes ABC, $AB'C'$, $BC'A'$, $CA'B'$ meet in a point, O', and inferred that O' is on the quadric by remarking that O, A, B, C, A', B', C', O' are a set of associated points. This follows from what is said above, p. 21; for let the poles of $\alpha, \beta, \gamma, \delta$ be, respectively, U, V, W, T; let the conic through O, U, V, W, T meet the generators at O again in I and J. Then the second tangent plane to the quadric from IJ has its point of contact on every one of the planes ABC, $AB'C'$, $BC'A'$, $CA'B'$.

Ex. 3. We may consider the generalisation to three dimensions of the pedal properties above given for a plane. A particular result, leading to a cubic surface with four double points, has been mentioned in Vol. III, p. 223. Defining the perpendicular from a point to a plane by means of an Absolute conic, ω, namely as the line, from this point, to the pole of the plane in regard to this conic, ω, the condition that the feet of the perpendiculars, drawn from a point E, to the planes containing four points A, B, C, D, should lie in a plane, is the same as that the quadric which touches these planes, and has the cone $E\omega$ as enveloping cone, should touch the plane of ω. To prove this, consider first, instead of the conic ω, a quadric, Ω, the perpendicular from E to a plane being the join of E to the pole of this plane in regard to Ω. Let the poles of the planes BCD, ..., ABC be denoted, respectively, by

A', ..., D', and let the lines EA', ..., ED' meet these planes, respectively, on a plane ϖ, whose pole is P. Let the polar plane of E be ϵ, and denote the planes BCD, ..., ABC by α, ..., δ, respectively. The line EA' then intersects the line (ϖ, α), which is the polar line, in regard to Ω, of the line PA'; in other words, the lines EA', PA' are conjugate. So, likewise, are the pairs (EB', PB'), (EC', PC'), (ED', PD'). The locus of a point whose joins to E and P are conjugate lines in regard to the quadric Ω is, however, that quadric, through the plane sections of Ω by the polar planes ϵ, ϖ, which contains both E and P, as is easy to see. This description of the quadric locus is, however, redundant, since any quadric, through the section of Ω by the polar plane ϵ, which contains also the pole E, will meet Ω in another conic and contain the pole of the plane of this. Thus the condition for E, in relation to A, B, C, D, is that the quadric, which contains A', B', C', D', and also the conic in which Ω is met by the polar plane, ϵ, of E, should also contain E. Or, the condition may be stated in dual form, recalling that the planes ϵ, ϖ meet each of α, β, γ, δ in a pair of lines which are conjugate in regard to Ω, and reciprocating in regard to Ω, by saying that the quadric which touches α, β, γ, δ, and has, for enveloping cone, that drawn from E to Ω, should touch the polar plane, ϵ, of E. When Ω consists of the planes containing the tangent lines of a conic, ω, the polar plane of E becomes the plane of ω, and the condition is as stated above; namely, the quadric touching α, β, γ, δ and the tangent planes of the cone $E\omega$, touches the plane of ω. This quadric has then, also, as generating lines, the two tangent lines of ω which pass through the point of contact of the quadric with this plane.

Ex. 4. If the perpendiculars, in regard to an Absolute conic ω, drawn from a point E to the four planes containing points A, B, C, D, meet these planes in points which lie on a plane, then each of the five points A, B, C, D, E is in the same relation to the other four. For let σ be the conic, in the plane of ω, in regard to which the joining lines and planes of the points A, B, C, D, E determine a polar system. Then, as we have seen (above, p. 11), the enveloping cone from E to any quadric touching the four planes BCD, ..., ABC, and touching also the plane of ω, meets this plane in a cone which is inpolar to σ. Thus, from Ex. 3 preceding, when the perpendiculars, in regard to ω, drawn from E to the four planes BCD, ..., ABC, meet these in points of a plane, the conic ω is inpolar to σ, and conversely. As ω is given, and σ is symmetrical in regard to A, B, C, D, E, the property in question is likewise symmetrical.

Ex. 5. The theorem of the symmetry of the points A, B, C, D, E in Ex. 4 is due to W. Mantel, *Wiskundige Apgaven*, 1899–1902, p. 396, No. 199. See H. W. Richmond, *Camb. Phil. Proc.*, Vol. XXII, Part I, 1924. In this paper Mr Richmond proves, for the rational curve of order n in space of n dimensions, in extension of the Wallace theorem for a circle in a plane, a result which, for the cubic curve in three dimensions, may be stated: The necessary and sufficient condition that a cubic curve should be such that, in regard to an Absolute conic ω, the perpendiculars from any point of the curve to the four planes containing any other four points of the curve, should have their feet on a plane, is that the conic ω should touch the three chords of the curve which lie in its plane. Let the three points of the curve which lie in this plane be P, Q, R; let σ be the conic, of the plane PQR, in regard to which the joining points and planes of five points, A, B, C, D, E, of the curve, form a self-polar system. We have shewn above (p. 12) that the only condition for σ is that P, Q, R should form a self-polar triad in regard thereto; also (Ex. 4, preceding) that the condition for A, B, C, D, E is that ω should be inpolar to σ. A conic, ω, inpolar to all conics, σ, for which P, Q, R form a self-polar triad, is given by any conic which touches PQ, QR, RP; and, conversely, only by such a conic. This proves the result.

Ex. 6. Prove that, if Ω be any quadric, the necessary and sufficient condition that the lines joining a point E to the poles, A', B', C', D', respectively, of the planes BCD, CAD, ABD, ABC, in regard to Ω, should meet these planes, respectively, in points lying on a plane, is that the lines $D'E$, $D'E_1$ should be conjugate in regard to Ω, where E_1 is the definite point such that the enveloping cones from E and E_1 to Ω are also enveloping cones of a quadric touching the four planes BCD, ..., ABC. It can be shewn (cf. Ex. 11 above) that, if D_1 be defined from D, and the four planes containing A, B, C, E, just as E_1 is here defined, then the line D_1E_1 contains D'. Hence the condition for E in regard to A, B, C, D, is that the line $D_1D'E_1$ should intersect the polar line of $D'E$. The condition that the lines joining D to the poles of the planes BCE, CAE, ABE, ABC, in regard to Ω, should meet these planes in points of a plane, is that the line $D_1D'E_1$ should intersect the polar line of $D'D$. One condition does not involve the other, in general; this will be so, however, when the points D', D, E are in line. It will also be so when Ω reduces to a conic.

Ex. 7. The results may be obtained analytically. As before, let A, B, C, D, E be any five points, and E_1 be determined from E by the condition that the quadric which touches the planes BCD, ..., ABC, and the tangent cone from E to the given quadric Ω, has E_1 as the vertex of the further common enveloping cone of the two quadrics, while D_1 is determined from D and Ω similarly, by a quadric touching the four planes joining A, B, C, E and the enveloping cone to Ω drawn from D; let coordinates be taken with respect to A, B, C and a further arbitrary point; and the tangential equation of Ω be $(A,B,C,D,F,G,H,U,V,W \between l,m,n,p)^2=0$. Then prove that the line D_1E_1 contains the pole, D', of the plane ABC, and meets the plane ABC in the point whose coordinates are

$$\frac{A\tau\tau' - U(\xi\tau' + \xi'\tau) + D\xi\xi'}{\xi\tau' - \xi'\tau}, \quad \frac{B\tau\tau' - V(\eta\tau' + \eta'\tau) + D\eta\eta'}{\eta\tau' - \eta'\tau},$$
$$\frac{C\tau\tau' - W(\zeta\tau' + \zeta'\tau) + D\zeta\zeta'}{\zeta\tau' - \zeta'\tau}, \quad 0,$$

where (ξ, η, ζ, τ), $(\xi', \eta', \zeta', \tau')$ are the coordinates of D and E, respectively. In order that the perpendiculars from E, in regard to Ω, drawn to the planes BCD, ..., ABC, should meet these in the points of a plane, we have to express that the lines $D'E$, $D'E_1$ should be conjugate in regard to Ω; that is that the polar plane of E should contain the point in which $D'E_1$ meets the plane ABC. If the point equation of Ω be $(a, b, c, d, f, g, h, u, v, w \between x, y, z, t)^2=0$, this condition is that E should lie on the quartic surface whose equation, with x, y, z, t as current coordinates, is

$$\frac{A\tau t - U(\xi t + \tau x) + D\xi x}{\xi t - \tau x}(ax + hy + gz + ut) + \ldots$$
$$+ \frac{C\tau t - W(\zeta t + \tau z) + D\zeta z}{\zeta t - \tau z}(gx + \ldots + wt) = 0.$$

When coordinates are referred to A, B, C, D, so that $\xi = 0$, $\eta = 0$, $\zeta = 0$, this equation is

$$\frac{At - Ux}{x}(ax + hy + gz + ut) + \ldots + \frac{Ct - Wz}{z}(gx + \ldots + wt) = 0,$$

or

$$\frac{A(ax+hy+gz+ut)}{x} + \ldots + \frac{C(gx+\ldots+wt)}{z} + \frac{D(ux+\ldots+dt)}{t} - \Delta = 0,$$

where Δ is the discriminantal determinant of the point equation of Ω.

If Ω be a conic, lying in the plane $\lambda x + \mu y + \nu z + \varpi t = 0$, so that there are four equations such as $A\lambda + H\mu + G\nu + U\varpi = 0$, the point equation of Ω is $(\lambda x + \ldots + \varpi t)^2 = 0$. The equation then divides by $\lambda x + \ldots + \varpi t = 0$. The remaining cubic surface is given by

$$\lambda(\xi t - \tau x)^{-1}[A\tau t - U(\xi t + \tau x) + D\xi x] + \ldots + t = 0$$

or, referred to A, B, C, D, by

$$A\lambda x^{-1} + B\mu y^{-1} + C\nu z^{-1} + D\varpi t^{-1} = 0,$$

and is a cubic surface with four double points. The equation expresses that the point E_1, derived from E as in the preceding Example, is on the plane of the Absolute conic.

Ex. 8. In regard to the Absolute conic given by

$$\lambda x + \mu y + \nu z + \varpi t = 0, \quad Ax^2 + By^2 + Cz^2 + Dt^2 = 0,$$

the four points of reference for the coordinates are such that their opposite joins are at right angles; and they have an orthocentre, the intersection of the four perpendiculars from the points to the opposite planes, which is $(\lambda A^{-1}, \mu B^{-1}, \nu C^{-1}, \varpi D^{-1})$.

Ex. 9. The quadrics touching $x=0$, $y=0$, $z=0$, $t=0$ in regard to which the point (ξ, η, ζ, τ) is the pole of the plane $\lambda x + \mu y + \nu z + \varpi t = 0$, give, in this plane, ∞^2 conics. The quadrics of the form $Ax^2 + By^2 + Cz^2 + Dt^2 = 0$, which pass through (ξ, η, ζ, τ), give, in this plane, other ∞^2 conics. Prove that every conic of the latter system is outpolar to every conic of the former system.

Ex. 10. The surface $x^{-1} + y^{-1} + z^{-1} + t^{-1} = 0$ is the locus of a point from which the perpendiculars to $x=0$, $y=0$, $z=0$, $t=0$ have their feet on a plane, when a proper conic is taken as Absolute conic. Prove that, of such conics, there are ∞^2 in an arbitrary plane, $\lambda x + \mu y + \nu z + \varpi t = 0$, namely the intersections of this plane with quadrics touching $x=0$, $y=0$, $z=0$, $t=0$ which are such that the pole of this plane, in regard to the quadric, is

$$(\lambda^{-\frac{1}{2}}, \mu^{-\frac{1}{2}}, \nu^{-\frac{1}{2}}, \varpi^{-\frac{1}{2}}).$$

Ex. 11. It should be remarked in connexion with preceding theorems for a cubic curve, that, if three tetrads of points of the cubic be taken, say, A, B, C, D; A', B', C', D'; A'', B'', C'', D'', then the twelve planes, of which each contains three points of one tetrad, are all touched by a quadric. Further, taking any two other arbitrary points of the curve, the two tangent planes of the quadric, through the chord joining these two points, determine two further points of the curve, and hence a tetrad, of which the two other connecting planes also touch the quadric.

Let the planes $BCD, \ldots, ABC$ be denoted, respectively, by $\alpha, \beta, \gamma, \delta$, with a similar notation for the planes of the two other given tetrads, namely $\alpha', \beta', \gamma', \delta'$, and $\alpha'', \beta'', \gamma'', \delta''$. Since the quadrics touching the planes $\alpha, \beta, \gamma, \delta, \alpha', \beta', \gamma'$ likewise touch δ', these quadrics, expressed tangentially, are ∞^2, and such a quadric exists touching also the planes joining D to the chords $A''B''$, $A''C''$. The enveloping cone from D to this quadric then touches the five planes $\alpha, \beta, \gamma, DA''B'', DA''C''$. But the lines $DA, DB, DC, DA'', DB'', DC''$ lie on a quadric cone (of vertex D, containing the curve). Hence the quadric cone touching the five planes $\alpha, \beta, \gamma, DA''B'', DA''C''$ also touches the plane $DB''C''$. Wherefore, the quadric constructed, touching the planes $\alpha, \beta, \gamma, \delta, \alpha', \beta', \gamma', \delta'$ and $DA''B''$, $DA''C''$, equally touches the plane $DB''C''$. As touching $\alpha', \beta', \gamma', \delta'$ and $DB''C''$, $DC''A''$, $DA''B''$, this quadric also touches the eighth plane, $A''B''C''$, or δ'', these eight planes being associated, Vol. III, p. 139. Similarly it touches the planes α'', β'', γ''.

Now, let A_3 be any further point of the curve, and let the tangent planes of the quadric from DA_3 meet the curve again in B_3 and C_3. Then, as above, the quadric also touches the plane DB_3C_3, and thence, also, the plane $A_3B_3C_3$. If, then, D_3 be taken arbitrarily, on the curve, and the tangent planes be drawn from A_3D_3 to this quadric, determining, by their further intersections, the points B_3', C_3' of the curve, it follows, as before, that this quadric also touches $A_3B_3'C_3'$, and, thence, also the plane $D_3B_3'C_3'$. This establishes the statement made, the two arbitrary points taken being A_3 and D_3.

Ex. 12. If the coordinates of a point of the cubic curve be written $(\theta^3, \theta^2, \theta, 1)$, and the points A, B, C, D be given by $a_0\theta^4 + a_1\theta^3 + \ldots + a_4 = 0$, or say $f = 0$, the points A', B', C', D' being given by $\phi = 0$, where $\phi = b_0\theta^4 + b_1\theta^3 + \text{etc.}$, and the points A'', B'', C'', D'' by $\psi = 0$, where $\psi = c_0\theta^4 + c_1\theta^3 + \text{etc.} = 0$, shew that the planes of every tetrad of points of the cubic, given by an equation of the form $\xi f + \eta\phi + \zeta\psi = 0$, touch the quadric whose tangential equation is

$$\begin{vmatrix} a_0, & a_1, & a_2, & a_3, & a_4 \\ b_0, & b_1, & b_2, & b_3, & b_4 \\ c_0, & c_1, & c_2, & c_3, & c_4 \\ l, & m, & n, & p, & 0 \\ 0, & l, & m, & n, & p \end{vmatrix} = 0.$$

Theorems for the circumscribed circles when an indefinite number of lines is given in a plane. Recurring now to the theorem in which four arbitrary points were taken in a plane, and arbitrary planes were drawn through the joins of each two, we were able, with the use of Pappus' theorem, to shew that the four points, obtained as intersections of the planes through the joins of each triad of points, lie in a plane (above, p. 18). If we start with five arbitrary points, it can be shewn that the five planes, each obtained as above from four of these, all meet in a point; and for the proof of this the Propositions of Incidence only are sufficient. If we begin with six points, the six points so obtainable, one from each five of these, lie in a plane. And so on, indefinitely.

In a plane, α, let five points P_1, P_2, ..., P_5 be arbitrarily taken; and through the join of every two let an arbitrary plane be drawn, for instance the plane α_{12} through the join P_1P_2. The planes $\alpha_{23}, \alpha_{31}, \alpha_{12}$ determine a point, P_{123}, and so on. The four points P_{123}, P_{234}, P_{314}, P_{124} lie in a plane; this is what was proved above (p. 18). When we start with five points there arise five such planes. Denoting these by α_{1234}, ..., α_{2345}, we now prove that these five planes meet in a point.

In the plane α_{12} are five points, namely P_1, P_2, P_{123}, P_{124}, P_{125};

and the process followed gives another plane than α_{12} passing through the line joining any two of these points. Of these five points consider, at first, only the four P_1, P_{123}, P_{124}, P_{125}, and apply to these the process which was followed when we started with four points, P_1, P_2, P_3, P_4, lying in a plane α. Through the lines joining the respective six pairs, of the four points,

$$(P_{124}, P_{125}),\ (P_{125}, P_{123}),\ (P_{123}, P_{124}),\ (P_1, P_{123}),\ (P_1, P_{124}),\ (P_1, P_{125})$$

there pass, beside the plane α_{12}, the planes

$$\alpha_{1245},\quad \alpha_{1235},\quad \alpha_{1234},\quad \alpha_{13},\quad \alpha_{14},\quad \alpha_{15};$$

of these, however, the planes α_{1245}, α_{14}, α_{15} meet in P_{145}; the planes α_{1235}, α_{13}, α_{15} meet in P_{135}; and α_{1234}, α_{13}, α_{14} meet in P_{134}. Thus, the plane α_{1345}, which is the plane of the points P_{145}, P_{135}, P_{134}, contains the point of intersection of the planes α_{1245}, α_{1235}, α_{1234}. If we next consider the four points P_2, P_{123}, P_{124}, P_{125}, we similarly prove that the same point of intersection lies on the plane α_{2345}. That is, the five planes, $\alpha_{p,q,r,s}$, where p, q, r, s are every four of the numbers 1, 2, 3, 4, 5, meet in a point. This is what we desired to prove. The final point may be denoted by P_{12345}.

If we now begin with six points, $P_1, \ldots, P_6$, of the original plane, every five of these, by the same process, will give rise to a point. It can be shewn that the six points so obtained lie in a plane. The process gives rise, with others, to the four points P_{123}, P_{124}, P_{125}, P_{126}, all lying in the plane α_{12}. Beside this plane there pass, through the six joins of pairs of these points, namely

$$(P_{124}, P_{125}),\ (P_{125}, P_{123}),\ (P_{123}, P_{124}),\ (P_{123}, P_{126}),\ (P_{124}, P_{126}),\ (P_{125}, P_{126}),$$

respectively the planes

$$\alpha_{1245},\quad \alpha_{1235},\quad \alpha_{1234},\quad \alpha_{1236},\quad \alpha_{1246},\quad \alpha_{1256},$$

which, for brevity, we may denote, momentarily, by (45), (53), (34), (36), (46), (56), respectively. By what we have shewn, the points of intersection of threes of these planes, which are

$$(45, 53, 34),\quad (45, 46, 56),\quad (53, 56, 36),\quad (34, 36, 46),$$

lie in one plane. These points are, however, respectively, P_{12345}, P_{12456}, P_{12356}, P_{12346}. By a similar argument it follows that every four of the six points in question, whose symbols have two digits in common, are in one plane. From this, the fact that all six points are in one plane is clear.

If we start with seven points, $P_1, \ldots, P_7$, in the original plane, there will be seven planes, of which one arises, as in the case considered, from every six of these points. It can be shewn that these seven planes meet in a point. The proof may begin by considering the five coplanar points P_{12r}, where $r = 3, 4, \ldots, 7$. And so on.

We may consider the dual of these theorems, obtained by taking planes all passing through a point, and an arbitrary point on the line of intersection of any two of these planes. The case when four planes are drawn through the point was considered above. In particular, the points which are taken on the lines of intersection of the pairs of planes, may be the further intersections of these lines with a quadric drawn through the original point. When the number of planes originally taken is even, the theorem leads finally to a point; it can be shewn, as in the case of four planes, that this point is also on the quadric. When we begin by considering five planes through the original point, we obtain, by projection on to a plane, the part of the theorem proved above (p. 1) which is expressed by saying that the foci of the five parabolas, which touch five lines in fours, lie on a circle. When we begin by considering six planes through the original point, the result is that the six circles, obtained from every five parabolas, have a point in common. And so on. These theorems were given by Clifford (1870), *Math. Papers* (1882), p. 38, whose method of proof (in dual statement) is by a curve of order n with a fixed $(n-1)$-fold point.

Ex. 1. Another representation of the preceding results may be referred to. On a quadric surface, any generator of one system may be associated with a value of a parameter, say θ, and any point of the surface with the values of a pair of parameters, say θ and ϕ. Now take two fixed lines of space, say x and y, both meeting a line h; and associate the points of the line x with the values of θ, the point (h, x) corresponding to $\theta=0$, say, and two other assigned points of x corresponding to assigned values of θ; similarly, associate the points of the line y with the values of ϕ. Next, take a further line p, meeting h but not x nor y. Then any transversal of the three lines x, y, p, as meeting x and y in points, say θ and ϕ, corresponds to a definite point (θ, ϕ) of the original quadric; and the aggregate of all such transversals, which meet x and y in related ranges, corresponds to the points of a plane section of the original quadric; upon this plane section there is a point, say H, independent of the line p, which corresponds to the transversal h. Conversely, any plane section of the quadric passing through the point H, corresponds to such an aggregate of transversals of the fixed lines x, y and another line p, meeting h but not x nor y, wherein however the line p is not unique. Two such plane sections, α_1 and α_2, have, beside H, another common point, say P_{12}; this corresponds to the fact that two such reguli of lines meeting x and y, both containing h, have in common another line. If three such sections of the quadric be taken through H, and the three further intersections of pairs of these be P_{23}, P_{31}, P_{12}, the points of the plane section of the quadric, which contains these points P_{23}, P_{31}, P_{12}, have parameters
